18 **Abstract**

19 STUDY QUESTION

20 Can a large-scale genome-wide association study (GWAS) meta-analysis identify the genomic
21 risk loci and associated candidate genes for female genital tract (FGT) polyps, provide insights
22 into the mechanism underlying their development, and inform potential overlap with other
23 traits, including endometrial cancer?

24 SUMMARY ANSWER

25 GWAS meta-analysis of FGT polyps highlighted the potentially shared mechanisms between
26 polyp development and cancerous processes.

27 WHAT IS KNOWN ALREADY

28 Small-scale candidate gene studies have focused on biological processes such as estrogen
29 stimulation and inflammation to clarify the biology behind FGT polyps. However, the exact
30 mechanism for the development of polyps is still elusive. At the same time, a genome-wide
31 approach, which has become the gold standard in complex disease genetics, has never been
32 used to uncover the genetics of the FGT polyps.

33 STUDY DESIGN, SIZE, DURATION

34 We performed a genome wide association study (GWAS) meta-analysis including a total of
35 25,100 women with FGT polyps (International Classification of Disease, ICD-10 diagnosis
36 code N84) and 207,193 female controls (without N84 code) of European ancestry from the
37 FinnGen study (11,092 cases and 94,394 controls) and the Estonian Biobank (EstBB, 14,008
38 cases and 112,799 controls).

39 PARTICIPANTS/MATERIALS, SETTING, METHODS

40 A meta-analysis and functional annotation of GWAS signals were performed to identify and
41 prioritise genes in associated loci. To determine associations with other phenotypes, we
42 performed a look-up of associated variants across multiple traits and health conditions, a genetic
43 correlation analysis, and a phenome-wide association study (PheWAS) with ICD10 diagnosis
44 codes.

45 MAIN RESULTS AND THE ROLE OF CHANCE

46 Our GWAS meta-analysis revealed ten significant ($P < 5 \times 10^{-8}$) genomic risk loci. Two signals,
47 rs2277339 ($P = 7.6 \times 10^{-10}$) and rs1265005 ($P = 1.1 \times 10^{-9}$) (in linkage disequilibrium (LD) with
48 rs805698 $r^2 = 0.75$), are exonic missense variants in *PRIMI*, and *COL17A1* genes, respectively.
49 Based on the literature, these genes may play a role in cellular proliferation. Several of the
50 identified genomic loci had previously been linked to endometrial cancer and/or uterine
51 fibroids. Thus, highlighting the potentially shared mechanisms underlying tissue overgrowth
52 and cancerous processes, which may be relevant to the development of polyps. Genetic
53 correlation analysis revealed a negative correlation between sex hormone-binding globulin
54 (SHBG) and the risk of FGT polyps ($rg = -0,21$, $se = 0.04$, $P = 2.9 \times 10^{-6}$), and on the phenotypic
55 level (PheWAS), the strongest associations were observed with endometriosis, leiomyoma of
56 the uterus and excessive, frequent and irregular menstruation.

57 LARGE SCALE DATA

58 The complete GWAS summary statistics will be made available after publication through the
59 GWAS Catalogue (<https://www.ebi.ac.uk/gwas/>).

60 LIMITATIONS, REASONS FOR CAUTION

61 In this study, we focused broadly on polyps of FGT and did not differentiate between the polyp
62 subtypes. The prevalence of FGT polyps led us to assume that most women included in the
63 study had endometrial polyps. Further study on the expression profile of FGT polyps could
64 complement the GWAS study to substantiate the functional importance of the identified
65 variants.

66 WIDER IMPLICATIONS OF THE FINDINGS

67 The study findings have the potential to significantly enhance our understanding of the genetic
68 mechanisms involved, paving the way for future functional follow-up, which in turn could
69 improve the diagnosis, risk assessment, and targeted treatment options, since surgery is the only
70 line of treatment available for diagnosed polyps.

71 TRIAL REGISTRATION NUMBER:

72 Not applicable

73 Key words: Genome-wide association study, Female genital tract polyps, Endometrial polyps,
74 Benign disorders, cell proliferation, *PRIMI*, *COL17A1*.

75 Introduction

76 Polyps of the female genital tract (FGT) are generally benign tissue overgrowths found
77 in both reproductive-aged and postmenopausal women. While the prevalence of polyps can be
78 as high as 50%, most women are asymptomatic. Hence, polyps are usually detected incidentally
79 during routine ultrasound examinations, diagnostic hysteroscopy for other gynaecological
80 disorders, or infertility treatment among women of reproductive age (Hinckley and Milki, 2004;
81 Fatemi *et al.*, 2010; Karayalcin *et al.*, 2010; Bettocchi *et al.*, 2011). However, the occurrence
82 of polyps is age-dependent, with a higher prevalence among postmenopausal women compared

83 to premenopausal women (Dreisler *et al.*, 2009). Despite the asymptomatic and benign nature
84 of FGT polyps, for some women, they can negatively impact the daily quality of life by causing
85 abnormal vaginal bleeding and infertility.

86 Endometrial polyps (EPs) are the most common type of FGT polyps, with a prevalence
87 ranging from 7.8% to 50% (Dreisler *et al.*, 2009; de Azevedo *et al.*, 2016; Tanos *et al.*, 2017).
88 In contrast, endocervical polyps occur only in 2% to 5% of cases, whereas vaginal polyps are
89 rarer (Tanos *et al.*, 2017); therefore, limited evidence is available about their biology and
90 clinical implications. Some known risk factors for the development of EPs are advanced age,
91 hypertension, diabetes, obesity, hyperoestrogenism, administration of hormone replacement
92 therapy (HRT), and tamoxifen (Vitale *et al.*, 2021; Vieira *et al.*, 2022). Nevertheless, the exact
93 pathogenesis of FGT polyps remains unclear. Histologically, EPs are characterised by large,
94 thickened blood vessels with fibrous stroma and irregularly shaped glandular spaces (Tanos *et*
95 *al.*, 2017). Moreover, EPs can be associated with concomitant intrauterine pathologies like
96 endometrial hyperplasia, adenomyosis, endometriosis and chronic endometritis (Annan *et al.*,
97 2012; Raz *et al.*, 2021). Despite the benign nature of EPs, around 3.5% of cases progress into
98 carcinoma (Lee *et al.*, 2010; Sasaki *et al.*, 2018; Uglietti *et al.*, 2019). At the same time, the
99 extent of biological mechanisms and pathways shared between EPs and carcinoma, as well as
100 unique molecular characteristics of each condition remain unclear.

101 Very little is known about the heritability and genetic background of FGT polyps.
102 Genetic factors, including chromosomal translocations in 6p21-22, 12q13-15, or 7q22 regions,
103 may contribute to polypoid morphology (Dal Cin *et al.*, 1995; Nijkang *et al.*, 2019; Vieira *et*
104 *al.*, 2022), and genetic disorders like Lynch or Cowden syndrome have been reported to be
105 accountable for the development of EPs (Vieira *et al.*, 2022). However, a recent study by Sahoo
106 *et al.* did not confirm the presence of chromosomal rearrangements in endometrial polyps
107 (Sahoo *et al.*, 2022).

108 Thus, the confirmed pathophysiology for the development of FGT polyps is still
109 unknown. However, it can be assumed that the development and mechanism of polyps are
110 multifactorial and can also depend on genetic predisposition. Thus far, the proposed genetic
111 mechanisms are primarily based on small candidate gene studies and are inconclusive (Altaner
112 *et al.*, 2006; Pal *et al.*, 2008; Banas *et al.*, 2018; Doria *et al.*, 2018; Takeda *et al.*, 2019). Studies
113 in other complex diseases have shown that genome-wide association studies (GWAS) can
114 provide valuable insight into disease biology (Claussnitzer *et al.*, 2016), but as far as we are
115 aware, no large-scale GWAS have been published for FGT polyps. Therefore, we performed a
116 GWAS meta-analysis to identify the genetic variants associated with FGT polyps, followed by
117 numerous post-GWAS analyses to understand the shared and unique genetic underpinnings of
118 FGT polyps and endometrial cancer. Ultimately, this knowledge can highlight potential clinical
119 avenues for appropriate diagnosis and management of FGT polyps.

120 **Materials and methods**

121 **Ethical approval**

122 All Estonian Biobank (EstBB) participants have signed a broad informed consent form,
123 and analyses were carried out under ethical approvals 1.1-12/624 and 1.1-12/2733 from the
124 Estonian Committee on Bioethics and Human Research (Estonian Ministry of Social Affairs)
125 and data release application 6-7/GI/630 from the EstBB. For the FinnGen study, we used only
126 publicly available GWAS summary statistics without individual-level data and thus, a separate
127 ethics approval was not needed.

128 **Study cohorts**

129 Our analyses included a total of 25,100 women with polyps of the FGT (International
130 Classification of Disease, ICD-10 diagnosis code N84) and 207,193 female controls (without

131 the N84 code) of European ancestry from two studies: summary level statistics from the
132 FinnGen R7 data release (11,092 cases and 94,394 controls) and individual-level data from the
133 EstBB (14,008 cases and 112,799 controls). In FinnGen, cases were defined using the ICD-10
134 code N84 or corresponding ICD-9 (6210, 6227, 6237, 6246) and ICD-8 (62520) codes. Similar
135 to EstBB, controls were defined as women who did not have the abovementioned disease codes.

136 To increase study power, we did not distinguish between different types of FGT polyp
137 location in our phenotype definition. However, according to the FinnGen Risteys browser
138 (https://r7.risteys.finngen.fi/phenocode/N14_POLYPFEMGEN), 20% of FGT polyp cases
139 were also cases for phenotype “Uterine polyps”, while in the EstBB data, 70.5 % of N84 cases
140 had a diagnosis for uterine polyps (as defined by the presence of the ICD-10 code N84.0). This
141 most likely reflects differences in the source of phenotype information - FinnGen phenotype
142 definitions mostly use hospital records and thus involve more severe cases, while the EstBB
143 also uses primary care records.

144 **Cohort-level analyses**

145 The EstBB is a population-based biobank including more than 200,000 individuals
146 (approximately 135,000 of them women) representing 20% of the Estonian adult population.
147 Information on ICD codes is obtained via regular linking with the National Health Insurance
148 Fund and other relevant databases. Individuals with ICD-10 code N84 (mean age at recruitment
149 49.2 years, standard deviation 12.1) were categorised as cases having been diagnosed with
150 polyps of the genital tract, and all female biobank participants without the diagnosis were
151 considered as controls (mean age at recruitment 44.3 years, sd 16.6). The genotyping procedure
152 for EstBB has been described previously (Koel *et al.*, 2023; Laisk *et al.*, 2021; Pujol-Gualdo *et*
153 *al.*, 2022). Briefly, Illumina GSAv1.0, GSAv2.0, and GSAv2.0_EST arrays were used for the
154 genotyping of biobank participants at the Core Genotyping Lab of the Institute of Genomics,

155 University of Tartu. Individuals with a call-rate less than 95% and sex mismatch between
156 phenotypic and chromosomal data were excluded from the analysis. Before imputation,
157 genotyped variants were filtered by applying criteria of call rate $< 95\%$, Hardy-Weinberg
158 equilibrium $P < 10^{-4}$ (for autosomal variants only), and minor allele frequency $< 1\%$. Eagle
159 v2.3 software was used for pre-phasing, and Beagle was used for imputation. The population-
160 specific imputation reference of 2297 whole genome sequencing samples was used. Association
161 analysis was performed using REGENIE v2.2.4 with year of birth and 10 principal components
162 as covariates in step I, and variants with a minor allele count < 5 were excluded by default. In
163 downstream association analysis, poorly imputed variants with an INFO score < 0.4 were
164 excluded.

165 For FinnGen, GWAS summary statistics from the R7 data release were used, and
166 therefore, individual-level data was not available. The summary statistics were obtained from
167 https://www.finnngen.fi/en/access_results, whereas the FinnGen cohort and the genotyping/data
168 analysis details have been previously described in Kurki et al. (Kurki *et al.*, 2023). To
169 summarise, age, 10 principal components, and genotyping batch were used in REGENIE v2.0.2
170 analysis as covariates, and for FinnGen summary statistics, variants with a minor allele count
171 > 5 and imputation INFO score > 0.6 were included.

172 **GWAS meta-analysis**

173 A meta-analysis using fixed-effects inverse variance weighting with genomic control
174 was performed with the GWAMA v2.1 tool. The genome-wide significance level was set to
175 $P < 5 \times 10^{-8}$. The genomic inflation factors (lambda) for the individual study summary statistics
176 were 1.046 (EstBB) and 1.045 (FinnGen). Variants present in both cohorts ($n = 12,363,169$)
177 were included in downstream analyses.

178 **Annotation of GWAS signals**

179 To annotate the GWAS signals and prioritise potential biologically relevant genes at
180 associated loci, we adopted the following approach.

181 First, we used the Functional Mapping and Annotation of Genome-Wide Association
182 Studies (FUMA GWAS) platform v1.5.2 to identify genetic association loci. FUMA is an online
183 platform designed for the annotation, prioritisation, and interpretation of GWAS results that
184 uses data from multiple databases to annotate GWAS signals (Watanabe *et al.*, 2017). In the
185 first step of this analysis, independent significant variants, lead signals and genomic risk loci
186 were defined. Independent significant variants (IndSigSNPs) were defined as variants that were
187 genome-wide significant ($P < 5 \times 10^{-8}$) and had a pairwise LD $r^2 < 0.6$, according to the 1000G
188 EUR reference panel. From this subset, lead variants were derived. Finally, risk loci were
189 defined from independent significant SNPs by merging LD blocks if they are less apart than r^2
190 < 0.6 . Thus, a genomic risk locus can contain several lead SNPs and/or independent significant
191 SNPs, depending on the size of the locus and the LD structure. Thereafter, potential significant
192 candidate SNPs (GWAS meta-analysis $P > 0.05$) were determined to be in LD with any of the
193 IndSigSNPs ($r^2 \geq 0.6$) within a 1Mb window and had a MAF of $\geq 1\%$. These candidate SNPs
194 were subjected to further annotation using multiple databases such as Annotate Variation
195 (ANNOVAR) (Wang *et al.*, 2010), RegulomeDB scores (ranging from 1 to 7, where lower
196 score indicates greater evidence for having regulatory function) (Boyle *et al.*, 2012), and
197 Combined Annotation-Dependent Depletion (CADD) (a continuous score showing how
198 deleterious the SNP is to protein structure/function; scores >12.37 indicate potential
199 pathogenicity) (Kircher *et al.*, 2014), 15 chromatin states from the Roadmap Epigenomics
200 Project (ENCODE Project Consortium, 2012; Roadmap Epigenomics Consortium *et al.*, 2015),
201 expression quantitative trait loci (eQTL) data (genotype-tissue expression (GTEx) v6 and v7)
202 (GTEx Consortium, 2013) and 3D chromatin interactions from HI-C experiments of 21
203 tissues/cell types (Schmitt *et al.*, 2016). This process provides information on the location,

204 functional impact, and potential regulatory effects of detected SNPs. For eQTL annotations, we
205 focused on tissues similar to uterine/vaginal tissue (GTEx Consortium, 2020).

206 Using the lead signal identified by FUMA, we performed a look-up in the Open Targets
207 genetics database (Ghoussaini *et al.*, 2021). This database combines several layers of evidence
208 across a wide range of cell types and tissues to generate an aggregate ‘variant to gene’ (V2G)
209 score. The V2G score provides identification and correlation of likely causal variants and genes
210 to prioritise the potential functional genes associated with the identified variants. V2G score
211 aggregates several parameters like distance from the canonical transcript start site, eQTLs and
212 protein QTLs (pQTLs) datasets, datasets for chromatin interactions and conformation,
213 molecular phenotypes, and *in silico* functional predictions (using the Variant Effect Predictor
214 or VEP score).

215 Briefly, we prioritised genes in the identified loci by selecting three genes having the
216 highest V2G score. Then we additionally identified those loci where the GWAS signal includes
217 a missense variant using annotation data from FUMA. To provide additional support for
218 prioritisation and further explore regulatory effects, we looked at eQTL associations according
219 to FUMA annotations, and if none were reported, we looked at potential chromatin interactions
220 as these may also indicate regulatory effects. To gain insight into endometrial-specific eQTLs,
221 we queried the candidate SNPs defined by FUMA in the endometrial eQTL database (Fung *et*
222 *al.*, 2018).

223 **Gene-based testing**

224 Analysis by Multi-marker Analysis of GenoMic Annotation (MAGMA) v1.6 (de Leeuw
225 *et al.*, 2015), with the default settings in FUMA (Watanabe *et al.*, 2017), was used to perform
226 gene-based association analysis to complement the single variant analyses. Gene-based analysis
227 enables to detect the joint effect of multiple genetic variants and can thus increase the power to
228 detect associations. Briefly, variants located in the gene body were assigned to protein-coding

229 genes (n = 18,895; Ensembl build 85), and the SNP P-values were merged into a gene test
230 statistic using the SNP-wise mean model (de Leeuw *et al.*, 2015). The level of genome-wide
231 significance was set at $0.05/18,895 = 2.6 \times 10^{-6}$, taking into account the number of tested genes.

232 **Genetic associations with other traits:**

233 During the FUMA functional mapping, candidate SNPs were linked with the GWAS
234 catalogue (<https://www.ebi.ac.uk/gwas/>, GWAS Catalogue e0_r2022-11-29, FUMA v1.5.1) to
235 explore the association of genetic variants with previously published GWAS of different
236 phenotypic traits.

237 **Genetic correlation analysis**

238 To estimate the genetic correlations between our FGT polyps meta-analysis and 1,335
239 other traits, we utilised the LD Score Regression method implemented in the Complex Traits
240 Genetics Virtual Lab (CTG-VL) (<https://genoma.io/>) and 3 additional endometrial cancer traits
241 available in the GWAS catalogue (accession codes GCST006464, GCST006465 and
242 GCST006466) (Bulik-Sullivan *et al.*, 2015). Statistical significance was determined by
243 applying a multiple testing correction (FDR < 5%) using the `p.adjust` function in R v3.6.3.

244 **Associations with other phenotypic traits**

245 To determine the associations between ICD-10 diagnosis main codes and the N84
246 diagnosis of polyps in the FGT, we conducted an analysis using individual level data from the
247 EstBB. Logistic regression was used to test the associations between N84 and other ICD-10
248 codes while controlling for age at recruitment and 10 genetic principal components to account
249 for population stratification and avoid false associations due to ancestry/regional differences
250 between cases and controls. Age was included as a covariate to account for incomplete
251 electronic diagnosis data for older participants in the biobank. Our analysis was limited to the
252 diagnosis main codes along with all the subcodes to increase the power of the data. Statistically

253 significant associations were determined by applying Bonferroni correction (2000 tested ICD
254 main codes, corrected P threshold of 2.5×10^{-5}). Odds ratios (ORs) were calculated by the
255 logistic regression method and represented as adjusted ORs. The resulted associations were
256 filtered to remove the diagnoses related to exogenous factors (such as injuries, poisoning,
257 accidents, assaults, etc. in the S, T, U, V, W, X, and Y subchapters) and the PheWAS library
258 (<https://github.com/PheWAS/PheWAS>) was used to visualise the results. All analyses were
259 performed using R v4.1.3

260 In the FinnGen data, we did not have access to the individual level data, but using the
261 Risteys portal (https://r7.risteys.finnngen.fi/phenocode/N14_POLYPFEMGEN), we explored
262 the results of the survival analysis evaluating associations between FGT polyps and other
263 selected phenotypes. A detailed description of the survival analysis can be found in the Risteys
264 documentation (<https://r7.risteys.finnngen.fi/documentation>), but briefly, this type of analysis
265 tests the association between an exposure endpoint and an outcome endpoint. For example, in
266 the context of FGT polyps, what is the association between a diagnosis of FGT polyp (exposure
267 endpoint) and endometrial carcinoma (outcome endpoint).

268 **Results**

269 **Summary of GWAS**

270 GWAS of a total of 25,100 women with polyps of the FGT and 207,193 female controls
271 revealed ten significant ($P < 5 \times 10^{-8}$) genomic risk loci and 23 independent signals (Fig. 1,
272 Table 1). The strongest signal, rs1702136 ($P = 2.17 \times 10^{-19}$), was observed on chromosome 3,
273 which is an intronic variant of the *EEFSEC* gene. The majority of the significant signals
274 (91.3%) were either intronic or intergenic variants, whereas two signals, rs2277339 ($P = 7.57 \times$
275 10^{-10}) and rs1265005 ($P = 1.09 \times 10^{-9}$, in LD with rs805698, $r^2 = 0.75$) on chromosomes 12 and
276 10, respectively, were exonic missense variants.

290 **Figure 1. Manhattan plot for significant genomic risk loci identified for polyps of female**

291 **genital tract.** On the Manhattan plot, the x-axis represents chromosomes, while the y-axis

292 represents $-\log_{10}(\text{P-values})$ for the association of variants identified in polyps of the female

293 genital tract. The horizontal red dashed line represents the genome-wide significance threshold

294 ($P < 5 \times 10^{-8}$). The prioritised genes for each locus are labelled on the top, and genes associated

295 with exonic missense variants are coloured red.

296 **Functional annotation of associated variants and gene prioritisation**

297 We performed a look-up in the Open Targets Genetics database to evaluate the

298 functional association of identified genomic loci and potentially mapped genes reflected by the

299 V2G score. We additionally highlighted those loci where the GWAS signal includes a missense
 300 variant using annotation data from FUMA (Table 2). Full details of gene prioritisation together
 301 with supporting evidence from FUMA eQTL and chromatin interaction mapping, can be found
 302 in Supplementary Table 1.

303 **Table 2. Summary of gene prioritisation results**

Locus	Lead variant	Highest V2G score	Exonic variants	Biological evidence
3:128118711: A:G	rs1702136	<i>EEFSEC</i> <i>RPN1</i> <i>DNAJB8</i>	NA	<i>EEFSEC</i> potential endometrial cancer susceptibility gene (Kho <i>et al.</i> , 2021)

304

305 Based on coding variants in our GWAS signals, we were able to prioritise *PRIM1* and *COL17A1*
306 in loci on chromosomes 12 and 10, respectively. *PRIM1* is a DNA primase involved in the
307 initiation of DNA replication by synthesising RNA primers for Okazaki fragments during
308 discontinuous DNA replication (Shiratori *et al.*, 1995). rs2277339 is also a cis-eQTL for *PRIM1*
309 in endometrial tissue, which further supports *PRIM1* as a candidate gene in this locus.

310 *COL17A1*, on the other hand, is primarily involved in cellular migration, cellular differentiation,
311 and extracellular matrix organisation (Jones *et al.*, 2020). While these genes have not yet been
312 directly associated with FGT polyps, their biological functions, particularly those related to
313 cellular proliferation, highlight their potential involvement in the development of polyps.

314 Several of the prioritised candidate genes had previously been associated with
315 (endometrial) cancer - *EEFSEC*, *TRPS1*, *TERT/CLPTMIL*, one could be directly linked with
316 endometrial biology (*BMPRI1B*), and for the remaining, their biological significance in FGT
317 polyps remains unclear.

318 **Gene-based associations of female genital tract polyps:**

319 To combine the joint effect of multiple genetic variants and increase the power to detect
320 associations, we performed a MAGMA gene-based test implemented in FUMA. Eight genes
321 were identified which passed the recommended threshold for significance ($P = 2.6 \times 10^{-6}$,
322 Bonferroni correction for association testing of 18,895 protein-coding genes): *EEFSEC*, *TERT*,
323 *RUVBL1*, *BMPRI1B*, *TRPS1*, *COL17A1*, *BETIL*, *WBP4* (Supplementary Figure 1,
324 Supplementary Table 2). Majority of these associations mirror the genes prioritised in the single
325 variant analysis, while the *BETIL* locus was not genome-wide significant in the single variant
326 analysis and is thus novel. Previously, *BETIL* has been associated with endometrial cancer
327 (Bateman *et al.*, 2017) and uterine fibroids (Cha *et al.*, 2011; Edwards *et al.*, 2013; Liu *et al.*,
328 2018).

329 **GWAS catalogue look-up**

330 We searched the GWAS catalogue for associations between previously published
331 phenotypic traits and candidate SNPs identified by the FUMA tool to gain additional insight
332 into their potential biological roles (Fig. 2, Supplementary Table 3). Based on the GWAS
333 catalogue look-up, the *TERT-CLPTMIL* (rs7705526) locus was clearly associated with cancers,

334 including the development of reproductive cancers such as ovarian cancer and prostate cancer.
335 Potential involvement in cancerous processes was also observed for the *EEFSEC* locus
336 (rs4857866), which was associated with prostate cancer and also nominally with endometrial
337 cancer ($P < 1 \times 10^{-6}$). Several identified signals were related to reproductive traits, including
338 menarche (rs2277339-*PRIMI*), menopause (rs2277339-*PRIMI*), gestational age (rs4857866-
339 *EEFSEC*) and uterine fibroids (rs2277339-*PRIMI*, rs193097753-*COL17A1*, rs17116149-
340 *COL17A1*). The rs193097753 signal was additionally associated with the known risk factors
341 for the development of FGT polyps, such as type 2 diabetes ($P < 5 \times 10^{-8}$) and waist-to-hip ratio
342 ($P < 2 \times 10^{-11}$), further substantiating its functional significance.

343

344

345

346 **Figure. 2: GWAS catalogue look-up showing associations between genetic variants**
 347 **associated with female genital tract polyps and other phenotypes.** The figure highlights the
 348 genome-wide significant ($P < 5 \times 10^{-8}$) association between FGT polyps genetic risk factors
 349 (individual significant SNPs) and previously published phenotypic traits and disorders.

350 **Look-up of variants associated with endometrial cancer**

351 Since there is some overlap between FGT polyp genetic risk loci and those known to be
 352 associated with (endometrial) cancer, we conducted a look-up of variants associated with
 353 endometrial cancer (O'Mara *et al.*, 2018) in our GWAS data. Of the 19 SNPs queried, seven

354 were nominally significant ($P < 0.05$) (rs9668337-*SSPN*, rs1740828-*SOX4*, rs17601876-
355 *CYP19A1*, rs882380-*SNX11*, rs3184504-*SH2B3*, rs1129506-*EVI2A*, rs11263761-*HNF1B*) in
356 the FGT polyp analysis as well (Supplementary Table 4). When querying the 10 lead variants
357 associated with FGT polyp in the endometrial cancer summary statistics, we observed that three
358 were nominally significant ($P < 0.05$) in the endometrial cancer and also in the endometrial
359 cancer with endometrioid histology studies (rs1702136-*EEFSEC*, rs2865375-*BMPR1B*,
360 rs7705526-*TERT*).

361 **Genetic correlation between FGT polyps and other traits**

362 We conducted pairwise genetic correlation (r_g) analyses to examine the relationship
363 between polyps of the FGT and 1,335 different traits obtained from the Complex Traits
364 Genetics Virtual Lab (CTG-VL, <https://genoma.io/>) and 3 additional endometrial cancer traits
365 available in the GWAS catalogue (accession codes GCST006464, GCST006465 and
366 GCST006466). After running the analysis and correcting for multiple testing, we identified a
367 total of 11 significant ($FDR < 0.05$) genetic correlations. Selected genetic correlations between
368 polyps and various phenotypic categories such as anthropometrics, cardiovascular diseases,
369 genitourinary traits, mood disorders, sex hormones and surgical procedures are displayed in
370 Fig. 3, full results in Supplementary Table 5. As expected, a positive genetic correlation was
371 observed with genitourinary traits and hysterectomy, emphasising that polyps are commonly
372 occurring incidental findings in gynaecological disorders. Furthermore, sex hormone-binding
373 globulin (SHBG) was negatively correlated with the risk of FGT polyps. We were not able to
374 detect a significant genetic correlation between FGT polyps and estradiol level or BMI, known
375 risk factors of FGT polyps, in our dataset. FGT polyps showed weak correlation with two of
376 the three endometrial cancer phenotypes tested (endometrial cancer and endometrial cancer -
377 endometrioid histology, both r_g 0.25-0.27, se 0.12-0.13), but these associations were only
378 nominally significant ($P = 0.03$) and did not pass multiple testing correction threshold.

379

380 **Figure 3: Results of genetic correlation analysis between endometrial polyps and other**
 381 **relevant traits.**

382 The plot displays selected genetic correlations between female genital tract polyps and traits
 383 from various phenotypic categories such as anthropometrics, cardiovascular traits,
 384 genitourinary traits, mood disorders, sex hormones and surgical procedures that are colour-
 385 coded. Significant associations after FDR multiple correction are shown in the lower panel,
 386 while the upper panel shows selected traits of interest that do not pass the multiple testing
 387 correction. The centre dot marks the estimated genetic correlation (r_g) value, and error bars
 388 indicate 95% confidence limits. The dotted red line indicates no genetic correlation.

389 **Associations between polyps of FGT and other diagnosis codes**

390 Additionally, to evaluate other phenotypes' association with FGT polyps, we performed
 391 a phenome-wide phenotype association analysis using the EstBB data for disease codes. All
 392 239 phenotypic associations with a $P < 2.5 \times 10^{-5}$ (corresponding to a Bonferroni-corrected
 393 threshold of 0.05/2020) are shown in Supplementary Table 6. The most significant association
 394 of FGT polyps related to other phenotypes were: i) leiomyoma of uterus (D25), which are

395 uterine fibroids known to often occur together with EPs (Kinay *et al.*, 2016); ii) endometriosis
396 (N80), which has been correlated with a high prevalence of endometrial polyps; iii) excessive,
397 frequent and irregular menstruation (N92) which is one of the classical symptoms of EPs, and;
398 iv) other noninflammatory disorders of uterus except cervix (N85) (Fig. 4). Moreover, women
399 with a diagnosis for FGT polyps had significantly more diagnoses for benign neoplasms in
400 several tissues, such as the uterus (D26), ovary (D27), unspecified female genital organs (D28
401 and D39) and skin (D23) as well as malignant neoplasms of the uterus (C54) and skin (C44).
402 In our analysis, nasal polyps (J33) and K62 (which includes anal/rectal polyps) were also
403 nominally significant, which supports the idea of some systemic tissue overgrowth in epithelial
404 tissues similar to endometrial polyps harbouring glandular and luminal epithelium.

405 For the highlighted associations, we queried the FinnGen Risteys R7 portal to see if we
406 observe similar associations in the Finnish data. While the analysis in the Estonian data does
407 not consider which diagnosis in the tested pair comes first, the FinnGen data survival analysis
408 tests the association in both directions. Uterine leiomyoma, endometriosis, other benign
409 neoplasm of uterus, benign neoplasm of ovary, malignant neoplasm of uterus, and carcinoma
410 in situ of endometrium were significantly associated with FGT polyps in the survival analysis
411 in FinnGen data, (Supplementary Table 7) both if the diagnosis occurred before, or after the
412 FGT polyp diagnosis.

413 The results of phenotypic associations of FGT polyps are in concordance with the observed
414 genetic associations and point to the fact that benign and cancerous processes share some
415 mechanisms (such as cellular proliferation) on a genetic level.

416

417

418

419

427 **Figure 4: Association of Polyps of female genital tract (N84) with other phenotypes.**

428 Each triangle in the plot corresponds to one ICD10 main code, and different colours represent
429 different diagnosis categories. The direction of the triangle represents the direction of effect and
430 upward-pointing triangles show increased significance of diagnosis code in female genital tract
431 polyps. The red line indicates the Bonferroni corrected threshold for statistical significance.

432 Discussion

433 Gynaecological polyps are a common diagnosis in women, with potential negative
434 implications for women's reproductive health and well-being. We conducted the first large-
435 scale GWAS meta-analysis to study the genetic underpinnings of FGT polyps and their
436 association with other phenotypic traits from two European ancestry biobanks. The analysis
437 revealed ten genomic risk loci, of which two (rs2277339 and rs193097753) tagged exonic
438 missense variants suggestive of plausible functional importance in the development of polyps.
439 Furthermore, several of the identified genetic risk loci have previously been associated with
440 (endometrial) cancer and/or uterine fibroids. Genetic correlation analysis additionally showed
441 negative correlation with SHBG levels, but no statistically significant genome-wide correlation

442 with endometrial cancer. PheWAS analysis showed an increased prevalence of endometriosis,
443 irregular and excessive menstruation, uterine fibroids and neoplasms of the uterus and other
444 tissues in women with FGT polyps.

445 Even though most EPs are benign, there is still a certain level of risk these polyps may
446 progress to malignant transformation (Antunes *et al.*, 2007; Lenci *et al.*, 2014). According to a
447 systematic review and meta-analysis, 2.7%-3.6% of EPs can be considered malignant, with
448 significant heterogeneity in prevalence among pre- and postmenopausal women (Lee *et al.*,
449 2010; Sasaki *et al.*, 2018; Uglietti *et al.*, 2019). While we saw no statistically significant genetic
450 correlation between FGT polyps and endometrial cancer, several of the mapped genetic risk
451 loci/prioritised genes (rs1702136-*EEFSEC*, rs800578-*TRPS1*, rs2865375-*BMPR1B*, and
452 rs7705526-*TERT-CLPTMIL*) have previously been associated with cancer either in GWAS or
453 functional studies (Liang *et al.*, 2012; Wu *et al.*, 2014; Kho *et al.*, 2021; Dos Santos *et al.*,
454 2022), most likely reflecting the fact that both benign and malignant tissue overgrowths may
455 utilise the same cellular mechanisms to some extent. This is supported by the results of the
456 associated diagnoses analysis where women with a diagnosis of FGT polyp also have more
457 diagnoses related to benign and malignant neoplasms of the uterus, ovary, and skin. While the
458 associations with reproductive tract neoplasms may arise due to incidental findings during
459 diagnostic procedures, it cannot be ruled out that some women have a genetic predisposition to
460 tissue overgrowth that may manifest in either benign or malignant neoplasms in certain tissues.
461 Apart from a few small-scale reports (Unler *et al.*, 2016), there are no relevant studies
462 evaluating the prevalence of different neoplasms among women with FGT polyps, therefore,
463 our observations need to be confirmed and further evaluated in future studies.

464 We further saw significant associations of FGT polyps with uterine leiomyoma and
465 endometriosis. Though the cellular composition, characteristics, and mechanism of origin of
466 uterine fibroids and endometrial polyps differ from each other, they can occur concurrently due

467 to common risk factors like advanced age, obesity, and hormonal dysregulation (Kinay *et al.*,
468 2016; Pavone *et al.*, 2018). Further, increased prevalence of endometriosis among women with
469 FGT polyps emphasises the reported evidence of a higher prevalence of endometrial polyps in
470 endometriosis patients (Shen *et al.*, 2011; Zhang *et al.*, 2018; Lin *et al.*, 2020; Peters *et al.*,
471 2022).

472 Our genetic correlation analysis showed a significant negative correlation between
473 SHBG levels and the risk of FGT polyps. In females, testosterone and oestrogen levels are
474 regulated through their binding to SHBG, which helps maintain hormonal balance in the
475 bloodstream. Lower levels of SHBG can result in elevated levels of free testosterone and free
476 oestrogen. As EPs are oestrogen dependent, lower SHBG may directly stimulate EP
477 development. Moreover, the expression of aromatase 450 enzyme in the EPs, converts free
478 testosterone into oestrogen, further augments the stimulation of polyps' development (Filho *et*
479 *al.*, 2007). Thus, our study's finding of the negative correlation of SHBG in FGT polyps
480 concurs with this mechanism. Unexpectedly, our analysis did not reveal a genetic correlation
481 between oestradiol and EPs. The discrepancy between circulating plasma levels and localized
482 endometrial levels of oestradiol may underlie the lack of this correlation. In the literature, serum
483 levels of oestradiol were shown to be significantly lower (five times) than the endometrial
484 oestradiol concentration in the proliferative phase (Huhtinen *et al.*, 2012). The same trend was
485 observed in women with abnormal uterine bleeding and hyperplasia (Cortés-Gallegos *et al.*,
486 1975). Given that abnormal bleeding and hyperplasia are important symptoms of endometrial
487 polyps, it suggests that localised oestradiol may play a more crucial role in EP development.
488 Additionally, a study reported no significant difference in circulating oestradiol concentration
489 among women with and without endometrial polyps (Cortés-Gallegos *et al.*, 1975), which
490 further supports our finding. This can also explain the lack of correlation of FGT polyps with

491 BMI to some extent, as higher BMI is often associated with increased circulating oestradiol
492 levels.

493 To understand how genetic variation impacts trait susceptibility, it is important to link
494 associated genetic variants with specific genes and mechanisms. We employed a diverse range
495 of data layers to map potential candidate genes for the identified genomic loci. Among others,
496 *PRIMI* (rs2277339) and *COL17A1* (rs193097753) were prioritised since the GWAS signals
497 tagged coding variants in these genes. In the literature, neither of these genes has been directly
498 correlated with FGT development. The *PRIMI* gene is a key regulator of DNA replication
499 during cellular proliferation process. It has been shown that the *PRIMI* expression was
500 upregulated in breast tumour tissues compared to healthy tissues, and its inhibition led to
501 tumour cell growth regression (Lee *et al.*, 2019). Furthermore, the *PRIMI*-induced tumour cell
502 growth is stimulated by oestrogen through activation of the oestrogen receptor (ER) (Lee *et al.*,
503 2019). As per one of the postulated hypotheses, polyp development is related to oestrogen
504 stimulation with predominantly increased ER alpha (ER-alpha) and decreased progesterone
505 receptors (PRs) A and B in the glandular epithelium. On the other hand, in the stromal cells of
506 polyps, lower concentrations of ER and PR hinder the decidualization process, preventing them
507 from shedding off during menstruation (Mittal *et al.*, 1996; Peng *et al.*, 2009; Nijkang *et al.*,
508 2019). Since the *PRIMI* gene signalling is oestrogen-associated, this can provide important
509 insights into the probable functional mechanisms underlying the development of polyps. The
510 *COL17A1* gene is closely associated with epithelial tumour progression and invasiveness (Jones
511 *et al.*, 2020), suggesting that a shared biological mechanism related to epithelial cell
512 proliferation could be associated with the development of EPs. However, further functional
513 assays on *PRIMI* and *COL17A1* genes are needed to confirm these associations.

514 While our study is a large-scale study, it had certain limitations. The cohort from
515 Estonian and Finnish biobanks encompasses women with all kinds of reproductive polyps, and

516 our phenotype definition did not differentiate between the types/location of polyps to increase
517 study sample size power. However, considering the overall occurrence of polyps in the general
518 population, endometrial polyps would be more prevalent than the other types. A complete
519 understanding of the transcriptome profile of endometrial polyps is still lacking, resulting in
520 knowledge gaps regarding the interplay between genomic loci and the regulation of gene
521 expression. By addressing these knowledge gaps, we can gain valuable insights into the genetic
522 factors and gene expression patterns that contribute to the pathogenesis of endometrial polyps
523 and potentially identify novel therapeutic targets for their management.

524 In conclusion, the first GWAS meta-analysis of FGT polyps highlights and clarifies the
525 genetic mechanisms shared between EP development (tissue overgrowth) and cancerous
526 processes. Furthermore, an analysis of associated diagnoses showed that women diagnosed with
527 EPs have an increased prevalence of other diagnoses, such as endometriosis, uterine fibroids
528 and both benign and malignant neoplasms, which could have implications for patient
529 management and counselling.

530 **Supplementary data:** Supplementary data are available at Human reproduction online.

531 **Data availability:** FinnGen cohort level summary statistics can be accessed as described here:
532 https://www.finnngen.fi/en/access_results. Protocol for accessing the Estonian Biobank data is
533 described here: <https://genomics.ut.ee/en/content/estonian-biobank>. GWAS meta-analysis
534 summary statistics will be made available via the GWAS Catalogue (data upload pending).

535 **Author's roles:** Authors A.D.S.P., N.P.G, A.S., M.P and T.L. participated in the conception of
536 the study, data analysis, and interpretation of the data, and writing the manuscript. V.R., J.D.,
537 and R.M. contributed to data analysis and interpretation. T.L., M.S., M.P., V.R., J.D. and A.S.
538 critically reviewed and provided feedback on each version of the manuscript and all the authors
539 approved the final version. The EstBB Research Team provided the EstBB genotype and
540 phenotype data.

541 **Acknowledgements:** We want to acknowledge the participants of the Estonian Biobank and
542 the participants and investigators of the FinnGen study. We also acknowledge the Estonian
543 Biobank Research team members Andres Metspalu, Tonu Esko, Mari Nelis, Georgi Hudjashov,
544 and Lili Milani.

545 **Funding:** N.P.G. was supported by MATER Marie Sklodowska-Curie which received funding
546 from the European Union's Horizon 2020 research and innovation programme under grant
547 agreement No. 813707. T.L. was supported by the Estonian Research Council grant PSG776.
548 This study was funded by European Union through the European Regional Development Fund
549 Project No. 2014-2020.4.01.15-0012 GENTRANSMED. Computations were performed in the
550 High-Performance Computing Center of University of Tartu. The study was also supported by
551 the Estonian Research Council (grant no. PRG1076 and MOBJD1056) and Horizon 2020
552 innovation grant (ERIN, grant no. EU952516).

553 **Conflict of interest:** All the authors declared no conflict of interest.

758 **Supplementary materials:**

759 **Supplementary figure 1: Genome-wide gene association analysis of our GWAS dataset**
760 **using ‘Multi-marker Analysis of GenoMic Annotation (MAGMA) wherein input SNPs**
761 **were mapped to 18895 protein-coding genes.** On the Manhattan plot, the y-axis represents
762 $-\log_{10}(\text{P-values})$ for the association of variants identified in polyps of the female genital tract.
763 The horizontal red dashed line represents the genome-wide significance threshold ($P < 5 \times$
764 10^{-8}) and prioritised genes for each locus are shown. Genes associated with exonic missense
765 variants are denoted in red text.
