26 communities

27

28 **Abstract**

29 Wastewater can play a vital role in infectious disease surveillance, especially in underserved
30 communities where it can reduce the equity gap to larger municipalities. However, using
31 wastewater surveillance in a predictive manner remains a challenge. We tested if detecting
32 SARS-CoV-2 in wastewater can predict outbreaks in rural communities. Under the CDC
33 National Wastewater Surveillance program, we monitored several rural communities in Idaho
34 (USA). While high daily variations in wastewater viral load made real-time interpretation
35 difficult, a SEIR model could factor out the data noise and forecast the start of the Omicron
36 outbreak in five of the six cities that were sampled soon after SARS-CoV-2 quantities increased
37 in wastewater. For one city, the model could predict an outbreak 11 days before reported clinical
38 cases began to increase. An epidemiological modeling approach can transform how
39 epidemiologists use wastewater data to provide public health guidance on infectious diseases in
40 rural communities.

41 **Main text**

42 **Introduction.**

43 Wastewater-based epidemiology (WBE) is a promising approach for broad-scale, agnostic
44 surveillance of infectious diseases and antimicrobial resistance within and across communities.
45 Indeed, many infectious agents such as SARS-CoV-2, poliovirus, RSV, and flu shed through
46 stool (1,2), and potentially urine (3), and are thus detectable in wastewater (4,5). Additionally,
47 WBE assesses infectious disease circulation in both symptomatic and asymptomatic populations.
48 Most importantly, WBE can improve and accelerate the early detection of infectious disease
49 outbreaks by public health authorities, providing actionable data for epidemiologists. However,
50 barriers remain to how epidemiologists might use or interpret this data to inform public health in
51 a predictive way rather than a retrospective approach. A modeling-based approach to wastewater
52 data can provide the framework to interpret infectious disease spread and burden by estimating
53 epidemiological parameters such as incidence (6), prevalence (7–9), or effective reproductive
54 number (10).

55 WBE also presents a unique opportunity to support vulnerable and underserved communities
56 (11). In particular, rural communities are at a higher risk of severe outcomes associated with
57 certain infectious diseases due to demographic factors (e.g., age), underlying healthcare
58 challenges (e.g. obesity, smoking), limited resources (12–15), or reduced risk perception (16).
59 Moreover, as rural communities often lack the resources for broader-scale clinical testing, WBE
60 can help sustain rural community health. Unfortunately, WBE has mainly focused on urban areas
61 and larger cities, leaving rural communities with reduced access to this critical data (11,17–20).
62 In that regard, WBE is a tool that promotes equity (21).

63 The COVID-19 pandemic provided a unique opportunity to leverage and expand WBE while
64 concurrently establishing greater value for epidemiologists. Concentrations of SARS-CoV-2
65 found in wastewater correlate well with the number of COVID-19 cases (22–24). Thus, with the
66 right tools in place WBE can serve as an early warning for a potential COVID-19 outbreak
67 (4,25–28). Perhaps more critically for epidemiologists, the utility of wastewater-based detection
68 of SARS-CoV-2 has become even more significant with reduced COVID-19 clinical testing due
69 to home tests and general lack of clinical reporting (29). However, there remains a gap in
70 translating WBE data in a timely manner for use by public health officials. Moreover, a primary
71 obstacle for epidemiologists is the variability and uncertainty inherent in wastewater monitoring
72 (30,31).

73 Modeling SARS-CoV-2 wastewater data represents an opportunity to bridge the information
74 gap with epidemiologists while bringing enhanced and timely health monitoring to rural
75 communities. Here we present and discuss a susceptible-exposed-infectious-recovered (SEIR)
76 epidemiological model developed based on wastewater detection of SARS-CoV-2 for
77 epidemiological surveillance of COVID-19 in rural area. We specifically tested the hypothesis
78 that the detection and quantification of SARS-CoV-2 in wastewater forecasts the start of an
79 outbreak in rural communities.

80

81 **Material & Methods.**

82 **Sites and sample collection**

83 Wastewater samples were collected from wastewater treatment facilities (WWTFs) located in
84 five rural communities serving approximately 1,000 or less inhabitants and a small city in a rural

85 county in Idaho, USA (Table 1). These rural communities are defined as "rural" according to the
86 2020 U.S. Census Bureau. The county itself falls under the category of a "rural" or
87 "nonmetropolitan" county, as classified by the U.S. Office of Management and Budget. Rural
88 cities are abbreviated RC1 to RC5 and the small city SC. All WWTFs primarily treat domestic
89 wastewater; the SC WWTF also receives effluent from a regional hospital.

90 Samples were collected three times a week from October 2021 to March 2022. Rural WWTF
91 samples were time-composite samples collected using Teledyne ISCO 3700 Full Size Portable
92 Sampler (Teledyne ISCO, Lincoln, NE, USA) autosamplers or homemade autosamplers
93 constituted of a Sci-Q 323 peristaltic pump (Watson-Marlow, Falmouth, UK) controlled by an
94 Omron H3CR timer (Omron Corporation, Kyoto, Japan) and housed in a cooler box. Sampling
95 frequencies were comprised between 10 and 30 minutes for 24h. Approximately 3L of
96 wastewater was collected, and subsamples were collected at the end of the 24h sampling period
97 and transported within 6h to the laboratory, where samples were kept at 4°C until further
98 processing. Samples from the SC WWTF were collected using a Teledyne ISCO model 3700
99 autosampler (Teledyne ISCO, Lincoln, NE, USA), with samples collected paced with influent
100 flow. Sampling failed for less than 10% of the total samples sampled. Samples were kept at 4°C
101 until further processed, at most 3 days later.

102 Confirmed COVID-19 case counts per zip code were obtained from the Idaho Public Health
103 District 2 website (<https://idahopublichealth.com/district-2/novel-coronavirus>).

104 **Sample processing for SARS-CoV-2 detection and quantification.**

105 The detailed protocols presented below are publicly available on protocol.io (32). In brief,
106 before concentrating the viral fraction of two replicate wastewater fractions through
107 electronegative membrane filtration, each sample was spiked with the Bovilis® Coronavirus

108 (BCoV) (Merck, Kenilworth, NJ, USA) as a process internal control. Subsequently, filters were
109 inserted together with the DNA/RNA Shield™ (Zymo Research, Irvine, CA, USA) into the Lysis
110 Bead tubes from the AllPrep® PowerViral® DNA/RNA Kit (QIAGEN, Inc., Germantown, MD,
111 USA). Lysis was performed on a FastPrep™ (MP Biomedicals, Santa Ana, CA, USA) for 4
112 cycles of 20 seconds each at 4.5 m/s and the RNA was then extracted as per the kit
113 manufacturer's protocol on a QIAcube Connect automated extraction instrument (QIAGEN, Inc.,
114 Germantown, MD, USA).

115 SARS-CoV-2 was quantified by dPCR using the QIAcuity Digital PCR System (QIAGEN,
116 Inc., Germantown, MD, USA) using the GT-Digital SARS-CoV-2 Wastewater Surveillance
117 Assay For QIAcuity® (GT Molecular, Fort Collins, CO, USA). Each 40 µl reaction contained 1x
118 of the Qiagen QIAcuity One-Step Viral RT-PCR Kit (QIAGEN, Inc., Germantown, MD, USA),
119 1x of the GT Molecular N1-N2-BCoV Assay Solution, and 20 µl RNA template. RNA extraction
120 blanks, dPCR non-template controls and positive controls were included in each dPCR run.

121 **Data processing and analysis**

122 Fluorescent thresholds were manually set based on the fluorescent level of the positive
123 controls. Then we excluded data from samples for which (i) the recovery rate of the internal
124 processing control BCoV was lower than 1%, or (ii) the RNA extraction process control or dPCR
125 negative control were positive and more than 10% of the measured sample concentration.

126 The date of an outbreak's start was determined with a piecewise regression model using
127 either the cumulative sum of the copies per day of the N1 target or the cumulative sum of
128 COVID-19 clinically confirmed cases to estimate the breakpoint in a linear dataset. For each
129 city, we subsampled the linear data around the inflection points corresponding to the dates of the
130 main surge of N1 copies or COVID-19 reported cases in early 2022. Then we fitted a linear

131 regression model in R using the “lm” function with cumulative copies of cases as the response
132 (Y) and the date as the predictor (X). Finally, we fitted the piecewise regression model to the
133 original model, estimating a breakpoint around the inflection of the line, using the segmented()
134 function from the segmented package in R (33).

135 *SARS-CoV-2 Epidemiological Model.*

136 We constructed a compartmental model to approximate the dynamics of the epidemic in each
137 city. Due to the small size of populations in the rural areas, we expected stochastic effects to be
138 important, and opted to use a discrete-time discrete-state Markov process to approximate the
139 spread of the disease. In this model, individuals in the population can be in one of four states:
140 susceptible (S), exposed (E), infectious (I), and removed (R). Importantly, in this model exposed
141 individuals have contracted the disease and shed the virus but are not yet infectious. The changes
142 in the compartments are assumed to be binomially distributed: $X_t \sim \text{Bin}\left(S(t), \frac{\beta I(t)}{N(t)}\right)$ is the
143 number of newly exposed individuals on day t , $Y_t \sim \text{Bin}\left(E(t), \frac{1}{\tau}\right)$ is the number of newly
144 infectious individuals on day t , and $Z_t \sim \text{Bin}\left(I(t), \frac{1}{\delta}\right)$ is the number of newly recovered
145 individuals on day t . The parameter β is the transmission rate, τ is the mean incubation period,
146 and δ is the mean infectious period, and $N(t) = S(t) + E(t) + I(t) + R(t)$ is the total
147 population at time t . The discrete-time Markov process is given by:

148

$$149 \quad (1a) \quad \Delta S(t) = -X_t,$$

$$150 \quad (1b) \quad \Delta E(t) = X_t - Y_t,$$

$$151 \quad (1c) \quad \Delta I(t) = Y_t - Z_t,$$

152 (1d) $\Delta R(t) = Z_t.$

153

154 The number of virus particles shed by exposed individuals was assumed to be log-normally
155 distributed (34). However, the log-normal distribution is difficult to work with mathematically,
156 so we approximated the log-normal distribution using the Gamma distribution by matching the
157 first two moments. For simplicity, we assumed that only the individuals in the exposed class
158 $E(t)$ shed virus in the stools. This assumption is reasonable since it has been shown that the
159 amount of virus shed by a single individual is time-varying, with a peak occurring around
160 symptoms onset (35,36). If there are $E(t)$ exposed individuals, the amount of virus in the
161 wastewater is a random variable $V(t)$ with probability density function:

162

163 (2) $\Phi(V; k, \theta, E) = \gamma(V; Ek, \theta),$

164 where $\gamma(V; k, \theta)$ is the probability density function for the gamma distribution with rate $k = \frac{E_v^2}{V_v}$

165 and scale $\theta = \frac{V_v}{E_v}$. See Table 2 for parameter values.

166 We used a sequential Monte Carlo (particle filter) method to fit the collected wastewater data
167 to the stochastic model to the collected wastewater data (Figure 1). In simulations, 50,000
168 particles (initial conditions) were sampled, using the normalized likelihood distribution for the
169 initial concentrations of virus measured in the wastewater to determine the number of exposed
170 individuals (Figure 1 top row). The initial states of the other classes were sampled uniformly
171 from the remaining population.

172 Each time step, every particle evolved according to the Markov process in equation 1 (Figure
173 1 bottom left). On days that we have collected wastewater data, the particles were weighted
174 according to their likelihood (Figure 1 bottom center) and resampled using a systematic sampling
175 method to filter out the least likely particles and reinforce the most likely particles (Figure 1
176 bottom right).

177 Data and scripts of this study are available on [https://github.com/Tyler-Meadows/wastewater-](https://github.com/Tyler-Meadows/wastewater-surveillance)
178 [surveillance](https://github.com/Tyler-Meadows/wastewater-surveillance).

179

180 **Results.**

181 **Dynamics of SARS-CoV-2 in rural wastewater vs. clinically confirmed cases.**

182 For the period investigated, clinically reported cases revealed that the cities experienced one
183 or two COVID-19 outbreaks, as shown in Figure 2. The first outbreak occurred in late October
184 2021, but it was not detected in all cities and was relatively small compared to the second
185 outbreak experienced by all cities in early January 2022. This second surge was driven by the
186 Omicron variant, which emerged in the United States in early December 2021 (37).

187 Examining the collected wastewater data, 293 samples were retained following data
188 processing, with each WWTF yielding 44-58 measurements over a five-month period. The daily
189 load of SARS-CoV-2 present in wastewater varied greatly day-to-day, making interpretation of
190 the real-time spread of COVID-19 challenging. Interestingly, the variability in the order of
191 magnitude tended to be larger as the city population decreased, indicating a greater level of
192 randomness (as shown in Figure 3). Additionally, the difference in variance of daily SARS-CoV-
193 2 quantities between cities was significant, as confirmed statistically using Brown-Forsythe,

194 Levene, Barlett, and Klinger-Killeen tests (test results provided in the Supplementary Material).
195 These results suggest that the fluctuations in daily SARS-CoV-2 measurements in smaller cities
196 are more stochastic than in larger cities.

197 Despite this stochasticity, the Omicron outbreaks resulted in a sharp increase of quantities of
198 the virus collected at the WWTFs above the background levels (Figure 2) by 7- to 81-fold. After
199 estimating the date of the outbreak start (vertical dashed line in Figure 2), we estimated that the
200 SARS-CoV-2 wastewater signal tends to lead the clinically confirmed COVID-19 cases by 0 to
201 10 days. This supports other retrospective observations, mostly performed in larger cities, that
202 wastewater surveillance could improve and even accelerate the early detection of infectious
203 diseases in rural communities (36,38,39). However, the lead times were variable, and in one
204 case, the wastewater signal was not inferred to precede the clinically reported case data. Other
205 studies have also observed cases where wastewater signal was not preceding clinical testing
206 (38,40).

207

208 **Epidemiological model to forecast a COVID-19 outbreak from wastewater detection of the** 209 **SARS-CoV-2.**

210 We used an SEIR-based model (Figure 4A) to investigate whether wastewater-based
211 surveillance of SARS-CoV-2 could enhance the prediction of a COVID-19 outbreak. To test the
212 model's ability to forecast upcoming trend of cases, we determined if the model could have
213 predicted the Omicron outbreak using exclusively wastewater data. Specifically, we fit the
214 predicted cases using the wastewater measurements up to the onset of the outbreak. This
215 corresponded to the first measurement performed two days after the inflection point defining the
216 start of the outbreak using wastewater data. Then we let the model forecast the upcoming trend

217 in active cases (Figure 4B). When comparing the forecasted COVID-19 cases with the clinically
218 confirmed cases we found that the model successfully captured the clinically active cases in five
219 of the six cities. For the rural cities, the forecasts were within the 95% confidence interval at
220 least up to eight days ahead; corresponding to R4 (Figure 4). While the number of predicted
221 cases tended to be lower than the number of the clinically confirmed cases reported, they were
222 following them closely in two rural cities and in the small city. For those two rural cities (sites
223 R1 and R2), the model accurately predicted the number of active cases more than 14 days ahead.
224 In city SC, the model was able to forecast the number of active cases accurately more than eight
225 days ahead. These results show that in the majority of sewersheds surveyed the model would
226 have confidently predicted the outbreaks even before the COVID-19 reported cases started to
227 increase. Anticipation of the model on the COVID-19 reported cases ranged from 0 days for R5
228 to 11 days for R2 (see blue dashed line on Figure 4).

229 Since our objective was primarily to test if a SEIR model could predict an outbreak occurring
230 in rural communities, we then focused on the capacity of the model to predict an increase in the
231 trend of active cases. To that end, we used a simulated wastewater dataset to count the number of
232 times the model predicted upward or downward trends in cases correctly (i.e., true positive rate)
233 or incorrectly (i.e., false positive rate). We varied the threshold used to accept predictions to
234 create receiver operating characteristic (ROC) curves (Figure 5). Measured area under the curve
235 (AUC) values presented in Figure 6 reflect the sensitivity and specificity of the forecast for a
236 range of forecasted days. The model tends to predict trends better as the forecast range increases.
237 The ROC curves for predictions made less than a week in advance were significantly lower than
238 those made over nine days (p-values presented in Supplementary Material). After nine days, the

239 AUC medians were above 0.7, and increased to 0.75 at 15 days. These results suggest
240 epidemiologists could rely on these 9 to 15-day forecasts.

241

242 **Discussion**

243 Wastewater-based detection of SARS-CoV-2 has been primarily focused on large urban and
244 metropolitan areas and much less on rural towns. Here we address this gap by having conducted
245 a surveillance effort of the SARS-CoV-2 in the wastewaters of several rural cities of the state of
246 Idaho (USA) since October 2021. Below we discuss the barriers associated with WBE in rural
247 areas and how SEIR modeling could help overcome some of these challenges by forecasting
248 trends in COVID-19 cases based on wastewater-based measurements.

249 While epidemiologists can examine wastewater data side-by-side with clinical testing to help
250 understand what is happening, many infectious diseases are not reportable, or in the case of
251 COVID-19, at-home self-testing replaced clinical testing (41). For example, influenza and
252 COVID-19 are not reportable diseases in Idaho (USA). Thus, epidemiologists are left with few
253 tools to help them characterize epidemiological trends and forecasts; ultimately only wastewater
254 data may be available to provide insight into disease burden in rural areas.

255 However, as we experienced, the variability in viral quantities arriving at the rural WWTF
256 per day made the determination of the start of the outbreak in real-time difficult without
257 retrospective statistical analysis. As we observed, the variability in the order of magnitude tended
258 to be larger as the rural sewershed size decreased (42), making interpretation of wastewater-
259 based detection of infectious diseases in rural areas even more complicated for public health.

260 This noise is typically lower in larger sewersheds that are more active over a 24-hr time
261 compared to smaller ones (43).

262 SEIR epidemiological models offer a framework for epidemiologists to analyze the dynamics
263 of outbreaks using wastewater data (7,8,44–48). Specifically, in our study, we demonstrate that
264 our SEIR model can provide reliable forecasts of when case numbers are trending upwards in
265 rural communities. Sensitivity and specificity assessments of the model in predicting start of the
266 outbreak revealed that the forecasts were more reliable when looking at trends beyond a week,
267 with the best forecast being over a period of nine to 15 days. Similar ranges of short-term
268 forecasts of seven to nine days to predict upcoming cases based on wastewater detection of the
269 SARS-CoV-2 were reported for larger cities using SEIR or SEIR-like approaches (8,46,48). The
270 fact that the model was not performing well under 9 days may, in part, be attributed to the noise
271 of the SARS-CoV-2 quantities in rural wastewater that creates a sawtooth pattern in the trend.
272 Thus, while the trend over a week goes up, there is a chance that some of the points between
273 went down. This led us to hypothesize that the noise in the wastewater data may have made
274 short-term trend predictions less accurate.

275 While our SEIR model functions well to provide advanced warning of a COVID-19
276 outbreak, it failed to predict the outbreak peak (Fig. S1) and we could not assess the accuracy of
277 case number predictions. Predicted cases tended to be lower than reported clinical cases for the
278 area, contrasting with other studies on larger sewersheds that have shown that SEIR models
279 typically estimate more COVID-19 cases than the reported number (45,53,54). The
280 underestimation of COVID-19 cases observed in this study may be attributed, in part, to
281 differences between the population of the city sampled and the zip code used (Table 1); the latter
282 corresponds to the clinically recorded cases. When comparing city with zip code census, 39 to

283 71% of the residents of rural zip codes were not connected to the sewer system of the cities. In
284 rural areas, zip codes often cover a larger geographical area beyond the city limits, which means
285 that comparisons between wastewater data and reported cases should be approached with
286 caution. It is important to note that we did not intend to use the model to predict case numbers;
287 the study was not designed for this purpose. Instead, it was intended to forecast an increase in
288 COVID-19 cases to provide an early warning that could be shared with the community.

289 Despite the successful application of SEIR models to wastewater surveillance of the SARS-
290 CoV-2, there are some uncertainties on how to connect the model with wastewater data. Some
291 authors have included the cumulative virus titer in the sewershed as a dynamic variable (8) or as
292 a linear combination of other dynamic variables (45). However, this approach can be problematic
293 when measurements are sparse or there are gaps between collection periods – which would be
294 very common in rural WWTFs. Most authors directly connect wastewater measurements to the
295 incidence rate, or prevalence, similar to what we have done herein. In addition, the connection
296 between the disease compartments (the exposed ‘E’ and infected ‘I’ compartments) in the SEIR
297 model and wastewater measurements is not well established. Contribution to viral load in
298 wastewater can tie to the individuals in the ‘I’ compartment (7,8,45) or to the ‘E’ compartment;
299 the SEIR model in this study resulted in better predictions than when connected to ‘I’. This
300 difference could be attributed to the fact that peak virus shedding in stool may occur for a few
301 days around the onset of symptoms (35,36). This means that individuals contributing to the load
302 of SARS-CoV-2 measured in wastewater may be at the transition between ‘E’ and ‘I’
303 compartments in the SEIR model. Some researchers have incorporated the results from
304 wastewater measurement in both ‘E’ and ‘I’ (44) while others created a new compartment
305 structure to account for viral shedding dynamic in wastewater (47,48).

306 Finally, our model was able to successfully forecast the upcoming cases in most of the cities
307 surveyed. In one city this resulted in predicting the outbreak as much as 11 days before reported
308 clinical cases started to increase. However, it failed for one city, suggesting that the disease
309 dynamics do not always follow the model assumptions. This may be because the model does not
310 include potential traveling between cities, which may impact the accuracy of predictions,
311 especially in rural areas where residents often have to commute to work. In the rural cities
312 surveyed between 79.4 and 94.5% of residents work outside their place of residence, versus
313 27.3% in the small city surveyed (data from U.S. Census Bureau Topic: Commuting – Survey:
314 American Community Survey – 2021, ACS 5-Year Estimates Subject Tables).

315 In conclusion, our study reveals that wastewater-based epidemiology (WBE) in rural
316 communities and small sewersheds in general is associated with high daily variation in SARS-
317 CoV-2 levels. This variation creates a challenge for epidemiologists who seek to monitor real-
318 time data in rural areas based solely on the raw data. However, our research also shows that the
319 SEIR modeling approach can help to decipher this data and actually predict the start of
320 outbreaks. Our model provides a suitable framework for epidemiologists to analyze the dynamics
321 of outbreaks using wastewater data.

* Data from the 2020 Decennial Census obtained from <https://data.census.gov/>

† Wastewater treatment facility collects effluents from a second city.

492

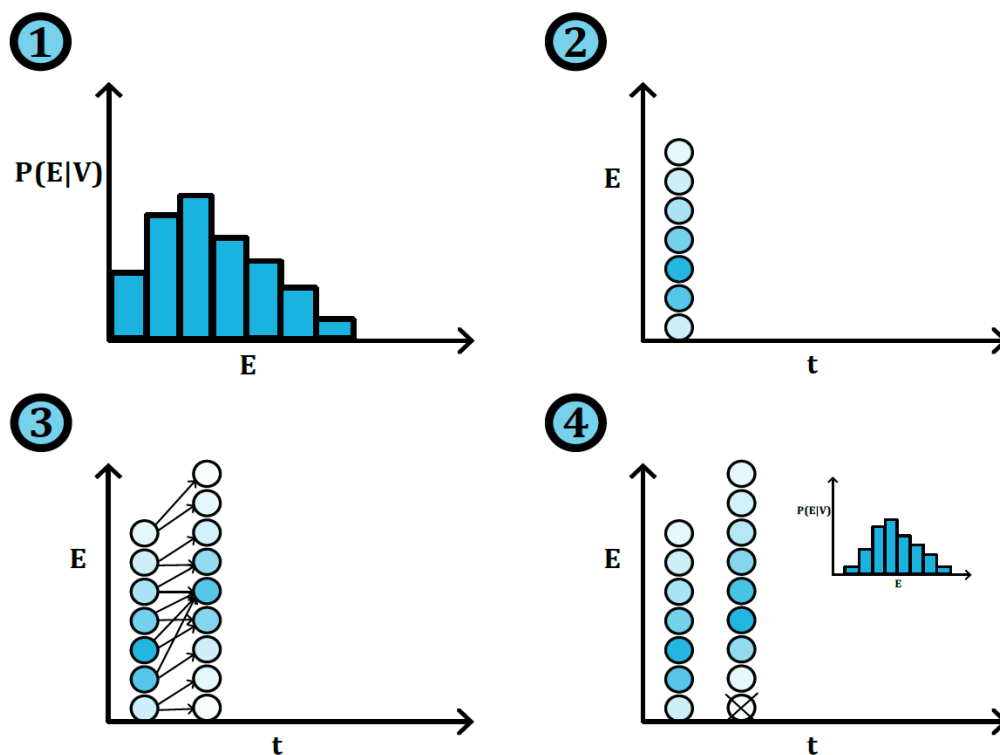

493

494 **Table 2: Parameters used in model fitting.**

Parameter	Description	Value	Reference
E_v	Mean virus copies shed by a single individual	4.49×10^7 gc/l	(8)
V_v	Variance of virus shed by individuals	2×10^7 (gc/l) ²	(49)
τ	Incubation period	3 days	(8)
δ	Infectious period	8 days	(8)
β	Force of infection	Fit from data	
Q	Flow rate of sewershed	Various	Individual treatment plants
	Average faeces produced per day	128 g	(50)

495

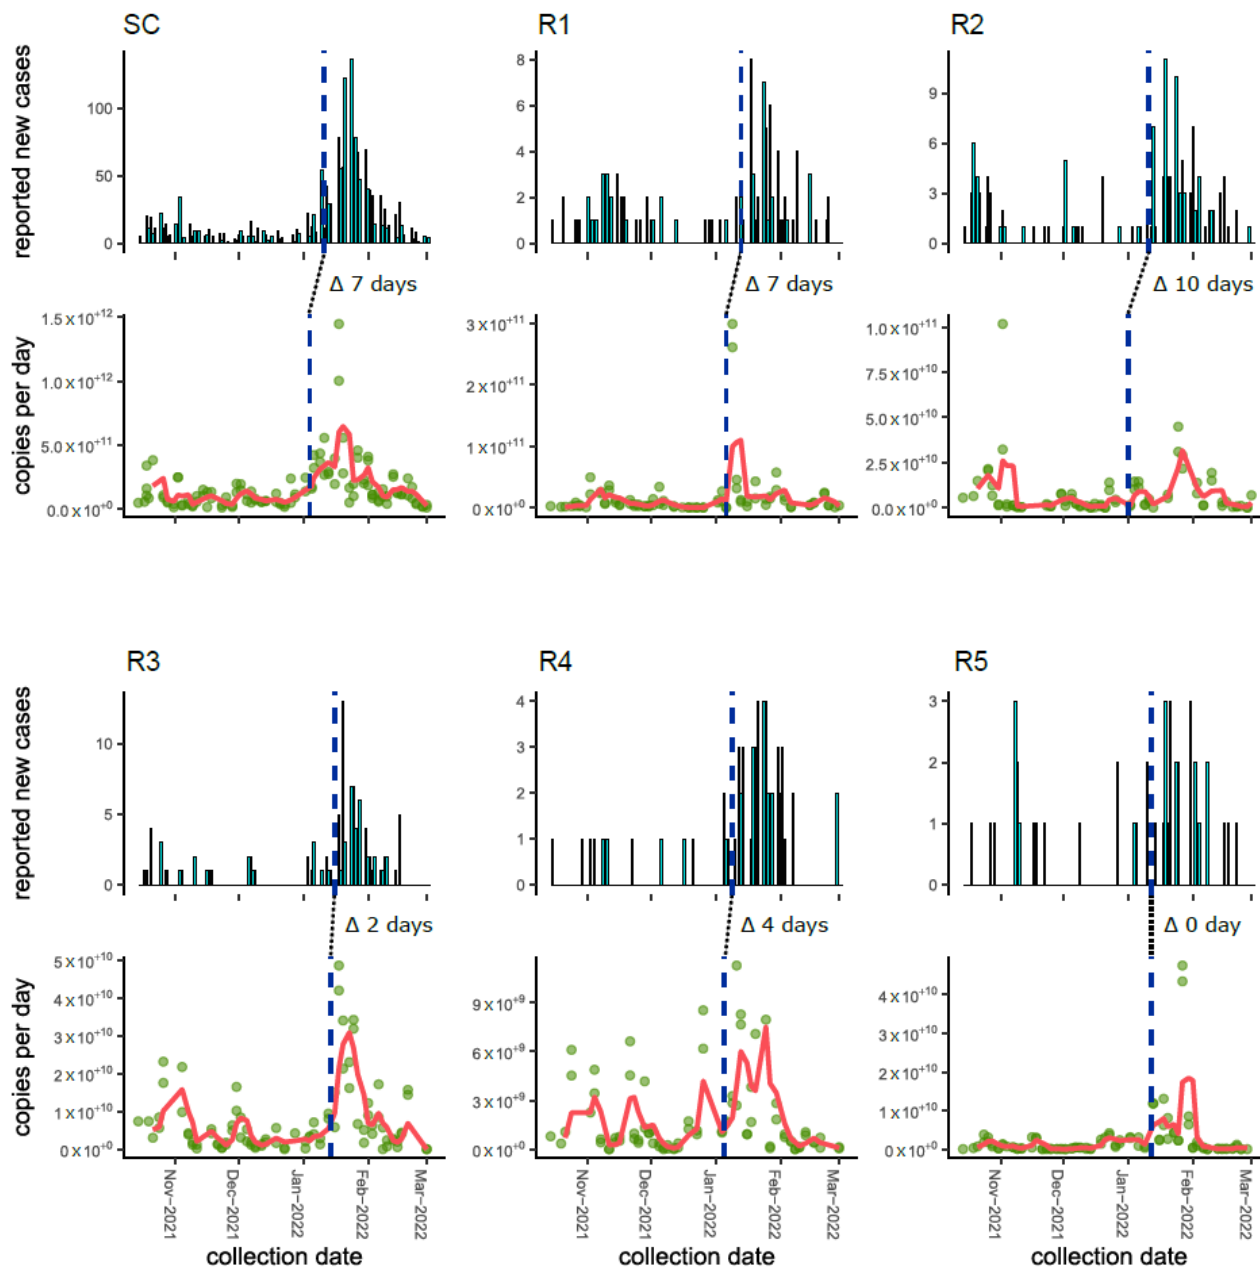

496 **FIGURE LEGENDS**

497

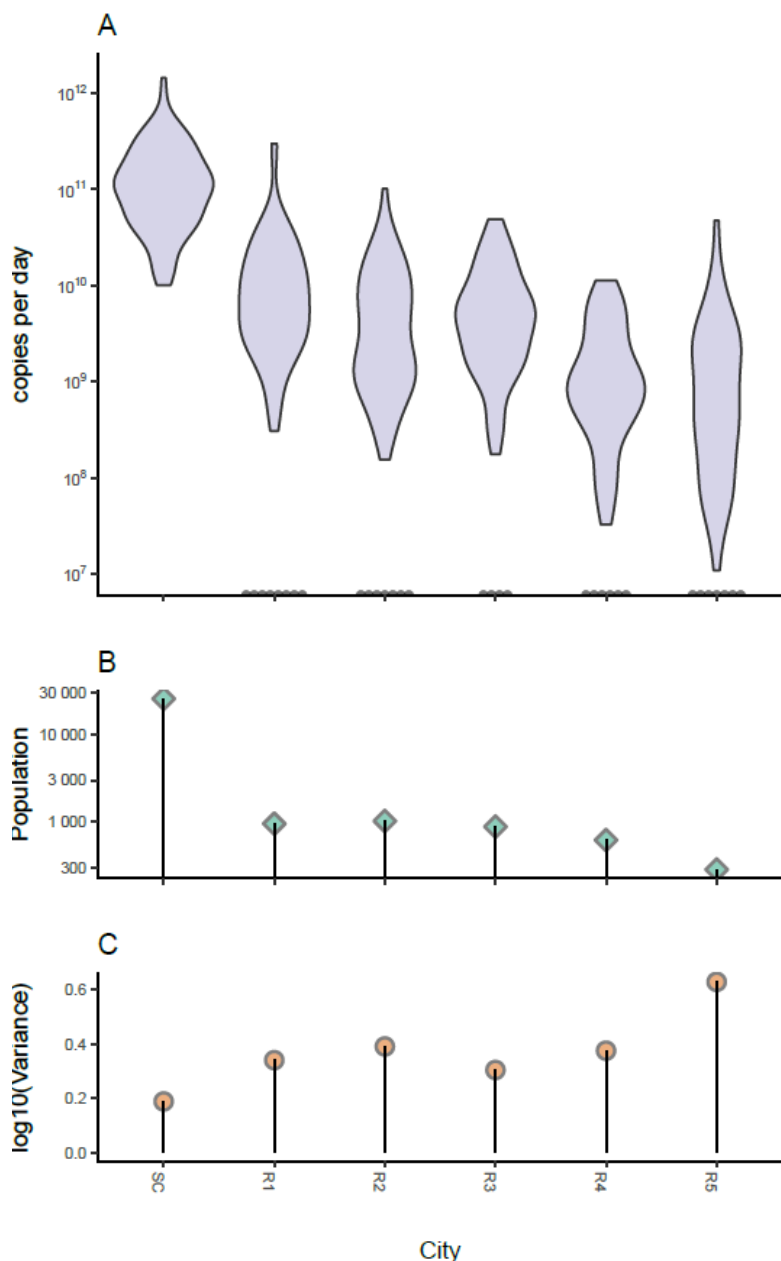

498 **Figure 1: Diagram showing steps of the particle filter method we use to determine the**
499 **number of active cases from the wastewater titers of SARS-CoV-2.** The particle filter is
500 initialized using the first measurement of virus concentration in the wastewater. We generate a
501 distribution of the possible number of infections in the community and sample many (50000)
502 values from this distribution. These values are used as the possible number of exposed
503 individuals (E) on day 1 (top right graph). Each of these values also gets a potential number of
504 Susceptible (S), Infected (I), and Recovered (R) individuals. Each set of values (S, E, I, R) is called
505 a particle. The darker dots in the diagram signify a higher number of particles with that value of
506 E . We apply one step of the stochastic $SEIR$ model to each particle to predict the number of
507 infections on the next day (bottom left graph). The measurement of the virus in the wastewater
508 on the next measurement is used to determine which particles are more likely than others. Less

509 likely particles are filtered out using a systematic resampling procedure and replaced with more
510 likely particles (bottom right graph).

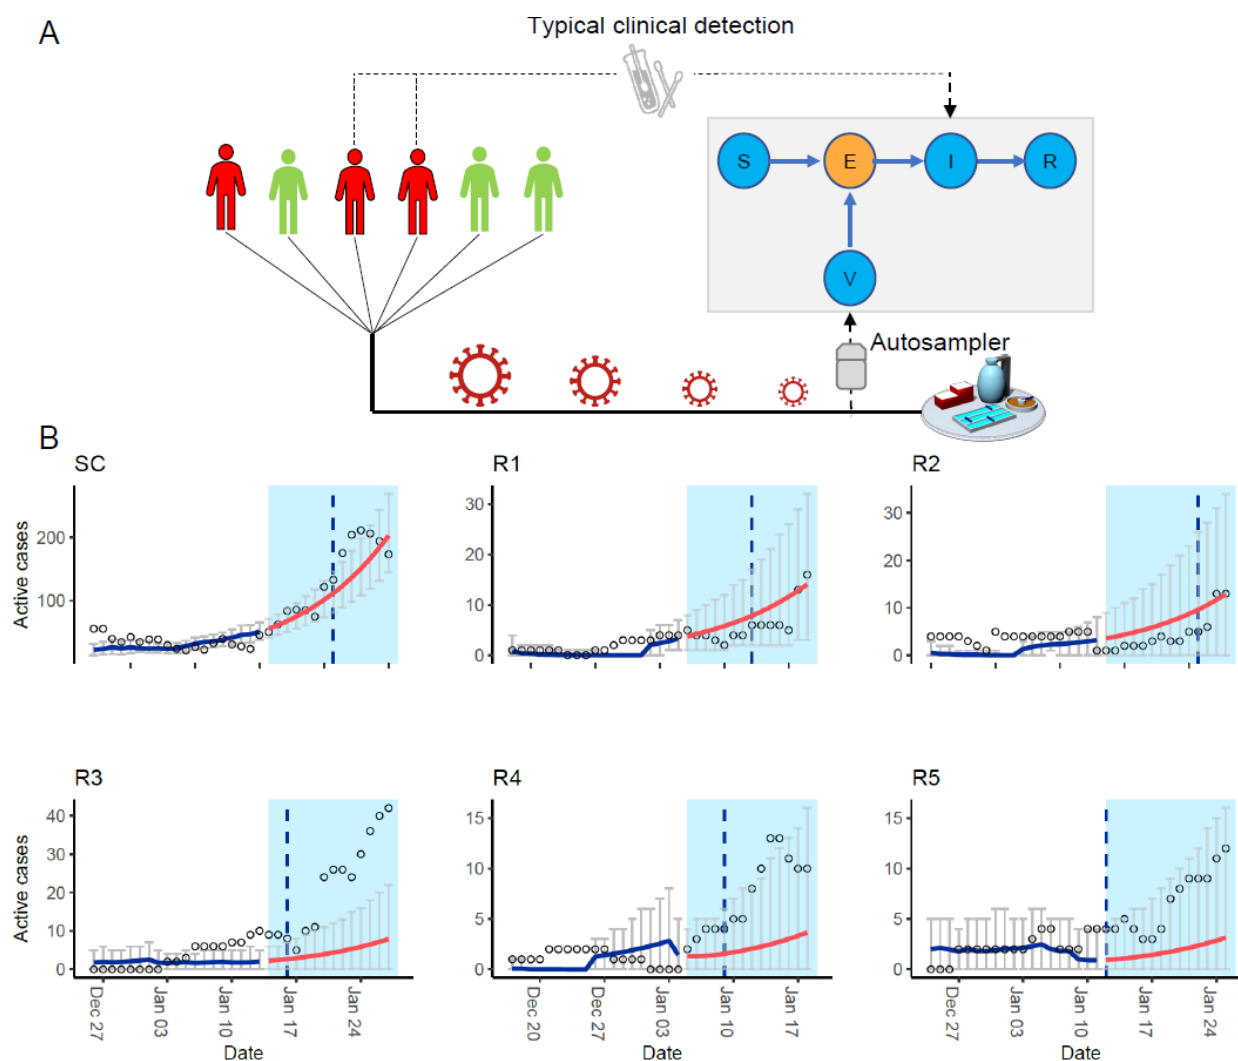

511
512 **Figure 2: Trend in SARS-CoV-2 in wastewater mirrors the dynamic of the COVID-19**
513 **outbreak in rural areas.** Each panel represents a city. In each panel, the bar graph shows the
514 time series of the COVID-19 clinically confirmed cases at the specimen collection dates and the

515 second graph shows the measured concentration of SARS-CoV-2 (green dots) with the 7-day
516 moving average (red line). Vertical dash lines represent the estimated start of the outbreak using
517 either the cumulative sum of the copies per day of the N1 target or the cumulative sum of
518 COVID-19 clinically confirmed cases, determined by the Piecewise regression model. Delta
519 shows the difference of days between predicted dates from wastewater-based detection of SARS-
520 CoV-2 and clinically confirmed COVID-19 cases. Cities are ordered by population size (largest
521 on the top left and smallest on the bottom right).

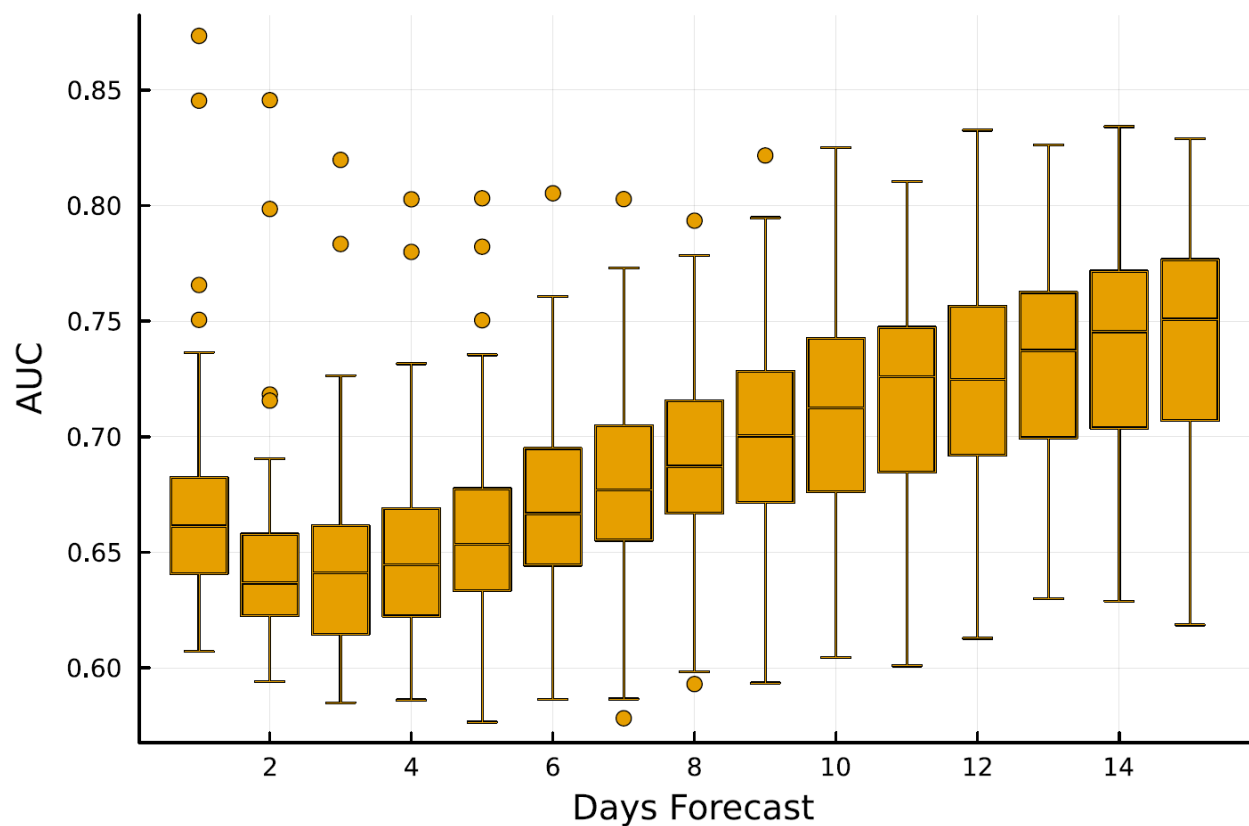

522
523 **Figure 3: Daily quantities of SARS-CoV-2 tend to be more spread as the city population get**
524 **smaller.** Panel A) shows the distribution of the copies per day of the SARS-CoV-2 on the log
525 scale over the sampling period at each site ordered by city size, detailed in panel B. Note: bin
526 width = 1/30. Dots on the x axis show the samples where N1 was under the detection limit (SC:
527 n = 0, R1: n = 8, R2: n = 8, R3: n = 4, R4: n = 6, R5: n = 7). Panels B) shows the population size
528 of the cities sampled, and C) shows the log scale sample variance measured for each city

529 calculated using the log10 of copies per day of the SARS-CoV-2. This essentially shows that the
530 magnitude of the estimate is less consistent as population size gets smaller (i.e., more
531 stochasticity).

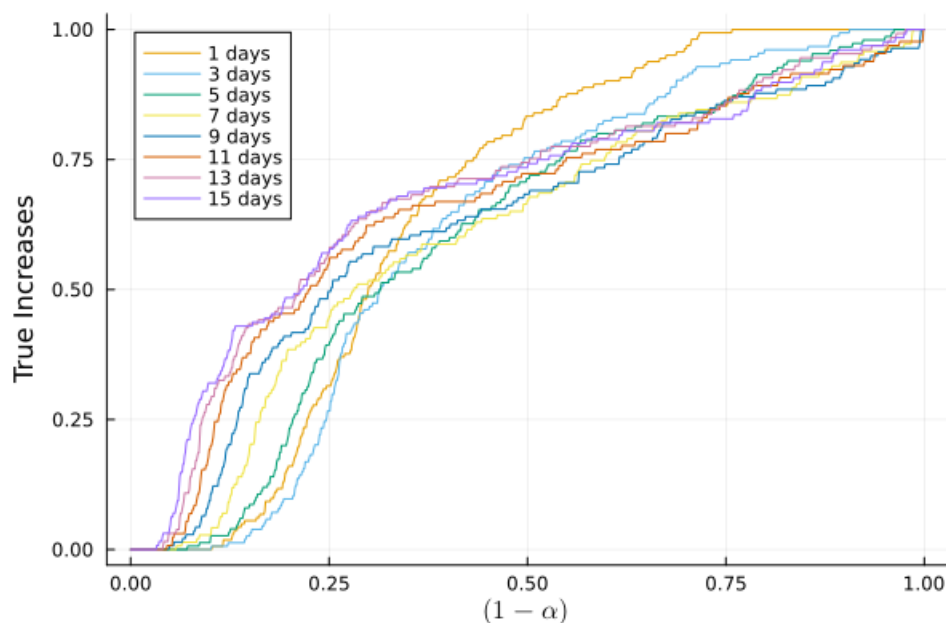

532
533 **Figure 4: Susceptible-exposed-infectious-recovered model can forecast cases in the early**
534 **stage of a COVID-19 outbreak. A) SEIR model framework depicting a population in green**
535 **with infected people in red. The SARS-CoV-2 shed by a fraction of the exposed population is**
536 **measured in the wastewater collected at the WWTF. This titer is integrated into a Susceptible**
537 **(S), Exposed (E), Infected (I), and Recovered (R) model to estimate the number of exposed**

538 individuals E. **B)** Left white side contains known data at the time of the forecast where the blue
539 lines show the fitted predicted active cases from wastewater up to the beginning of the outbreak,
540 and the blue shade shows the data not yet observed at the time of forecast whereas the red lines
541 are active cases forecasted. Vertical dashed lines represent the estimated start of the outbreak
542 based on clinically confirmed COVID-19 cases. Using the wastewater data, the model forecasted
543 the start of the outbreak between 0 to 11 days earlier than the onset of the increase in clinical
544 confirmed cases. 95% confidence intervals are shown by the gray bars. Dots show the active
545 cases determined as the 11-day moving sum of the clinically confirmed cases. Since the mean
546 infectious period from fitting data was 10.88 days, we determined the actual active cases as the
547 11-day moving sum of new clinically confirmed cases. Breakpoints between fitted and forecast
548 values were chosen to be two days after the start of the outbreak, determined by the Piecewise
549 regression model. Cities are ordered by population size (largest on the top left and smallest on
550 the bottom right).

551

552 **Figure 5: Receiver operating characteristic (ROC) curves for a synthetic data set.** A plot
553 showing the number of true increases against false increases for predicted case counts
554 1,3,5,7,9,11,13, and 15 days beyond the current measurements. A true increase is counted when
555 there was an increase in cases and the model predicted a greater than α probability of an
556 increase. A false increase is counted when there was no increase in cases but the model predicted
557 a greater than α probability of increase.

558

559 **Figure 6: Evaluating SEIR model predictability for an emerging COVID-19 outbreak.** Box

560 plot showing the distribution of measured area under the curve (AUC) when computing 50

561 receiver operating characteristic (ROC) curves when true positive rate is plotted as function of

562 the false positive rate for prediction forecasted from one to 15 days. A random classifier, which

563 represents the outcome if the model randomly picks predictions, has an AUC of 0.5. The further

564 away the curve is from the one of the random classifier, the higher the AUC and the better it

565 illustrates the ability of the model to forecast a trend, with the 1 representing the highest

566 accuracy corresponding to 100% positive rate and 0% false negatives. In general, for a

567 diagnostic test to be able to discriminate patients with and without a disease, the AUC must be

568 above 0.5. Values between 0.7 and 0.8 are considered to be 'fair' or acceptable (34,35).
