any financial support or benefits from commercial sources.

24 **Abstract**

25 **Objective:** We developed a novel imaging biomarker derived from knee dual-energy x-ray
26 absorptiometry (DXA) to predict subsequent total knee replacement (TKR). The biomarker is
27 based on knee shape, determined through statistical shape modelling. It was developed and
28 evaluated using data and scans from the UK Biobank cohort.

29 **Methods:** Using a 129-point statistical shape model (SSM), knee shape (B-score) and
30 minimum joint space width (mJSW) of the medial joint compartment (binarized as above or
31 below the first quartile) were derived. Osteophytes were manually graded in a subset of
32 DXA images. Cox proportional hazards models were used to examine the associations of B-
33 score, mJSW and osteophyte score with the risk of TKR, adjusted for age, sex, height and
34 weight.

35 **Results:** The analysis included 37,843 individuals (mean 63.7 years). In adjusted models, B-
36 score and mJSW were associated with TKR: a standard deviation increase in B-score was
37 associated with a hazard ratio (HR) of 2.32 (2.13, 2.54), and a lower mJSW with a HR of 2.21
38 (1.76, 2.76). In the 6,719 images scored for osteophytes, mJSW was replaced by osteophyte
39 score in the most strongly predictive model for TKR. In subsequent ROC analyses, a model
40 combining B-score, osteophyte score, and demographic variables had superior
41 discrimination (AUC=0.87) in predicting TKR at five years compared with a model with
42 demographic variables alone (AUC=0.73).

43 **Conclusions:** An imaging biomarker derived from knee DXA scans reflecting knee shape and
44 osteophytes, in conjunction with demographic factors, could help identify those at high risk
45 of TKR, in whom preventative strategies should be targeted.

46 Introduction

47 Knee osteoarthritis (kOA) exhibits distinct radiological features, including osteophyte
48 formation and joint space narrowing (JSN), the latter primarily affecting the medial joint
49 compartment in primary kOA. Additionally, the condition is associated with characteristic
50 shape alterations, including varus and valgus alignment, which can both result from and
51 contribute to the disease (1-3).

52 Currently, Joint Space Width (JSW) is the only accepted biomarker for kOA progression in
53 therapeutic trials (4, 5). However, grading systems such as the Kellgren-Lawrence system
54 (6), which incorporates both osteophytes and JSN into a single severity scale, are often used
55 in epidemiological studies. While the Kellgren-Lawrence grading system provides a valuable
56 tool for defining kOA in research, it has limitations in predicting clinical outcomes, as
57 evidenced by its weak association with pain and function (7, 8) and its limited sensitivity to
58 change (9, 10). As a consequence, it is not commonly employed in clinical practice. Indeed,
59 studies have shown that preoperative radiographs evaluated using the Kellgren-Lawrence
60 system often underestimate the severity of kOA (11). This underscores the need to consider
61 additional factors beyond the scope of the grading system, with knee shape emerging as a
62 potential influential factor in the progression of the disease.

63 Statistical shape modelling (SSM), facilitated by machine learning techniques, holds the
64 potential to enhance the prediction of osteoarthritis progression by identifying distinct joint
65 shape features that are associated with adverse clinical outcomes. However, the application
66 of this method in the context of the knee remains relatively unexplored, with existing
67 studies primarily focusing on three-dimensional (3D) imaging modalities (12-14). For
68 example, Bowes et al. developed the B-score to capture femoral shape changes in kOA on

69 MRI images (14). Elevated B-scores were associated with a 60% increased risk of TKR and its
70 predictive ability was comparable to that of the Kellgren-Lawrence grade.

71 DXA imaging is gaining interest for joint shape evaluation due to its advantages of low
72 radiation exposure and cost, and widespread availability. Moreover, modern high-resolution
73 DXA scanners generate high-quality images similar to radiographs, making it a viable option
74 for screening individuals at high risk of osteoarthritis progression. Observed shape variations
75 on hip DXA, including reduced acetabular coverage and cam morphology, have already been
76 linked to advanced disease (15, 16) and statistical shape modes have identified changes in
77 hip shape that are linked to disease progression (17). While the use of knee DXA scans in
78 assessing KOA has not been extensively investigated, a study successfully used SSM to
79 capture alterations in knee morphology in a small cohort of KOA patients through sequential
80 DXA images spanning 6–12 months (10).

81 In this study, we aimed to investigate the potential utility of knee DXA scans as a screening
82 tool for identifying individuals with KOA who are at a high risk of progressing to total knee
83 replacement (TKR), based on evaluating knee shape. To achieve this, we developed and
84 subsequently applied a statistical shape model to approximately 40,000 knee DXA scans
85 from UK Biobank (UKB). We examined the relationship between knee shape, quantified by
86 B-score, and risk of subsequent TKR. Additionally, we explored whether any predictive value
87 of B-score could be improved by incorporating additional features obtained from knee DXA
88 scans. Specifically, we examined the inclusion of minimum joint space width (mJSW) and
89 osteophyte classification (available in a subset of approximately 7,000 scans) along with
90 conventional risk factors, namely age, sex, height, and weight.

91 **Materials and methods**

92 *Participants*

93 We used data from the UKB extended imaging study (18), a large-scale research study that
94 aims to collect and analyse medical imaging data, including DXA scans, from approximately
95 100,000 participants in the UKB cohort (19). At both baseline and imaging visits, UKB
96 participants completed a touch-screen questionnaire, underwent a nurse-lead interview,
97 and had physical measurements taken. Further information was obtained via data linkage,
98 including hospital episode statistics (HES) (20).

99 All subjects provided written informed consent before participation. UKB has full ethical
100 approval from the National Information Governance Board for Health and Social Care and
101 the North-West Multi-Centre Research Ethics Committee (11/NW/0382). Permission to
102 access and analyse UKB data for this study was approved under UKB application number
103 17295.

104 *Acquisition of Knee DXA images*

105 DXA scans were acquired using a Lunar iDXA scanner (GE Healthcare), with participants in a
106 non-weight bearing supine position (21). High-resolution DICOM format images were
107 downloaded from the UKB showcase (downloaded in April 2021). Individuals with prior TKR
108 were excluded from the analysis.

109 *Ascertainment of outcomes*

110 Our primary outcome of interest was TKR. Additionally, we examined cases of hospital-
111 diagnosed knee osteoarthritis (HES-kOA), as a secondary outcome. Both outcomes were
112 identified via linkage to the HES database (see Supplementary Table 1 for a list of the

113 diagnostic codes). All UKB participants were linked, both prospectively and retrospectively
114 at baseline. Records begin on April 1st, 1997, and the data were downloaded in October
115 2022 (capturing information up until the end of December 2021).

116 *Assessment of covariates*

117 Participants' height and weight were measured prior to imaging using standardised
118 procedures (22). Age and sex were collected at the time of enrolment into UKB and were
119 self-reported.

120 *Statistical shape modelling*

121 The SSM techniques employed in this study have been described elsewhere (23, 24) and
122 additional information is provided in the Supplementary Methods. SSM was performed
123 using software developed at The University of Manchester (25). A 129-point template was
124 developed, covering the left distal femur, proximal tibia, proximal fibula, and superior
125 patella, and excluding any osteophytes (Supplementary Figure 1). An automatic
126 BoneFinder® (26) search model was trained (using 6,718 images from an initial pool of 7,000
127 images) to apply the template to new images. The accuracy of the search model was
128 evaluated using 3-fold cross-validation experiments (Supplementary Table 2). The
129 BoneFinder® model was applied to the remaining left knee DXA images (n=31,207; see
130 Supplementary Methods) to automatically place the points. When necessary (for 4,214
131 images), trained annotators (RB and FS) manually corrected point placements to improve
132 the precision of the SSM (Supplementary Table 3).

133 The first 27 statistical knee shape modes (KSMs) obtained from SSM were standardized
134 using the sample standard deviation. To limit multiple comparisons, we focused on the first

135 10 KSMs, explaining 79.5% of shape variance. Subsequent KSMs each made minimal
136 contributions to the sample variance ($\leq 2\%$) (Supplementary Figure 2).

137 *Generation of a quantitative measure of knee shape: B-score*

138 A knee shape variable was created using all KSMs from the SSM. A vector representing the
139 line connecting the mean knee joint shape of a "healthy" population and that of a
140 "diseased" population was generated for each outcome. The KSMs for each image were
141 projected onto this vector to obtain the B-Score (14). Each B-score unit represents one
142 standard deviation (SD) from the mean knee joint shape of the healthy population (assigned
143 a B-score of 0). As well as calculating B-scores for the entire population, sex-specific B-scores
144 were derived for sensitivity analysis (Supplementary Methods).

145 *DXA-based measures of joint space and osteophytes*

146 A custom script automatically measured mJSW of the medial and lateral compartments
147 using specific template points on the distal femur and proximal tibia (Supplementary
148 Methods). Medial mJSW values were divided into quartiles, and a binary variable was
149 generated to compare the first quartile against the second, third and fourth.
150 Osteophytes were assessed in a subset of 6,719 DXA images, selected from the initial pool
151 of 7,000 images designated for the search training set (see Supplementary Methods). Using
152 a DXA-based reference Atlas (Supplementary Document), we initially conducted visual
153 grading on a 0-3 scale. We then computed cumulative values (ranging from 0 to 12) by
154 aggregating grades from all four sites on the medial and lateral aspects of the femur and
155 tibia. An osteophyte score was then assigned based on the total sum: 0 (sum = 0), 1 (sum =
156 1), 2 (sum = 2-3), 3 (sum = 4 or greater), as outlined in Supplementary Table 4.

157 *Statistical analysis*

158 We employed Cox proportional hazards modelling and logistic regression to assess the
159 relationships between KSMs, B-scores, mJSW, and osteophytes with the incidence of TKR
160 and HES-kOA, respectively. The proportional hazards assumption was verified using the
161 Schoenfeld residuals approach. Results are reported as hazard ratios (HRs) and odds ratios
162 (ORs) with their corresponding 95% confidence intervals (CIs). Both unadjusted and adjusted
163 analyses were conducted, with adjustments made for age, sex, height, and weight. Age,
164 height, and weight were treated as continuous variables, while sex was considered as a
165 binary variable. Where death occurred before TKR, the event was censored at the time of
166 death.

167 To evaluate the predictive performance of the models for TKR and HES-KOA, we used the
168 Harrell's Concordance index (C-index) and area under the receiver operating characteristic
169 curve (AUC), in combination with Akaike information criterion (AIC) and Bayesian
170 information criterion (BIC). Initially, we ran univariate models for B-score, mJSW, and
171 osteophyte score using the subset of participants with osteophyte data (n=6,719). We then
172 examined a model incorporating the demographic factors age, sex, height, and weight as
173 additional variables. Subsequently, we evaluated models including an extra variable, either
174 B-score, mJSW, or osteophyte score, depending on the specific model. Finally, we developed
175 a comprehensive model incorporating all DXA-derived variables and demographic factors.
176 Goodness of fit was evaluated using AIC and BIC, while discriminative ability was assessed
177 using AUC or C-index for logistic and Cox regression models, respectively.

178 To further evaluate the discriminative ability of the models, we plotted receiver operating
179 characteristic (ROC) curves for HES-kOA and TKR at 5 years. Chi-squared tests were
180 employed to examine the equality of the area under the curves.

181 Analyses were conducted using Stata version 17 (StataCorp. 2021. *Stata Statistical Software:
182 Release 17*. College Station, TX: StataCorp LLC.) and python 3.10.5.

183 **Results**

184 *Participant characteristics*

185 In total 37,843 participants had SSM and clinical data available (Figure 1). A total of 358
186 participants underwent TKR (1.0%; Table 1), with an average time to surgery of 2.1 years
187 (SD=1.4 years; males= 2.2 years [1.5], females= 2.0 years [1.3]). There were 538 deaths
188 during the study period. The sub-sample with osteophyte data (n=6,719) were comparable
189 with respect to their baseline demographics (Table 1), but the proportion of individuals with
190 TKR was slightly higher (1.6%, n=110). The average time to TKR in this cohort was 2.6 years
191 [SD: 1.5; males: 3.0 [1.5], females: 2.3 [1.4]) and there were 93 deaths.

192 *Relationship between knee shape and kOA outcomes.*

193 We initially evaluated individual modes of variation (KSMs) in relation to kOA outcomes.
194 Adjusted analyses results are presented in Table 2, while unadjusted associations can be
195 found in Supplementary Table 5. A description of each KSM is provided in Supplementary
196 Table 6.

197 KSMs 7, 8, and 9 showed strong evidence of an association with TKR. Specifically, for each
198 standard deviation (SD) increase in KSM9 there was a 19% reduced risk of TKR, while

199 analogous increases in KSM7 and KSM8 were associated with a 45% and 69% increased risk,
200 respectively.

201 Five KSMs displayed strong statistical evidence of an association with HES-kOA. Increases in
202 modes 1, 9, and 10 were linked to reduced risks of 8%, 10%, and 8%, whilst increases in
203 modes 7 and 8 were associated with a 26% and 32% increased risk, respectively.

204 Given that variations in knee shape could be spread over multiple modes, we next assessed
205 the relationship between B-score, a single variable combining shape information across all
206 KSMs, and kOA outcomes. B-score distribution is shown in Supplementary Figure 3.

207 We observed strong positive associations between B-scores and our outcomes (Figure 2;
208 additional data in Supplementary Table 7). After adjustment, each SD increase in B-score
209 was associated with a 2.3-fold higher risk of TKR (HR=2.32 [2.13, 2.54]). Similar results were
210 found in the sex-stratified analysis (Supplementary Table 7). Additionally, each SD increase
211 in B-score was associated with increased odds of HES-kOA, with an OR of 1.80 (1.71, 1.89).
212 Stratifying by sex did not alter these findings.

213 Figure 3 depicts joint shape variations associated with B-scores $\pm 2SD$ from the healthy group
214 mean. An increase in B-score is linked with increasing varus alignment accompanied by
215 reduced medial joint space width, widening of the femoral articular surface, lateral patellar
216 displacement, and a potential upward displacement of the fibular head.

217 *Relationship between mJSW and kOA outcomes*

218 Results are presented in Supplementary Table 8. Individuals in the first quartile of medial
219 mJSW, representing the narrowest mJSW, had a 2.4-fold increased risk of TKR and a 54%
220 higher risk of HES-kOA, compared with those in the fourth quartile (HR for TKR = 2.44 [1.77

221 to 3.38]; OR for HES-kOA = 1.54 [1.31 to 1.81]). Conversely, when examining lateral mJSW,
222 the first and second quartiles showed a lower risk of TKR when compared with the fourth.
223 Considering the binary mJSW variable, individuals in the first quartile on the medial side had
224 a 2.2-fold higher risk of TKR (HR=2.21 [1.76, 2.76]), compared with individuals in higher
225 quartiles. They also experienced a 48% increased risk of HES-kOA (OR=1.48 [1.31, 1.67]), as
226 depicted in Figure 2.

227 *Relationship between osteophytes and kOA outcomes*

228 Supplementary Table 9 displays the prevalence of manually graded osteophytes(n=6,719).
229 The regression analysis (Table 3, with unadjusted results in Supplementary Table 10)
230 revealed a consistent pattern of increasing HRs and ORs for kOA outcomes with higher
231 osteophyte grades. This was apparent across all anatomical sites.

232 An osteophyte score of 3 (based on the sum of the osteophyte grades) was associated with
233 an 18-fold increased risk of TKR (HR=18.30 [9.98, 33.57]), and a 9-fold increased risk of HES-
234 kOA (OR=9.10 [6.54, 12.67]) compared to a score of 0 (Supplementary Table 11). Figure 2
235 visually depicts the incremental impact per unit increase in the osteophyte score.

236 *Performance of multivariable models in predicting TKR*

237 Table 4 displays the predictive performance of different models for TKR, combining
238 demographic variables (age, sex, height and weight), B-score, binary mJSW and osteophyte
239 score in the sub-group of 6,719 participants.

240 When assessing the B-score's relationship with TKR, the univariable model yielded a HR of
241 2.67 (2.25, 3.17), which decreased to 2.40 (2.00, 2.87) upon adjustment for demographic
242 variables. Adding osteophyte score had a greater impact compared to mJSW, resulting in

243 HRs of 1.80 (1.50, 2.15) and 2.29 (1.89, 2.76) respectively. Combining mJSW, osteophyte
244 score, B-score, and demographics resulted in a HR of 1.72 (1.42, 2.09).

245 The unadjusted HR for the mJSW-TKR association was 2.81 (1.94, 4.09), which decreased to
246 2.29 (1.54, 3.41) after incorporating demographic variables. Adding B-score to the latter
247 model had a more pronounced effect compared to osteophyte score, with HRs of 1.36 (0.90,
248 2.05) and 1.91 (1.29, 2.82), respectively. The addition of both B-score and osteophyte score
249 yielded an HR of 1.29 (0.85, 1.96).

250 In the context of the osteophyte-TKR association, the unadjusted hazard ratio (HR) was 3.42
251 (2.78, 4.19) per unit increase, decreasing to 2.92 (2.37, 3.60) after adjusting for
252 demographics. Adding mJSW further reduced the HR to 2.82 (2.30, 3.48), while the inclusion
253 of B-score had a more substantial impact, resulting in a HR of 2.35 (1.90, 2.90). Similar
254 effects were observed in the model including both B-score and mJSW, alongside
255 demographic variables (HR = 2.34 [1.89, 2.89]).

256 The model that exhibited the optimal fit, as indicated by the lowest AIC and BIC, and the
257 highest discrimination as reflected by C-index, comprised B-score, osteophyte score and
258 demographics.

259 We subsequently examined the predictive ability of this model in classifying TKR at five
260 years. A model including demographic factors alone achieved an AUC of 0.73 (Figure 4),
261 while the optimal model (including B-score, osteophyte score and demographics) had an
262 AUC of 0.87 ($p < 0.05$).

263 *Performance of multivariable models in predicting HES-kOA*

264 The associations between DXA-derived variables and HES-kOA were generally observed to
265 be weaker when compared with those with TKR (Table 4).

266 The B-score- HES-kOA association partially attenuated when demographic variables were
267 included in the model, with the OR decreasing from 1.98 (1.78, 2.20) to 1.85 (1.66, 2.07).

268 Additional adjustment for mJSW had minimal impact (OR=1.82 [1.63, 2.04]), but
269 incorporating osteophyte score further reduced the association (OR=1.59 [1.42, 1.77]).

270 Including both mJSW and osteophyte score in the model resulted in a comparable OR to the
271 model that adjusted for osteophyte score and demographics (OR=1.57 [1.40, 1.76]).

272 When considering mJSW, adjusting for demographic variables reduced the strength of the
273 association, causing the OR to shift from 1.65 (95% CI: 1.31, 2.07) to 1.55 (95% CI: 1.21,

274 1.98). Further adjustment for B-score led to a more pronounced attenuation, yielding an
275 odds ratio (OR) of 1.15 (95% CI: 0.89, 1.48), in contrast to the adjustment for osteophyte

276 score which produced an OR of 1.44 (95% CI: 1.13, 1.84). Including both B-score and

277 osteophyte score produced an OR similar to the model adjusting for demographics and B-
278 score alone (OR = 1.13 [0.87, 1.46]).

279 Osteophyte score exhibited the strongest association with HES-kOA, with an OR of 2.19
280 (1.97, 2.44) in univariable analyses and 2.02 (1.81, 2.26) after adjusting for demographics.

281 Adding mJSW as an additional adjustment did not change the estimate (OR=2.00 [1.79,
282 2.24]), but partial attenuation occurred when B-score was added (OR=1.80 [1.60, 2.01]). The

283 model with B-score, mJSW, and demographics was comparable to the one with B-score and
284 demographics (OR=1.79 [1.60, 2.01]).

285 As seen for TKR, the model that exhibited the optimal fit and discrimination comprised the
286 B-score, osteophyte score and demographic variables. When considering demographic
287 variables alone, the model yielded an AUC of 0.64. However, when the B-score and
288 osteophyte score were incorporated into the model, the AUC improved to 0.75.

289 **Discussion**

290 The purpose of this study was to develop an imaging biomarker derived from knee DXA
291 scans which incorporates joint shape and to investigate its potential prognostic value in
292 predicting TKR. In addition to capturing conventional features of radiographic KOA, namely
293 JSN (as reflected by mJSW) and osteophytes, an automated model was developed to extract
294 knee shape information using SSM. This information was quantified as a B-score. We found
295 strong correlations between all of the DXA-derived features investigated and subsequent
296 risk of TKR. Similar, although comparatively weaker associations were observed with HES-
297 KOA. Furthermore, when we combined B-score with osteophyte score and demographic
298 factors, we observed a significant improvement in the accuracy of predicting TKR at 5 years,
299 compared with demographic risk factors alone (AUC=0.87 compared with 0.73).

300 Few studies have examined knee shape using DXA-based SSM. One small study explored
301 knee shape changes in 109 individuals over 12 months. It found significant alterations in a
302 particular shape mode reflecting reduced medial mJSW in KOA cases, which aligns with our
303 findings (10). However, this investigation did not annotate osteophytes separately or
304 observe overall shape changes like varus alignment. In contrast, our analysis revealed a
305 strong relationship between DXA-derived osteophytes and subsequent joint replacement,
306 consistent with our previous hip DXA study (16). Our findings also align with an earlier
307 radiographic hip investigation which found that incorporating an SSM-derived Shape-Score

308 into a model alongside demographic factors, clinical assessment, and radiologists scores
309 enhanced the prediction of hip OA (27). The initial prediction model had an AUC of 0.795,
310 which improved to 0.864 with the inclusion of the Shape-Score.

311 The observed trend toward varus alignment in individuals with HES-kOA and subsequent
312 TKR in our study is consistent with the recognised varus malalignment characteristic in kOA
313 (1, 2). This malignment may be a predisposing factor, focusing weight-bearing forces
314 through the medial compartment causing considerable biomechanical stress. Alternatively,
315 varus may develop due to medial JSN, a recognized feature of primary kOA. Alongside the
316 varus alignment and reduced mJSW, there appeared to be an enlargement of the femoral
317 articular surface. These findings coincide with previous studies using MRI-based SSM
318 approaches, which have reported femoral condyle widening and flattening in osteoarthritic
319 knees (13, 28-30).

320 By employing a B-score, we were able to examine independent associations between knee
321 shape and other features related to kOA, namely mJSW and osteophytes. Whereas B-score,
322 osteophytes and mJSW were all related to TKR and HES-kOA in univariable analyses, the
323 association between mJSW and these outcomes attenuated following inclusion of B-score,
324 suggesting that mJSW is encompassed by the SSM and the resulting B-score. In contrast, B-
325 score and osteophyte score were both retained as independent predictors of clinical
326 outcomes, and their combination increased model performance. That said, the association
327 between osteophytes and risk of TKR/HES-kOA was partially attenuated by inclusion of B-
328 score. Since our SSM template excluded osteophytes, these are unlikely to have directly
329 contributed to the B-score, suggesting that joint malalignment may contribute to the
330 relationship between osteophytes and kOA progression, as previously proposed (31).

331 Demographic factors such as age, sex, and weight also strongly predicted risk of TKR/HES-
332 KOA, implying imaging biomarkers need to be considered as complementing these factors in
333 patient assessment rather than replacing them.

334 The exclusion of participants with previous TKR allowed us to assess the predictive capability
335 of DXA-derived imaging biomarkers for future TKR. On the other hand, participants could
336 have had pre-existing HES-KOA at the time of their DXA scan. It was reassuring that broadly
337 consistent relationships were seen between imaging biomarkers and HES-KOA and TKR.
338 Nonetheless, given we were only able to examine cross-sectional relationships with HES-
339 KOA, further studies are necessary to determine whether DXA biomarkers are also useful in
340 predicting subsequent HES-KOA when obtained in those with early disease.

341 Several approaches have been used to extract additional features on knee images for OA
342 diagnosis and prognosis, including Deep Learning methods, as has previously been applied
343 to knee radiographs (32-34). Our investigation is novel in exploring whether an imaging
344 biomarker incorporating knee shape might be useful in predicting TKR when applied to knee
345 DXA scans. This was made possible by application of SSM to DXA images obtained from a
346 large sample of individuals from UKB, in whom follow-up data for THR via HES linkage was
347 available. Given the study's scale, our SSM could serve as a reference model, making
348 replication, validation and clinical application more feasible. Indeed, the SSM, along with the
349 BoneFinder search model, will be made publicly available on the BoneFinder website.

350 Another strength of our study is that, unlike the majority of previous studies using SSM to
351 characterise knee shape, which generally focused on the tibia and femur, our SSM also
352 incorporated the superior patella and fibula.

353 A limitation of our study is that whereas knee shape data were obtained in all those with
354 available DXA scans, osteophytes, which required manual annotation, were only obtained in
355 a subset. Nevertheless, this smaller sample had sufficient numbers of individuals with TKR to
356 compare the predictive value of different models. A further limitation is that HES linkage
357 may have missed some cases of TKR through failure to capture procedures performed in the
358 private sector. Moreover, the HES data lacks laterality but this limitation is more likely to
359 reduce effect sizes rather than introduce bias into the study. Lack of generalisability may
360 also be an issue given UKB is 95% white and has lower rates of all-cause mortality compared
361 with the population at large, which aligns with the well-known "healthy volunteer" effect
362 (35). In addition, those 11% of UKB participants recruited from Scotland and Wales were
363 excluded as they have separate systems to HES linkage. Finally, it is important to stress that
364 the present study aimed to explore the utility of DXA-based measures of knee shape in
365 predicting clinical outcomes related to KOA, and to evaluate whether these provide
366 additional information compared to conventional radiographic measures, including JSW and
367 osteophytes. Further studies, including validation in an external dataset, are required to
368 establish the generalizability and reliability of this approach prior to clinical use.

369 In summary, our study highlights the potential value of SSM as a tool for characterising joint
370 shape in knee DXA scans. Importantly, the development of a DXA-derived imaging
371 biomarker combining knee shape and osteophyte formation shows promise in identifying
372 individuals at high risk of progression to TKR, particularly when combined with demographic
373 factors. Further studies are justified to examine the utility of using DXA scans, which are
374 widely available and involve much lower doses of radiation compared with conventional X-
375 rays, to identify individuals who are likely to benefit from interventions aimed at slowing
376 KOA progression.

377 **Acknowledgements**

378 The authors would like to express their gratitude to Dr. David Wilson, Consultant
379 Interventional Musculoskeletal Radiologist and honorary Clinical Lecturer at Aberdeen
380 University, for his valuable contribution to the development of the DXA-based osteophyte
381 Atlas. They also extend their appreciation to all the participants of the UK Biobank study.

382 **Author contributions**

383 Each author has made significant contributions to the study's conception, design, data
384 acquisition, analysis, and interpretation. Furthermore, all authors helped draft the article
385 before approving the final version of this manuscript.

386 **Funding:** This research was funded in whole, or in part, by the Wellcome Trust [Grant
387 numbers: 209233/Z/17/Z, 223267/Z/21/Z]. CL was funded by a Sir Henry Dale Fellowship
388 jointly funded by the Wellcome Trust and the Royal Society (223267/Z/21/Z). NCH is
389 supported by grants from Medical Research Council (MRC) [MC_PC_21003; MC_PC_21001]
390 and the NIHR Southampton Biomedical Research Centre. BGF is funded by an NIHR
391 Academic Clinical Lectureship.

392 **Conflict of Interest:** The other authors have declared no conflicts of interest. For the
393 purpose of open access, the author has applied a CC BY public copyright licence to any
394 Author Accepted Manuscript version arising from this submission. AS was affiliated with the
395 Bristol University at the time of the study conduct and is currently affiliated with Roche
396 Diagnostics International, Clinical Development and Medical Affairs. At the time this work
397 was conducted MF was an employee at the University of Bristol. MF is now employed by
398 Boehringer Ingelheim UK & Ireland.

Tables

Table 1: Descriptive characteristics of the total study population and the subset in which osteophytes were assessed.

The table presents the demographic and clinical characteristics of the study population, comprising all participants with statistical shape modelling data. The left-hand side provides information for the full dataset, while the right-hand side focuses on the sub-sample of participants who had additional osteophyte data available. Abbreviations: HES-kOA, hospital-diagnosed knee osteoarthritis; mJSW, minimum joint space width; SD, standard deviation; TKR, total knee replacement.

	Full dataset			Osteophyte subset

Table 2: Associations between the top 10 knee shape modes and knee osteoarthritis

outcomes.

Hazard ratios (HRs) and odds ratios (ORs) indicate the change in risk of total knee replacement (TKR) and hospital diagnosed knee osteoarthritis (HES-kOA) per standard deviation increase in knee shape mode (KSM). Models are adjusted for age, sex, height and weight. 95% confidence intervals (CI) are provided. Associations that met the Bonferroni-significant threshold of $p \leq 0.005$ are shown in bold.

TKR				
KSM	HR	95% CI		p-value

Table 4: Predictive performance of B-scores, binary mJSW and osteophyte score with TKR and HES-kOA (n=6,719).

The table includes results of univariable and multivariable models (left), and measures of model fit and discrimination (right). Demographic characteristics include age, sex, height and weight. For B-score, HRs and ORs indicate the change in risk per standard deviation increase in B-score. For mJSW, HRs and ORs reflect the risk difference between the first quartile (on the medial compartment) compared with quartiles two, three, and four.

Osteophyte score was entered into the model as a linear term and therefore HRs and ORs represent the difference in risk per unit increase in score. When evaluating the predictive accuracy of the time-to-event (cox) models we used Harrell's C-index. For logistic regression models, where the outcome was binary, we used the AUC. The most parsimonious model, containing the predictors B-score, osteophyte grade and demographic variables, is shown in bold.

Abbreviations: AIC, Akaike information criterion; AUC, area under the receiver operating characteristic curve; BIC, Bayesian information criterion; CI, 95 % confidence intervals; C-index, Harrell's concordance index; Demo, demographic variables; OP, osteophyte score; HR, hazard ratio; mJSW, minimum joint space width; OR, odds ratio; TKR, total knee replacement.

Figures

Figure 1: Flow Diagram of Participant Progression through the Study.

At the time of the analysis, approximately 39,000 left knee DXA scans were available. DXA images underwent a comprehensive assessment to determine their suitability for inclusion in the SSM. Reasons for exclusion included: poor image quality, artefacts, positioning issues, short femoral or tibial shafts, and search failure.

A total of 220 participants withdrew from the study, and an additional 80 participants were excluded due to having undergone TKR on the contralateral knee before obtaining the DXA image of the left knee.

All participants in the analytic dataset had SSM data available, which was used to derive B-score and minimum joint space width (mJSW). Within this dataset, a sub-sample of 6,719 participants had additional osteophyte data available. This sub-sample, comprising participants with B-scores, mJSW and osteophyte data, were used to develop an imaging biomarker for predicting TKR.

Abbreviations: QC, quality control; SSM, statistical shape model; TKR, total knee replacement; UKB, UK Biobank.

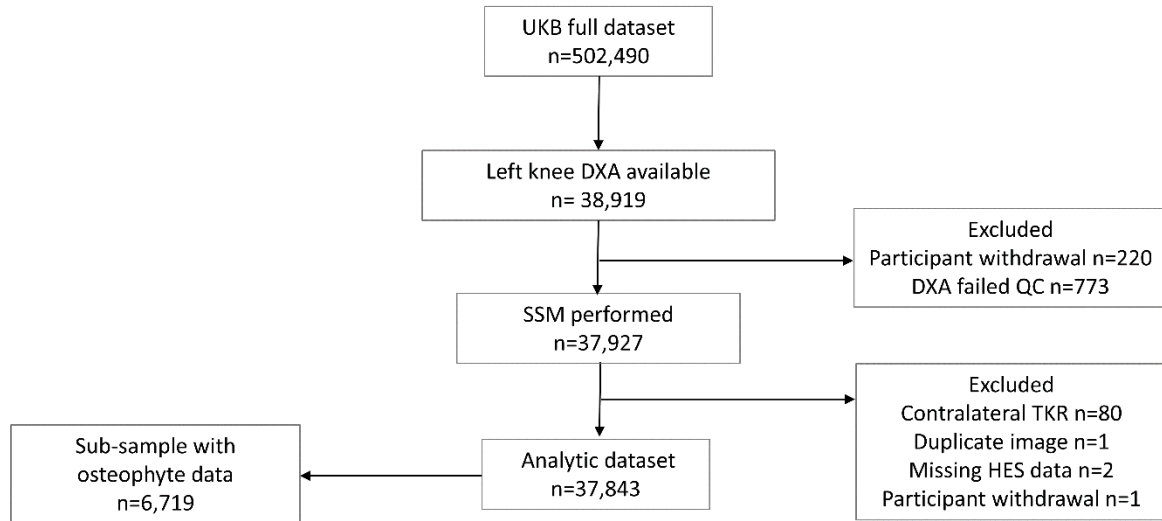

Figure 2: Association of B-scores, osteophyte score and mJSW with TKR and HES-kOA.

The associations of B-score, mJSW, and osteophyte score with total knee replacement (TKR) are presented in the top panel, while the corresponding associations with hospital diagnosed knee osteoarthritis (HES-kOA) are displayed in the bottom panel. For B-score, the hazard ratios (HRs) and odds ratios (ORs) quantify the difference in risk associated with a standard deviation (SD) increase in the score. Regarding mJSW, the HRs and ORs represent the change in risk for individuals in the second, third, or fourth quartile of mJSW in the medial compartment, compared with those in the first quartile. For osteophyte score, (based on the sum of osteophyte grades), the HRs and ORs represent the difference in risk per unit increase in score.

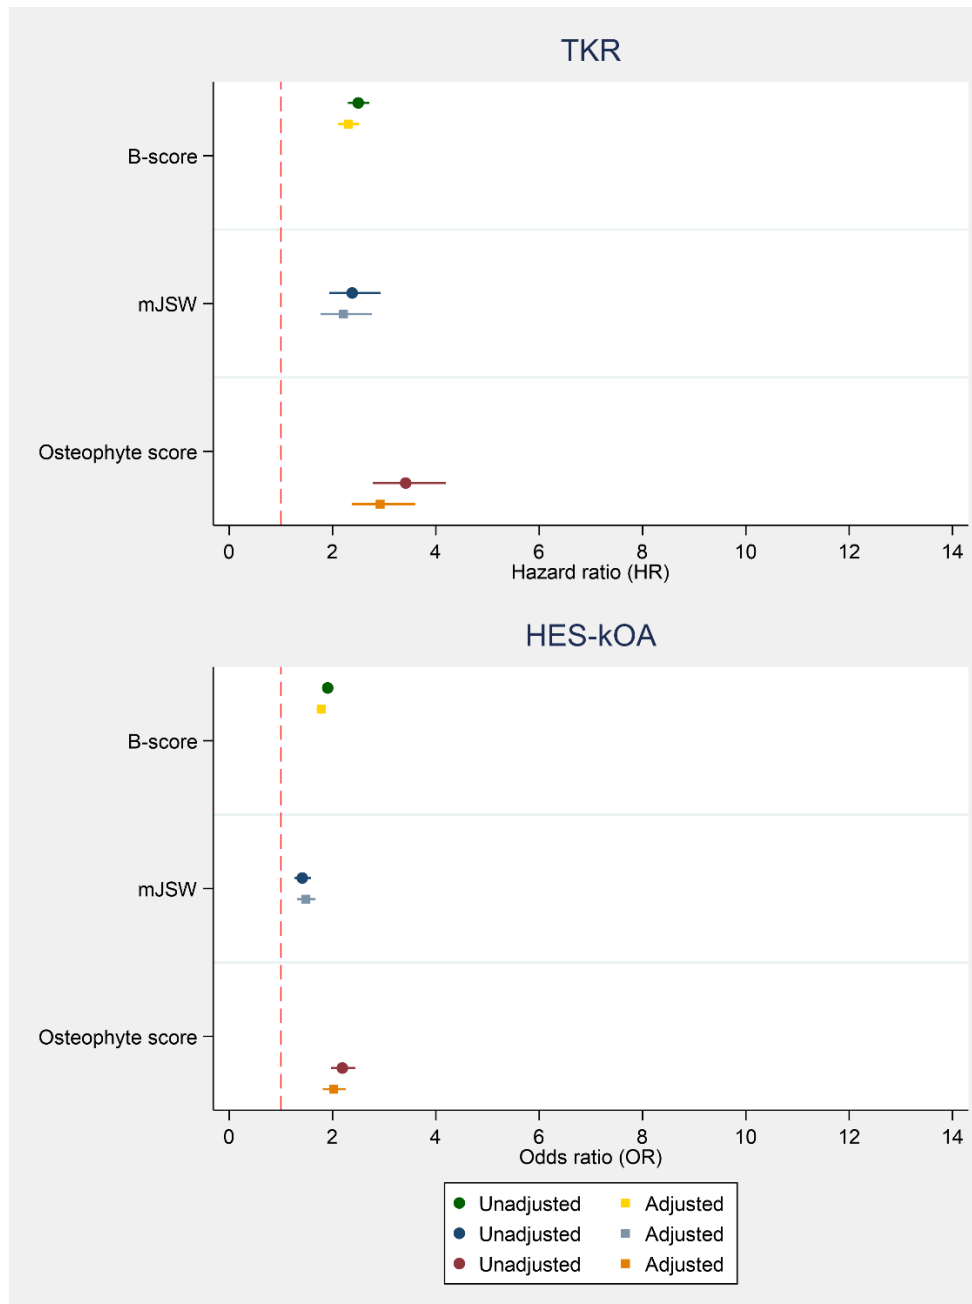

Figure 3: Examples of differences in bone shape corresponding to an increase and decrease in B-scores.

B-scores were obtained by projecting all statistical knee shape modes (KSMs) onto a vector connecting healthy and diseased knee joint shapes. The diseased population included individuals who underwent TKR (left) or had hospital-diagnosed knee osteoarthritis (HES-KOA) (right). The figure illustrates shape changes associated with ± 2 standard deviations (SD) from the mean B-score. The solid blue line depicts the shape at -2SD, while the dashed red line represents the shape at +2SD.

Figure 4: Receiver Operating Characteristic (ROC) Curve for Prediction of HES-kOA and TKR at 5 Years (n=6,719).

Model 1: age, sex, height, and weight; Model 2: age, sex, height, weight, B-score; Model 3: age, sex, height, weight, binary osteophyte grade; Model 4: age, sex, height, weight, B-score, binary osteophyte grade. Abbreviation: AUC, area under the receiver operating characteristic curve.
