21 of disease

22
23 **Structured Abstract**

24 *Introduction*

25 Respiratory Syncytial Virus (RSV) is a primary source of acute lower respiratory tract infection
26 (ALRTI), the leading cause of death in children under five. Over 99% of RSV-attributed deaths
27 occur in low-income countries, including Madagascar. RSV transmission is linked to climate,
28 driving highly seasonal dynamics.

29 *Methods*

30 We used generalized additive models (GAMs) to identify correlates of reported RSV infections
31 in Antananarivo, Madagascar from January 2011-December 2021, then fit catalytic models to
32 cumulative age-structured incidence to estimate age-specific force of infection (FOI). We fit a
33 time series Susceptible-Infected-Recovered (TSIR) model to the dataset to estimate weekly

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

34 RSV transmission, then evaluated associations with precipitation, humidity, and temperature
35 using generalized linear models. We used GAMs to quantify interannual trends in climate and
36 assess whether significant deviations in RSV burden occurred in years representing climatic
37 anomalies.

38 *Results*

39 Reported RSV infections in Antananarivo were significantly associated with patient ages ≤ 2
40 years. Highest FOI was estimated in patients ≤ 1 year, with transmission declining to near-zero
41 by age five before rising in older (60+) cohorts. TSIR models estimated a January–February
42 peak in RSV transmission, which was strongly positively associated with precipitation and
43 more weakly with temperature but negatively related to relative humidity. Precipitation,
44 humidity, and temperature all increased across the study period in Antananarivo, while reported
45 RSV infections remained stable. Significant deviations in RSV burden were not associated with
46 clear climate anomalies.

47 *Conclusions*

48 Stable rates of reported RSV infections in Antananarivo across the past decade may reflect
49 contrasting impacts of elevated precipitation and increased humidity on transmission. If future
50 climate changes yield more rapidly accelerating precipitation than humidity, this could
51 accelerate RSV burden. Introduction of recently-developed public health interventions to
52 combat RSV in low-income settings like Madagascar is essential to mitigating burden of disease
53 (RSV), in particular any future climate-driven increases in transmission or severity.

54

55 **Key Messages**

- 56 • *What is already known on this topic:* RSV is an important driver of acute lower respiratory
57 tract infections, which represent the leading cause of mortality in children under five
58 across the globe. RSV demonstrates highly seasonal dynamics, as its transmission is
59 linked to climate.
- 60 • *What this study adds:* We quantified correlates of RSV infection and estimated the
61 seasonal transmission rate for RSV from reported patient data in Antananarivo,
62 Madagascar. We found that RSV transmission is primarily concentrated in very young
63 children (≤ 1 year) in Antananarivo and positively associated with high precipitation and
64 low humidity, which focus most transmission in Madagascar's January-February rainy
65 season.

- 66 • *How this study might affect research, practice, or policy:* Our study suggests that RSV
67 burden may intensify with future climate change, particularly higher rainfall. We
68 emphasize the high public health importance of accelerating the introduction of recently-
69 developed mAbs (Monoclonal Antibody) and vaccination interventions to combat RSV to
70 low-income settings like Madagascar.

71

72 INTRODUCTION

73 Respiratory syncytial virus (RSV) is a highly contagious virus that primarily infects
74 infants and young children. Worldwide, most children contract RSV before reaching two years
75 of age ([Andeweg et al. 2021](#)). The virus infects the upper and lower respiratory tracts causing
76 infections that range from common cold to bronchiolitis and pneumonia. Globally, acute lower
77 respiratory tract infections (ALRTIs) are the leading cause of death in children under five (CU5)
78 ([Data 2019](#)), and approximately one-fourth of ALRTIs are estimated to be attributable to RSV
79 each year ([Nair et al. 2010](#), [Shi et al. 2017](#)). Over 99% of CU5 fatalities from RSV-related
80 ALRTIs occur in low-income countries ([Nair et al. 2010](#), [Shi et al. 2017](#)). RSV can also affect
81 older age groups and those immuno-compromised or with comorbidities such as asthma and
82 other lung diseases, diabetes, and heart failure ([Falsey et al. 2005](#), [Haber 2018](#)). In Madagascar,
83 RSV remains the most common cause of ALRTI and a major cause of hospital admission in
84 CU5 ([Razanajatovo et al. 2018](#)). It is estimated that approximately 11 299 hospitalizations per
85 year can be attributed to RSV in CU5 in Madagascar ([Rabarison et al. 2019](#)). Three years (2010-
86 2013) of laboratory surveillance from Institut Pasteur de Madagascar (IPM) aimed at
87 identifying the etiology of severe acute respiratory infections (SARI) showed that nearly 37.7%
88 of samples were positive for RSV, with the vast majority of patients (81%) representing CU5
89 ([Razanajatovo et al. 2018](#)). A further 38.9% of SARI surveillance samples collected between
90 2018-2022 in Madagascar additionally tested positive for RSV, again with the majority
91 concentrated in CU5 ([Razanajatovo et al. 2022](#)).

92

93 Given the globally significant impact of RSV on childhood morbidity and mortality,
94 RSV has been the subject of numerous research studies across many countries ([Shi et al. 2017](#),
95 [O'Brien et al. 2019](#), [Li et al. 2022](#)). Particular areas of focus have included standard reporting
96 of disease burden, clinical features, and at-risk groups for severe infections—typically aimed
97 at defining best practices for the monitoring of RSV infection in CU5 and avoiding the misuse
98 of antibiotics ([Linssen et al. 2021](#), [Obolski et al. 2021](#), [Li et al. 2022](#), [Pinquier et al. 2023](#)). In
99 addition, considerable work has been devoted to quantification of seasonal transmission

100 dynamics for RSV—in order to better predict the timing and magnitude of severe epidemics
101 ([Hogan *et al.* 2016](#), [Baker *et al.* 2019](#), [Wambua *et al.* 2022](#)).

102
103 The seasonality of RSV circulation shows different patterns depending on geographic
104 location, though most localities are characterized by a clear annual peak in transmission. In
105 temperate countries, peak cases generally predominate during the colder months—from
106 September to January in the Northern Hemisphere and from March to June in the Southern
107 Hemisphere ([Obando-Pacheco *et al.* 2018](#)). In tropical and subtropical countries, the timing of
108 the peak RSV season is more variable across locations, with some studies reporting highest
109 RSV activity during peak rains ([Sapin *et al.* 2001](#), [Mathisen *et al.* 2009](#), [Matthew *et al.* 2009](#))
110 and others reporting elevated caseloads during warmest months of the year ([Chew *et al.* 1998](#)).
111 Madagascar has been previously documented as an anomaly in the study of seasonal circulation
112 for respiratory viruses, particularly influenza, for which transmission is highly irregular
113 ([Heraud *et al.* 2019](#)). RSV circulation, however, is well defined, with burden concentrated in
114 the first half of each calendar year and the peak in cases between February and March
115 ([Razanajatovo *et al.* 2018](#), [Razanajatovo *et al.* 2022](#)).

116
117 Climate is known to play an important role in driving RSV circulation across diverse
118 geographic localities ([Shi *et al.* 2017](#), [Baker *et al.* 2019](#), [Heraud *et al.* 2019](#)) but has remained
119 largely unexplored in Madagascar. Quantitative understanding of the climatic factors that drive
120 intra-annual seasonality in RSV transmission is essential to predicting how RSV dynamics will
121 respond to future interannual climatic changes. Here, we aimed to (1) identify statistical
122 correlates of RSV infection from reported cases of respiratory infection in Antananarivo,
123 Madagascar over the past decade, (2) estimate variation in the age-structured force of infection
124 (FOI) for RSV cases in Antananarivo, (3) quantify the seasonality of RSV transmission across
125 the study period, and (4) identify climatic variables associated with peak RSV transmission.

126

127

128 **METHODS**

129

130 **Study location and setting**

131 The influenza sentinel surveillance network (ISSN) in Madagascar has been operational
132 since 1978 ([Rasolofonirina 2003](#), [Randrianasolo *et al.* 2010](#)). The aim is to monitor the
133 circulation of influenza viruses as well as other respiratory viruses of public health concern,

134 such as RSV and, more recently, SARS-CoV-2. The ISSN is comprised of an ILI (Influenza-
135 Like Illness) surveillance program that now involves 21 referral primary health care centers
136 (CSB_R) and a SARI (Severe Acute Respiratory Infection) surveillance program in five
137 selected hospitals. The ISSN is complemented via the monitoring of death certificate and
138 mortality data collected from six districts in Antananarivo through the Bureau Municipal
139 d'Hygiène recently renamed DEAH (Direction de l'Eau, l'Assainissement et l'Hygiène)
140 ([Rabarison et al. 2023](#))

141
142 For the present study, we used data collected from sentinel sites in Antananarivo, the
143 capital city of Madagascar, over 11 years (from January 2011 – December 2021). Antananarivo
144 is home to around three million inhabitants ([Desa 2018](#)) and hosts a tropical climate profile that
145 is hot and rainy in summer (November – April) and cold and dry in winter (May – October).
146 Sites used in our analysis included ILI three sites BHK: Ostie Behoririka (-18.90, 47.53), CSMI
147 TSL: Centre de Santé Maternelle et Infantile de Tsaralalana (-18.91, 47.53), MJR: Dispensaire
148 Manjakaray (-18.89, 47.53); and two SARI sites (CENHOSOA: Centre Hospitalier de
149 Soavinandriana (-18.90, 47.545) and CHUMET (Centre Hospitalier Universitaire Mère-Enfant
150 Tsaralalàna) (-18.91, 47.52). Respectively, each site serves a catchment population of: 28574
151 people (BHK); 43222 people (CSMI TSL), 8000 people (MJR), 89000 people (CENHOSOA),
152 and 43222 people (CHUMET).

153 154 **Study subjects**

155 All patients presenting to focal sites with ILI or SARI symptoms were enrolled. Details
156 on case definitions and enrollment procedures have been previously published. Briefly, ILI
157 classification criteria refer to patients of any age reporting with (a) a recorded temperature
158 $\geq 38^{\circ}\text{C}$ or a history of fever and (b) a cough of ≤ 10 days duration, who (c) do not require
159 hospitalization. SARI patients report with these same symptoms but additionally require
160 hospitalization ([WHO 2013](#)). For each enrolled patient, demographic, socio-economic, clinical,
161 and epidemiological data were recorded in case report forms.

162 163 **Virus detection**

164 Nasopharyngeal specimens were collected for each enrolled patient. After collection,
165 samples were shipped daily to the Virology Unit at IPM where they were immediately
166 processed or stored at 4°C until testing (a maximum of 2 days after collection, following WHO
167 guidelines) ([WHO 2002](#), [WHO 2011](#)). All procedures for the processing of biological samples

168 have been previously described ([Razanajatovo et al. 2011](#)). Briefly, nasopharyngeal swabs were
169 screened for influenza A and B, RSV, and, since March 2020, SARS-CoV-2, using discrete
170 real-time RT-PCR assays (Supplementary Text S1). Only the SARI sentinel site of
171 CENHOSOA supplied samples consistently across the entire study period, while most sites
172 supplied samples intermittently for shorter durations throughout the 2011-2021 time series
173 (Figure S1).

174

175 **Climate data**

176 Meteorological data reporting total precipitation (mm), mean relative humidity (%), and
177 mean temperature ($^{\circ}\text{C}$) at daily intervals in Antananarivo, Madagascar across the study period
178 were downloaded from the National Aeronautics and Space Administration (NASA) database
179 ([NASA](#)) and summarized by week (summed for precipitation and averaged for humidity and
180 temperature).

181

182 **Data analysis**

183 *RSV infection correlates from generalized additive models (GAMs)*

184 We first aimed to identify correlates of RSV infection in patients reporting to study sites
185 with ILI and SARI symptoms across the study period. To this end, we fit a series of Generalized
186 Additive Models (GAMs) in the binomial family, incorporating a response variable of RSV
187 infection outcome (0/1, indicating negative or positive) for all ILI and SARI patients tested in
188 dataset across all reporting sites ([Wood 2001](#)). In the first GAM, we modeled all predictor
189 variables as smoothing splines, with ‘day of year’ formatted as a cyclic cubic spline (to control
190 for intra-annual seasonality in our dataset), ‘age’ formatted as a thinplate smoothing spline, and
191 ‘sex’, ‘year’, and ‘reporting hospital’ formatted as factorial random effects (Table S1). We
192 additionally fit a second GAM with ‘year’ formatted as a numeric thinplate smoothing spline
193 to evaluate interannual patterns across the time series (Table S1). Finally, because age and sex
194 data were only available for a subset (N=3242) of tested cases, we fit a third GAM in the
195 binomial family to the full dataset of RSV test data (N=3432), incorporating only predictor
196 variables of ‘day of year’ (as a cubic smoothing spline) and ‘year’ (as a random effect) (Table
197 S1).

198

199 *Estimation of age-structured force of infection (FOI) for reported RSV cases in Antananarivo*

200 Building from age correlates of infection identified in GAMs, we next sought to quantify
201 age-structured variation in the FOI for reported RSV cases across the study period. Methods for

202 estimating FOI from age-stratified serological data for single-strain immunizing pathogens are
203 well-established (Muench 1959, Heisey *et al.* 2006, Long *et al.* 2010, Pomeroy *et al.* 2015), and
204 prior work has successfully adapted them for application to age-structured incidence data, in
205 lieu of serology (Grenfell *et al.* 1985). Assuming individuals are born susceptible and immunity
206 following infection is lifelong, the standard ‘catalytic’ model describes the cumulative
207 probability ($P(a)$) of encountering infection by age a as:

$$P(a) = 1 - e^{-\int_0^a \lambda(a) da}$$

[1]

210 where $\lambda(a)$ is the age-specific force of infection.

211 Following equation [1], we fit a series of catalytic models with variable number and
212 duration of age classes to the cumulative incidence of reported cases of RSV by age in
213 Antananarivo across the study period, then compared model fit to the data by AIC to evaluate
214 the most appropriate number and distribution of age classes by which to segregate FOI (Table
215 S2). We first evaluated a null model assuming a single constant FOI across all age classes, then
216 tested increasingly complex models that specified disparate piece-wise constant values for $\lambda(a)$
217 across age brackets (27 models tested in total; Table S2). We focused estimation of
218 heterogeneity in $\lambda(a)$ on young and old patients presumed to be at heightened risk for RSV
219 infection. Only models that achieved convergence in the fitting process were evaluated. All
220 models were fit using a quasi-Newton (L-BFGS-B) optimization method in the ‘optim’ function
221 of the base R (v 4.2.2) package ‘stats’; 95% confidence intervals on the resulting age-specific
222 FOI estimates were constructed from the hessian matrix.

223
224 *Seasonal transmission dynamics of RSV via time series Susceptible-Infected-Recovered (TSIR)*
225 *modeling*

226 We next sought to quantify the seasonality of RSV transmission across our study period,
227 using a time series Susceptible-Infected-Recovered (TSIR) modeling approach implemented in
228 the R package, tsiR (Finkenstädt *et al.* 2000, Bjørnstad *et al.* 2002, Grenfell *et al.* 2002, Becker
229 *et al.* 2017). One of the most widely-used classes of the general SIR model, the TSIR model
230 was originally developed to simplify the process of parameter estimation in fitting SIR models
231 to time series data for measles, a perfectly immunizing, widespread childhood disease
232 (Finkenstädt *et al.* 2000, Bjørnstad *et al.* 2002, Grenfell *et al.* 2002). More recently, TSIR has
233 been adopted for application to other immunizing childhood diseases, including varicella
234 (Baker *et al.* 2018), rubella (Metcalf *et al.* 2011, Wesolowski *et al.* 2016), and RSV (Baker *et*

235 *al. 2019, Wambua et al. 2022*). TSIR depends on two critical assumptions, requiring (i), that
236 over long time horizons, the sum of infected cases should be equivalent to the sum of births for
237 highly infectious childhood diseases (for which all individuals are assumed to be eventually
238 exposed), and (ii), that the infectious period of the pathogen modeled is equal to the sampling
239 interval for the time series data. TSIR thus captures epidemic dynamics in a series of simple
240 difference equations, whereby the susceptible population in a future timestep (S_{t+1}) can be
241 modeled as:

$$242$$
$$243 \quad S_{t+1} = S_t + B_t - I_t - \mu_t \quad [2]$$
$$244$$

245 where B_t corresponds to birth inputs to the population in each timestep, I_t indicates susceptibles
246 lost to infection, μ_t is additive noise, and S_t can be rewritten as $S_t = \bar{S} + Z_t$ where \bar{S} is the
247 mean number of susceptibles in the population and Z_t describes the (unknown) time-varying
248 deviations around this mean. From this, the susceptible population can be reconstructed
249 iteratively across a time series, after rewriting equation [2] in terms of Z_t and the starting
250 condition, Z_0 :

$$251$$
$$252 \quad \sum_{k=0}^{t-1} B_k = -Z_0 + \frac{\sum_{k=0}^{t-1} I r_k}{\rho} + Z_t + \mu_t \quad [3]$$
$$253$$

254 Equation [3] assumes that ρ is the reporting rate of infection and $I r_k$ is the reported incidence
255 (in our case corresponding to reported cases of RSV in our study region). Because TSIR
256 assumes no overlapping infection generations, the number of infections per timestep can then
257 be expressed as the product of the susceptible and infected populations in the preceding
258 generation, along with the time-varying transmission rate (β_t):

$$259$$
$$260 \quad I_{t+1} = \frac{\beta_{t+1} S_t I_t^\alpha}{N_t} \quad [4]$$
$$261$$

262 where the homogeneity parameter (α) corrects for epidemic saturation in the process of
263 discretizing a continuous epidemic. Equation [4] can then be easily log-linearized as:

$$264$$
$$265 \quad \ln I_{t+1} = \ln \beta_{t+1} + \ln(Z_t + \bar{S}) + \alpha \ln I_t - \ln N_t \quad [5]$$
$$266$$

267 allowing for estimation of β_t via simple regression techniques.

268 From above, we first followed (Baker *et al.* 2019) to reconstruct the population
269 susceptible to RSV in our catchment area in Antananarivo, Madagascar. To this end, we binned
270 RSV positive cases by week across the time series for all reporting sites, and correspondingly
271 summed the population catchments for each site over each week for which data were reported
272 (e.g. the population modeled was higher for timesteps reporting cases from a greater number of
273 sites). To avoid errors in TSIR, we substituted a value of 1 for weeks reporting zero cases. We
274 estimated weekly total births for our study population across the time series by multiplying per
275 capita publicly available birth rates for Madagascar reported by the World Bank (Bank 2023)
276 against the summed population size of the catchment of all reporting study sites, divided evenly
277 across weekly timesteps in a given year (per capita World Bank birth rates are reported as
278 annual means only). Again following (Baker *et al.* 2019), we reconstructed the susceptible
279 population using a simple linear regression of cumulative cases against cumulative births (Table
280 S3). We validated our susceptible reconstruction by comparing the coarse estimate of the basic
281 reproduction number (R_0) for RSV in Antananarivo that can be derived from the relationship
282 $\bar{S} = 1/R_0$ (Wesolowski *et al.* 2016, Becker *et al.* 2017) with that inferred from the mean birth
283 rate and average age of infection across the time series, assuming $R_0 = G/A$ where G is the
284 inverse of the population birth rate and A is the average age of infection (Rm 1991).

285 Finally, following susceptible reconstruction, we implemented a log-link linear
286 regression in the ‘Poisson’ family in the tsiR package to estimate the weekly RSV transmission
287 rate (β). Though we modeled our data in 52 weekly timesteps per year, to avoid overfitting, we
288 constrained our fitting to 26 distinct biweekly transmission rates across the 11-year dataset (e.g.
289 transmission was held constant between consecutive two-week intervals; Table S3). Consistent
290 with prior studies (Glass *et al.* 2003, Baker *et al.* 2019), we fixed the homogeneity parameter
291 (α) at 0.97 in the fitting process; previous work has demonstrated that inference into seasonal
292 transmission rates from TSIR is robust to the value of α (Metcalf *et al.* 2009).

293

294 *Climatic drivers of RSV transmission using generalized linear models (GLMs)*

295 Following estimation of seasonal transmission rates for RSV in Antananarivo, we
296 sought to quantify the impact of local climate variables on RSV transmission across the time
297 series. Here, we used a generalized linear model (GLM) in the ‘gaussian family’, fit to the
298 response variable of the natural log of the weekly RSV transmission rate, as estimated from
299 TSIR, with fixed predictor variables of total weekly precipitation (mm), weekly mean relative
300 humidity (%), and mean weekly temperature ($^{\circ}\text{C}$) for Antananarivo across the study period. Our
301 most comprehensive, global GLM thus took the following general form:

302
$$\ln(\text{Em}(\beta_t)) = b_1 P_t + b_2 \left(\frac{1}{H_t} \right) + b_3 T_t$$

303 [6]

304 where $\text{Em}(\beta_t)$ corresponds to the empirically estimated transmission rate from TSIR, and P_t ,
305 H_t , and T_t correspond respectively to total weekly precipitation, mean weekly relative humidity,
306 and mean weekly temperature at time t . Using the ‘dredge’ function in the R package MuMIn
307 (Barton *et al.* 2015), we then conducted model selection by comparing the relative AICc of all
308 predictor variable combinations of the global model defined in equation [6] (Table S4). We
309 used the fitted correlation coefficients of the top-performing model from this selection exercise
310 to explore the predicted impact of climatic variation on RSV transmission. Initially, we also
311 considered GLMs exploring lagged interactions between climate variables and transmission
312 response; however, likely because RSV is a directly-transmitted infection, these representations
313 were not well-supported by the data, and we eventually disregarded this approach.

314

315 *Interannual trends in Antananarivo climate variables and RSV case counts from GAMs*

316 Finally, we aimed to quantify interannual trends for all Antananarivo climate variables
317 considered across the 2011-2021 time series, while controlling for intra-annual seasonal
318 variation. To this end, we fit three separate climate GAMs in the ‘gaussian’ family to the
319 response variables of, respectively, total weekly precipitation (mm), mean weekly relative
320 humidity (%), and mean weekly temperature ($^{\circ}\text{C}$) for Antananarivo. Each GAM incorporated a
321 fixed, numerical effect of ‘year’ and cubic smoothing spline of ‘day of year’ (Table S5). We
322 additionally fit a fourth GAM in the ‘Poisson’ family, which took the same form as the climate
323 GAMs but included a response variable of total weekly reported RSV cases across the time
324 series (Table S5). Subsequently, we restructured all four GAMs with ‘year’ input as a
325 smoothing spline and formatted as factorial, random effect to identify any deviant years in the
326 overall climate or case time series (Table S5).

327

328 **RESULTS**

329 **Correlates of RSV infection by GAMs**

330 From January 2011 to December 2021, a total of 3432 samples from reporting sites were
331 screened for RSV. Of these, 989 (28.80%) tested positive for RSV infection (Fig. S1). RSV
332 prevalence varied considerably across the weekly time series, consistent with irregular reporting
333 and seasonality (Fig. 1A).

334 We first investigated correlates of RSV positivity using GAMs fit to 3242 datapoints
335 for which all possible metadata variables were reported. Our first GAM, in which we modeled
336 year as a factorial random effect performed slightly better than the second GAM modeling year
337 as a numerical variable (Table S1); thus, we report the results of the best fit model only here.
338 In this best fit GAM, we identified a significant effect of day of year, year, age, and reporting
339 sites on RSV positivity; no significant association was identified for sex (Fig. 1; Table S1). In
340 general, days 9-113 of each year (early January through the late April) were significantly
341 positively associated with RSV infection, consistent with records of the peak epidemic season
342 for RSV in Madagascar (Fig. 1B). This relationship turned negative for the rest of the year, with
343 a slight uptick at the end of December, as the onset of a new epidemic season approached. A
344 few discrete years in the time series demonstrated significant deviations in reported RSV
345 prevalence across the time series: years 2012 and 2013 were significantly positively associated
346 with RSV infection, while year 2015 was negatively associated with RSV infection. Patient
347 ages ≤ 2 years were additionally positively associated with RSV infection. Most other ages were
348 negatively associated with RSV infection, though no significant directionality in association
349 was identified in patient ages >85 years (Fig. 1D). The reporting hospital of CENHOSOA was
350 also positively associated with RSV infection (Fig. 1F), likely a result of the overwhelming
351 predominance of samples received from this locality. Day of year and annual patterns were
352 largely recapitulated when modeling (in a third GAM) the entire dataset of 3432 samples
353 without including age, sex, and reporting hospital as predictors: in this model, days of year 7-
354 111 were significantly positively associated with RSV infection, as were discrete years 2012,
355 2013, and 2019. As in the first GAM, year 2015 was also significantly negatively associated
356 with RSV positivity (Table S1).

357

358 **Estimation of the age-structured FOI for RSV cases**

359 Of the catalytic models tested, a model incorporating a piecewise, age-specific FOI
360 across nine discrete age bins (with respective lower bounds of 0, 0.5, 1, 2, 3, 4, 25, 60, and 70
361 years) offered the best fit to the data (Table S2). Within this model framework, we estimated
362 the highest FOIs in the two youngest cohorts (FOI = 1.03 [0.92-1.13] for ages 0 to <0.5 years;
363 FOI = 1.50 [1.27-1.73] for ages 0.5 to <1 year) (Fig. 2). From this peak, FOI then decreased
364 with increasing age across the first four years of life and sank to near-zero between ages 4 – 60
365 years (Fig. 2). FOI increased again in individuals aged 60 to <70 years (0.11 [0.05-0.16]) and
366 individuals 70+ years in age (0.34 [0.15-0.51]). In general, we found improved model fit to the
367 data when incorporating heightened specificity in $\lambda(a)$ for CU5, as well as in individuals >60

368 years in age. Additional complexity in modeled age structure in older adolescents or young-
369 and middle-aged adults did little to improve model performance (Table S2). Consistent with
370 the literature, these patterns suggest that the highest hazard of RSV infection is concentrated in
371 the youngest and, to a lesser extent, oldest populations in Antananarivo.

372

373 **Seasonality of RSV transmission by TSIR modeling**

374 We next binned reported RSV cases into weekly intervals across our time series for
375 TSIR modeling. Consistent with results from the binomial GAMs, we observed from the raw
376 data that weekly cases were highest in the first third of each year (January – April), excepting
377 the year 2012, for which the epidemic peak was observed between May and August (Fig. 3A).
378 Our efforts to reconstruct the population susceptible to RSV from publicly available birth rate
379 data indicated significant underreporting of RSV across the time series, with a mean estimated
380 reporting rate of only 2.9% (Fig. S2A-D). Nonetheless, the regression of cumulative reported
381 cases against cumulative births was well-supported ($R^2= 0.98$; Table S3) and produced a
382 plausible estimate for the mean susceptible population of roughly 20% (Fig. S2D). This quantity
383 corresponds to an estimated $R_0 = 5$ for RSV in our Antananarivo catchment area; coarse
384 estimation of R_0 using the inverse of the mean per capita birth rate (0.0327) and average age of
385 infection (6.67) across the time series yields a comparable estimate of $R_0 = 4.58$. Literature
386 reported R_0 values for RSV range from 1–9, with 3 as the most commonly-cited statistic ([Weber](#)
387 [et al. 2001](#), [White et al. 2007](#), [Pitzer et al. 2015](#), [Reis et al. 2016](#), [Reis et al. 2018](#)). Though our
388 estimates are in the upper half of this range, $R_0 = 4.5–5$ for RSV is not illogical given high birth
389 rates and densely aggregated populations in Antananarivo.

390 Consistent with prior patterns observed in the GAMs (Fig. 1) and in the raw data (Fig.
391 3A), our fitted TSIR model estimated that RSV transmission peaked in January–February,
392 slightly preceding cases, then declined throughout the rest of the year before climbing again in
393 December (Fig. 3B; Fig S2E). As with susceptible reconstruction, our log-link linear regression
394 to estimate transmission was well supported (McFadden pseudo- $R^2= 0.64$; Table S3) and
395 successfully reconstructed the time series of cases following simulation (Fig. S2F-G).

396

397 **Climate predictors of seasonal RSV transmission by GLMs**

398 From the Antananarivo raw climate data, we observed that annual precipitation largely
399 mirrored the seasonality of RSV, with most of the rainfall concentrated between January and
400 the end of April and a slight increase in November and December leading up to the onset of
401 each new year (Fig. 3C). Relative humidity also peaked in the early half of the year but remained

402 high through June, with lows concentrated between September and November (Fig. 3D). Mean
403 temperature followed the same broad pattern as the other climate variables but with a more
404 gradual, sinusoidal annual cycle, with highs concentrated in the summer between November –
405 March and lows between June – August (Fig. 3E).

406 Our top performing GLM to evaluate the strength of association between climate and
407 RSV transmission (as estimated from TSIR) included all three weekly Antananarivo climate
408 variables (precipitation, humidity, and temperature) as significant correlates of transmission,
409 with precipitation contributing the most to the total deviance explained by the model ($R^2=0.10$;
410 Fig. 4A-B; Table S4). The second-best performing model included only precipitation and
411 humidity as significant correlates of RSV transmission, again with a more pronounced effect
412 for precipitation. In all cases, precipitation demonstrated a highly significant, positive
413 correlation with the weekly RSV transmission rate ($p<0.001^{***}$; Fig. 4B-C; Table S4). By
414 contrast, relative humidity was significantly negatively associated with RSV transmission
415 ($p<0.01^*$; Fig. 4B-C; Table S4). Mean weekly temperature was positively correlated with
416 transmission, but the association was considerably weaker than that observed for precipitation
417 and only marginally significant ($p<0.1^*$; Fig. 4B-C; Table S4).

418

419 **Interannual trends for climate variables and RSV cases by GAMs**

420 GAMs fit to the 2011-2021 time series for all three Antananarivo climate variables
421 demonstrated a significant, positive interannual trend in all cases, suggesting that precipitation,
422 humidity, and temperature have all increased across the past decade (precipitation: $p=0.05^*$;
423 humidity: $p=0.07^*$; temperature: $p=0.004^{**}$; Fig. S3 A-C; Table S5). Intra-annual trends
424 captured in GAMs mimicked those previously described from observations of the raw data,
425 with precipitation peaking at the beginning and end of each calendar year, relative humidity
426 offset but still at its highest in the early half of the year, and temperature more evenly distributed
427 with highs concentrated between November – March and lows from June – August (Fig. S3A-
428 C; Fig. 3C-E). In contrast to climate patterns, a Poisson GAM fit to the weekly time series of
429 case counts demonstrated no significant interannual trend ($p>0.1$; Fig S3D; Table S5), after
430 controlling for intra-annual cycling. Climate GAMs considering year as a factorial random
431 effect indicated that year 2020 experienced significantly higher precipitation and humidity than
432 average, while 2019 was found to be significantly warmer (Fig. S3); by contrast, year 2011 was
433 found to have lower-than-average humidity and years 2013 and 2016 to be significantly cooler
434 than average (Fig. S3). We identified no correspondence between those years exhibiting
435 anomalous climate behavior and those previously identified to have a higher-than-average RSV

436 burden (2012 and 2013); RSV deviations already explored in Fig. 1 were largely confirmed by
437 the Poisson GAM tested here (Fig. S3).

438

439 **DISCUSSION**

440 In this study, we used a suite of modeling approaches to (1) characterize correlates for
441 reported RSV infections, (2) quantify age-structure in the force of RSV infection, (3) document
442 seasonality in RSV transmission, and (4) identify possible climatic drivers of this seasonality
443 in the low income setting of Antananarivo, Madagascar.

444 The results of our analysis of correlates of RSV transmission are consistent with those
445 previously documented for this disease, both in Madagascar and elsewhere ([Hall *et al.* 2013](#),
446 [Razanajatovo *et al.* 2018](#), [Razanajatovo *et al.* 2022](#)): we find that reported hospitalizations for
447 RSV are largely concentrated in very young patients (≤ 2 years of age) with a potential weaker
448 association in elderly individuals (>60 years of age). Our quantification of the age-structured
449 FOI for RSV indicates that the most intense transmission is focused in infants aged less than
450 one year, with transmission intensity steadily decreasing to near-zero after four years of age,
451 before rising again in elderly cohorts. Because we fit our FOI models to reported cases only, it
452 is possible that less pathogenic RSV transmission may dominate among older children,
453 resulting in asymptomatic infections, as has been previously suggested in the analysis of age-
454 structured *serological* data from other regions ([Nakajo *et al.* 2023](#)). Our crude estimates for
455 RSV R_0 , which we computed from the average age of infection and mean population-level birth
456 rate, as well as from the mean susceptible population estimated from TSIR, additionally suggest
457 that RSV transmission is elevated in Antananarivo, as compared with global averages ([Weber
458 *et al.* 2001](#), [White *et al.* 2007](#), [Pitzer *et al.* 2015](#), [Reis *et al.* 2016](#), [Reis *et al.* 2018](#)). Again, our
459 reliance on reported cases likely upwardly biases these calculations by overrepresenting more
460 pathogenic strains or more vulnerable populations or both. Nonetheless, these estimates fall
461 well within reported ranges for RSV R_0 ([Weber *et al.* 2001](#), [White *et al.* 2007](#), [Pitzer *et al.* 2015](#),
462 [Reis *et al.* 2016](#), [Reis *et al.* 2018](#)), and a slightly elevated RSV transmission rate is not illogical,
463 given Antananarivo's young and densely aggregated population.

464 In addition to describing the magnitude and age-structure of RSV transmission, our
465 study also successfully quantifies intra-annual seasonality in RSV dynamics in Antananarivo.
466 A seasonal concentration of RSV burden in the first half of the calendar year in Madagascar
467 has been previously suggested based on more qualitative examination of the raw case data
468 ([Rabarison *et al.* 2019](#), [Razanajatovo *et al.* 2022](#)); however, our study is the first to actually
469 quantify RSV transmission, which slightly precedes cases. Our investigation of climatic

470 correlates of the weekly transmission rate echoes recent work from the northern hemisphere
471 which highlights a significant positive role for precipitation and negative role for humidity in
472 driving RSV transmission dynamics (Baker *et al.* 2019). In addition, we identify a significant
473 (though weaker) positive correlation between RSV transmission and temperature in
474 Antananarivo. Because high temperatures and high precipitation are themselves correlated in
475 tropical Madagascar’s rainy season, which spans October – March, it is possible that this muted
476 contribution of temperature to RSV transmission dynamics may simply be an artifact of the
477 precipitation driver, rather than a causative association of its own. Our examination of
478 interannual trends in the climate data suggests that precipitation, humidity, and temperature
479 have all increased across the past decade study period in Antananarivo, but that average RSV
480 caseload has remained constant. As high precipitation is associated with elevated RSV
481 transmission rates, but high humidity is associated with lower RSV transmission rates in our
482 dataset, it is possible that these climate drivers have had largely neutralizing effects on the
483 overall RSV burden throughout our time series. Nonetheless, our statistical models demonstrate
484 a more pronounced effect of precipitation on the overall variation in observed RSV
485 transmission, as has been reported in other tropical locations that demonstrate high average
486 annual humidity with minimal variation across the year (Baker *et al.* 2019). Though there is no
487 animal model available for RSV, experimental work in influenza has demonstrated that low
488 humidity conditions favor transmission between guinea pigs, as a result of either increased
489 survival of the virus and/or extended duration of virus circulation in aerosols in drier conditions
490 (Lowen *et al.* 2007). Future climate impacts on RSV transmission are likely to depend on the
491 relative slope of each climate driver’s projected increase in a specific locality: over the past
492 decade, precipitation has increased at a faster rate than humidity in tropical Antananarivo. If
493 current trends hold, higher precipitation could drive future RSV transmission beyond the
494 tempering effects of humidity.

495 Finally, our analysis highlights a few years in our decade-long time series that vary
496 significantly from the overall trend, with higher- or lower-than-average RSV-attributed
497 infections and, in one year (2012), an irregular, off-season peak. Prior work in other systems
498 has described off-season RSV epidemics attributed to irregular climate patterns (De Silva *et al.*
499 1986), but we were unable to identify any association between deviant years in the RSV time
500 series in Antananarivo and any observed climatic anomalies. Higher- or lower-than average
501 RSV burden in a given year could instead reflect the complex interplay between host immunity
502 and circulating viral genotypes—both those of RSV itself, for which two major subtypes are
503 known (Peret *et al.* 1998), and those of other respiratory infections known to induce some

504 degree of anti-RSV cross-protective immunity (Bhattacharyya *et al.* 2015). Prior sequencing
505 efforts of Antananarivo RSV cases over the same time period indicate that year 2012 witnessed
506 a transition in caseload from the previously dominant RSV subtype B to RSV subtype A –
507 genotype NA1, which was subsequently replaced by the introduction of the novel RSV subtype
508 A – genotype ON1 in 2014 (Eshaghi *et al.* 2012, Razanajatovo Rahombanjanahary *et al.* 2020)).
509 It is possible that the irregular seasonality of the RSV epidemic of 2012 reflects a lack of prior
510 immunity in the Antananarivo CU5 population to RSV subtype B prior to turnover—though
511 this hypothesis is impossible to test in the absence of additional viral genomic sequencing and
512 paired subtype-specific serology. Off-season RSV transmission was well-documented globally
513 in 2020 and 2021 following relaxation of non-pharmaceutical interventions (NPIs)
514 implemented to counter the initial spread of SARS-CoV-2 (Eden *et al.* 2022). Intriguingly, our
515 analysis did not recover any signature of aberrant RSV transmission for the year 2020 or 2021
516 in Antananarivo, suggesting that NPIs were largely unsuccessful at reducing respiratory virus
517 transmission in this region during this time (Razanajatovo *et al.* 2022). Indeed, broadscale
518 serosurveys in 2020 and 2021 suggest that over 40% of the Antananarivo population was
519 exposed to SARS-CoV-2 within the first six months of the pandemic (Razafimahatratra *et al.*
520 2021), underscoring the relative ineffectiveness of NPIs on reducing respiratory disease burden.

521 Our study is limited by its focus to only a few reporting sites in Antananarivo, with most
522 samples received from one sentinel site (CENHOSOA). This restricted geography somewhat
523 impedes our ability to draw conclusions about broad trends in RSV dynamics across
524 Madagascar. In addition, our FOI estimation is limited by the necessarily arbitrary segregation
525 of the population into discrete age classes; while we attempted to consider all plausibly relevant
526 delineations of age with respect to transmission, it is possible that we may have overlooked
527 important dynamics hidden in untested hypotheses. In addition, we were challenged by
528 uncertainty in estimates of the population served by the catchment area of focal sites, which
529 subsequently undermines downstream estimation of local birth rates and corresponding
530 susceptible population reconstruction for input into TSIR. As a frequent limitation of TSIR
531 approaches, we were forced to extrapolate weekly birth rate data for our study population using
532 very broad national-level, annual birth rate estimates from the World Bank. More fine scale
533 birth data specifically tailored to our study region would do much to improve inference into
534 infection dynamics. Our climate records, which draw from Antananarivo at large, are similarly
535 broad, given the highly localized (e.g. within-household) nature of the majority of RSV
536 transmission (Hall *et al.* 1976, Munywoki *et al.* 2014). Finally, as mentioned, our dataset was
537 limited to reported RSV cases only. More widespread prospective sampling of less virulent

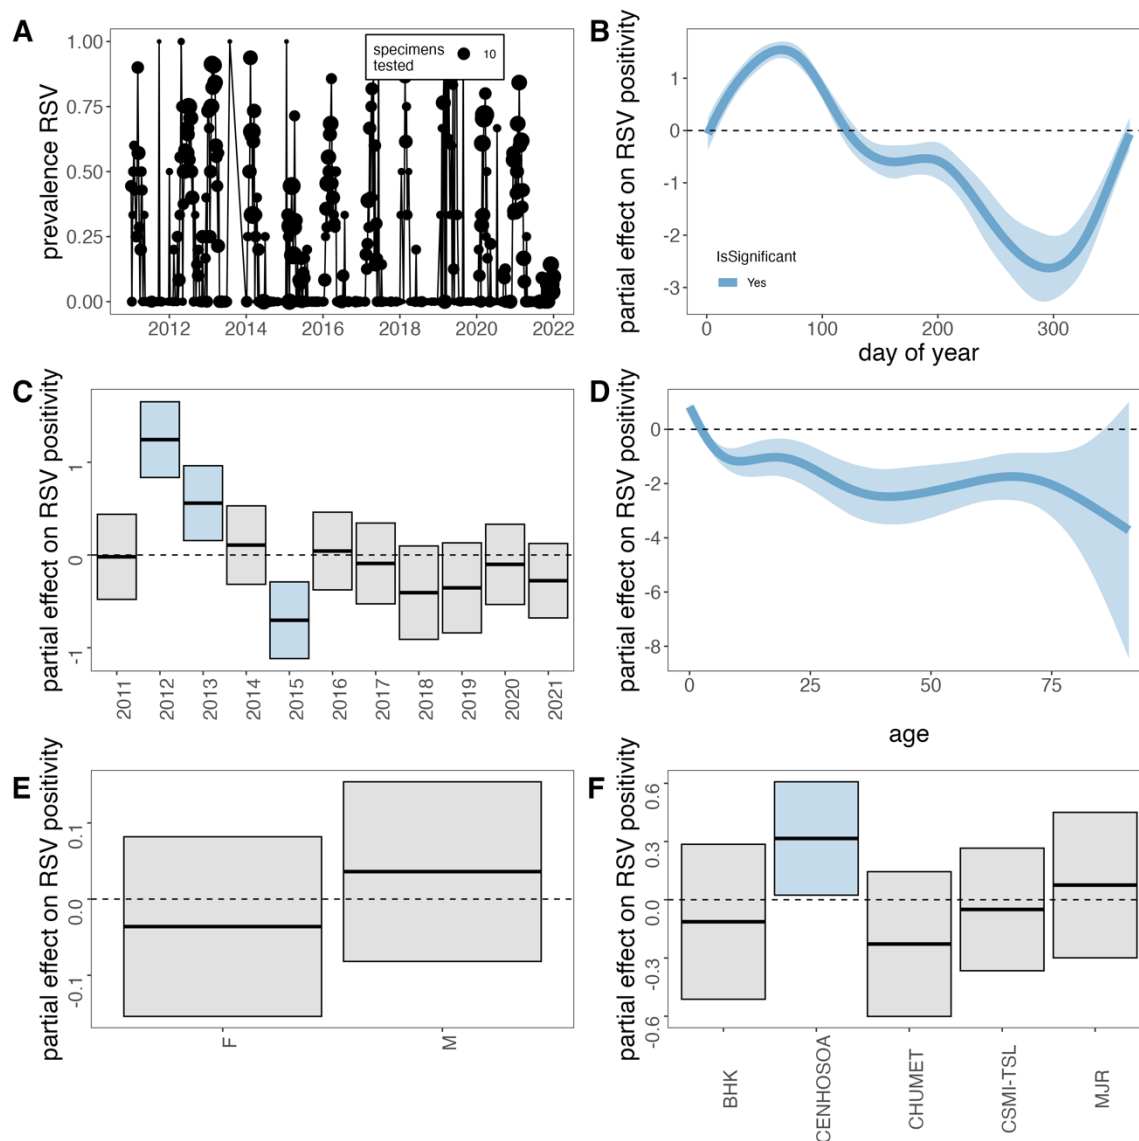

538 disease manifestations – either through molecular testing, or more feasibly, serology – would
539 greatly enhance our inference into RSV transmission. In addition, investigation of genome
540 sequences would enable us to test hypotheses about the impact of virus genotype diversity on
541 asynchronous and off-season dynamics. Despite these challenges, our modeling efforts recover
542 plausible estimates for both the seasonality and R_0 of reported cases of RSV in Antananarivo,
543 suggesting that these uncertainties did not seriously impact our results.

544 All told, our study underscores the heavy morbidity and mortality burden that RSV
545 presents to young children in Antananarivo and highlights an important role for climate in
546 driving seasonal epidemics. Future changes in climatic parameters, particularly precipitation,
547 are likely to impact RSV dynamics and may impact transmission, at least in the short-term, in
548 Madagascar. Introductions of new intervention strategies are greatly needed to mitigate RSV's
549 heavy mortality burden in LMICs—especially considering possible intensification of burden in
550 response to climate. RSV vaccines for older patients and pregnant mothers, as well as
551 monoclonal antibody treatment for neonates, have recently become available in high income
552 countries ([Langedijk *et al.* 2023](#)). Despite projections of positive impact ([Brand *et al.* 2020](#)),
553 these interventions have not yet reached the Global South, largely as a result of high cost
554 barriers and lack of awareness of regional health authorities and communities regarding the
555 burden of RSV. Shortages of human, financial, and material resources, which jeopardize the
556 provisioning of quality health services, are still a serious challenge in LMICs. Equitable global
557 distribution of these interventions needs to be a major public health priority for the next decade.

560 **FIGURES**

561 **Figure 1. GAM correlates of RSV positivity from influenza surveillance network testing**
 562 **in Antananarivo, Madagascar (2011-2021).** (A) Time series of weekly RSV prevalence,
 563 where point size corresponds to the number of samples tested (total 3432) from January 2011
 564 – December 2021. For GAM fitted to data with all available correlates (3242, partial effect sizes
 565 are shown for (B) day of year, (C) year, (D) age, (E) sex, and (F) sampling locality on the
 566 probability of a sample testing positive for RSV infection. All predictors except sex contributed
 567 significantly to overall model performance. Shading corresponds to 95% confidence intervals
 568 (CI) by standard error. An effect is shaded in gray if the 95% CI crosses zero across the entire
 569 range of the predictor variable; in contrast, an effect is shaded in blue and considered
 570 “significant” if the 95% CI does not cross zero. Metrics from GAM fits are reported in Table
 571 S1.

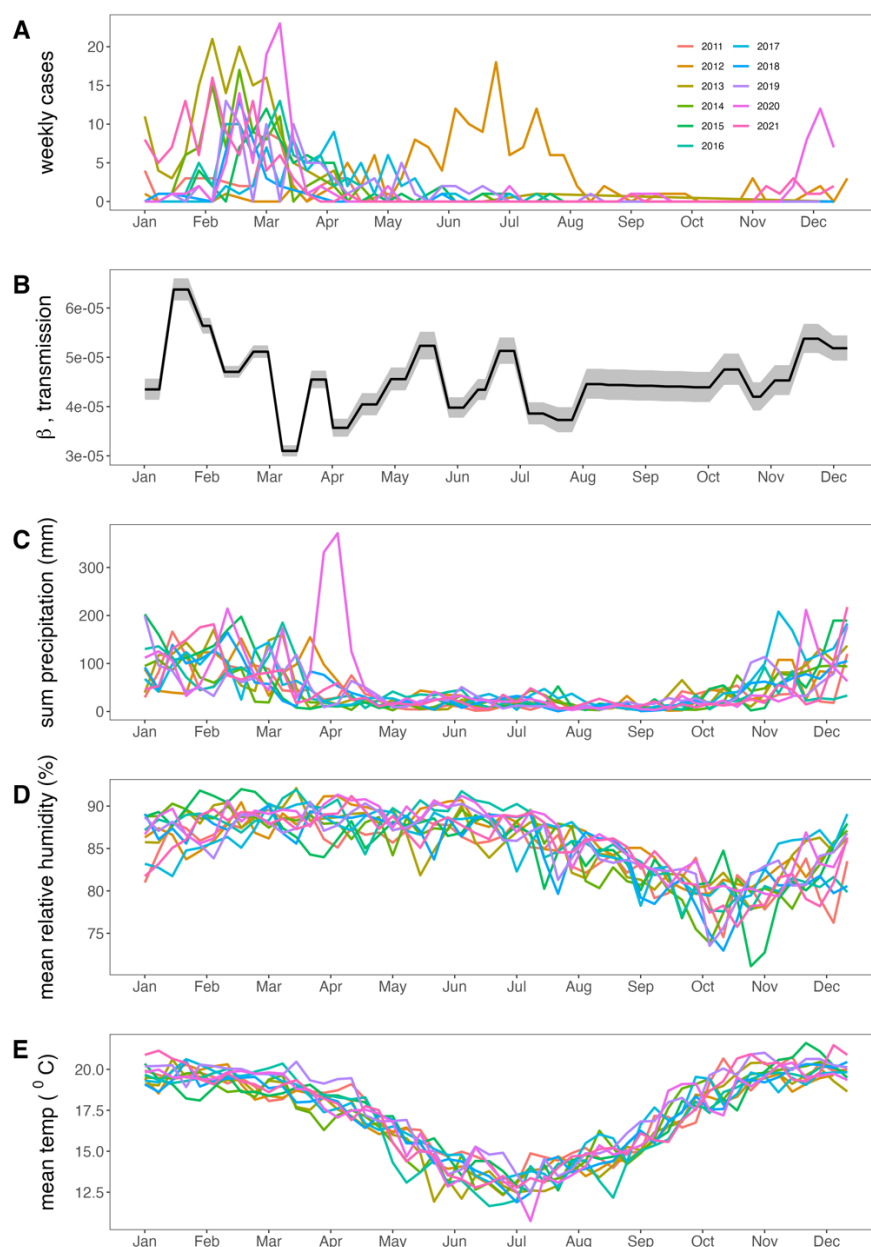

572

573 **Figure 2. Catalytic model estimation of age-structured force of infection for RSV**
574 **hospitalizations.** (A) Cumulative proportion of hospitalized cases by age, across 2011-2021
575 study period from all focal hospitals in Antananarivo (total = 3259 datapoints). Black dots and
576 connecting black line correspond to raw data binned across annual age brackets, with the first
577 year of life separated into two age brackets (<0.5 years and ≥ 0.5 years). Red line corresponds
578 to model output from best-fit FOI model, incorporating 9 piecewise constant, age-specific
579 hazards of infection across discrete age classes, as shown in (B). In both panels, red shading
580 corresponds to 95% CI on FOI estimates computed from the hessian matrix during model
581 fitting; upper and lower CI bounds are used to project 95% CIs on modeled cumulative
582 incidence in panel A. Comparisons of all models tested and exact FOI estimates from best-fit
583 model are reported in Table S2.

624 **ACKNOWLEDGEMENTS**

625 The authors thank all clinicians and nurses involved in the study, as well as staff involved in
626 daily surveillance reporting of ILI and SARI cases at sentinel sites. The authors additionally
627 thank the laboratory technicians at the Virology Unit of IPM and the Clinical and Medical
628 Laboratory for their tremendous work in the molecular testing of the biological samples.

629

630 **CONTRIBUTORS**

631 CEB and JMH conceived the project and acquired the funding, in collaboration with NRS,
632 and VL. Influenza and RSV Sentinel surveillance in Madagascar was coordinated by JMH,
633 LR, NHR, and JHR. Sample collection was carried out by LR, JHR, and AR. All laboratory
634 work, involving RNA extraction and subsequent PCR, was conducted by THR, NHR, and
635 CR. CEB led the statistical analysis and FOI and TSIR modeling, with support from HCR and
636 THR. THR and CEB co-wrote the original draft of the manuscript. All authors including
637 DADR edited and approved the manuscript.

638

639 **FUNDING**

640 This research was supported by the US Centers for Disease Control and Prevention
641 (Cooperative Agreement to JMH: NU51IP000812), the Bill and Melinda Gates Foundation
642 (grant awards to CEB: OPP 1211841 and INV 049262), and the National Geographic Society
643 Coding for Conservation program (grant award to CEB: 102825). The funders had no role in
644 the study design, data collection or analysis, the decision to publish, or preparation of the
645 manuscript.
