20 **Abstract**

21 The detection of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA in
22 sewage is well-established, but the concomitant changes in microbial compositions during the
23 pandemic remain insufficiently explored. This study investigates the impact of the SARS-CoV-2
24 virus on microbial compositions in raw sewage, utilizing 16S rRNA sequencing to analyze
25 wastewater samples collected from six dormitories over a one-year field trial at the University of
26 Tennessee, Knoxville. The concentration of SARS-CoV-2 RNA was assessed using a reverse
27 transcription-quantitative polymerase chain reaction. Significant variations in bacterial
28 composition were evident across the six dormitories, highlighting the importance of
29 independently considering spatial differences when evaluating the raw wastewater microbiome.
30 Positive samples for SARS-CoV-2 exhibited a prominent representation of exclusive species
31 across all dormitories, coupled with significantly reduced bacterial diversity compared to
32 negative samples. The correlation observed between the relative abundance of enteric pathogens
33 and potential pathogens at sampling sites introduces a significant dimension to our understanding
34 of COVID-19, especially the notable correlation observed in positive SARS-CoV-2 samples.
35 Furthermore, the significant correlation in the relative abundance of potential pathogens between
36 positive and negative SARS-CoV-2 raw sewage samples may be linked to the enduring effects of
37 microbial dysbiosis observed during COVID-19 recovery. These findings provide valuable
38 insights into the microbial dynamics in raw sewage during the COVID-19 pandemic.

39 **Introduction**

40 The interconnection between sewage and the human gut microbiota has garnered significant
41 interest, revealing a substantial overlap in microbial composition. Newton et al. (2015) noted that
42 the microbial composition of sewage, primarily originating from the human gut, comprises a
43 diverse array of both beneficial and pathogenic species, with bacteria and viruses playing central
44 roles. Robust evidence consistently supports the notable similarity between the microbial profiles
45 of raw sewage and the human gut. Cai et al. (2014) emphasized that the total abundance of high-
46 level genera in influent sewage is nearly 50%, similar to that of the human gut, thus highlighting
47 the human gut as the primary source of bacterial collection in sewage. Newton et al. (2015)
48 further reported that sequences representing approximately 78% of a stool sample comprised
49 around 12% of a sewage sample. Extrapolating this ratio to 100%, their estimation suggests that
50 only 15% of amplicons in a typical sewage sample originate from human stool. However, Fierer
51 et al. (2022) found that bacteria derived from fecal material constitute a relatively small fraction
52 of the taxa in collected samples, underscoring the significance of environmental sources in
53 shaping the sewage microbiome. It is still unclear if raw sewage truly reflects the microbial
54 composition of the human gut.

55 Crucially, numerous studies have illustrated that respiratory infections associated with COVID-
56 19 correlate with changes in the composition of the gut microbiota (Gu et al. 2020, Zuo et al.
57 2020). The dysbiosis of COVID-19 may enhance gut permeability, leading to secondary
58 infections and organ failure. Simultaneously, disruptions in gut barrier integrity could potentially
59 facilitate the translocation of SARS-CoV-2 from the lungs to the intestinal lumen (AKTAŞ and
60 Aslim 2020). Gu et al. (2020) and Zuo et al. (2020) observed that, compared to fecal samples
61 from healthy people, fecal samples from COVID-19 patients had significantly reduced bacterial
62 diversity, a significantly higher relative abundance of opportunistic pathogens and a lower
63 relative abundance of beneficial symbionts. Liu et al. (2022) even found that gut dysbiosis
64 persisted even after clearance of SARS-CoV-2 at 6 months. Patients with COVID-19 exhibit
65 significant alterations in fecal microbiomes, suggesting potential changes in the wastewater
66 microbiome during the pandemic. Currently, research on microbial compositions in wastewater
67 with positive and negative SARS-CoV-2 samples remains limited, with Gallardo-Escárate et al.
68 (2021) being the sole study to explore such dynamics across three sampling communities using

69 nanopore technology. Their findings highlighted a robust association between the microbiota of
70 positive SARS-CoV-2 wastewater samples and enteric bacteria. Notably, integrating the
71 Wastewater-Based Epidemiology tool with metagenomic analysis, employing 16S rRNA
72 sequencing technology to investigate changes in sewage microbiota during the COVID-19
73 pandemic, remains an unexplored avenue that warrants further research.

74 This study employs 16S rRNA sequencing to thoroughly analyze microbial compositions in raw
75 sewage samples, differentiating between those with positive and negative COVID-19 status. The
76 primary goal is to identify distinct patterns or shifts in the bacterial community associated with
77 the presence of the virus. Through the utilization of this technology, the research aims to provide
78 a nuanced understanding of the dynamics of viral shedding, microbial interactions, and the
79 overall impact of SARS-CoV-2 on the sewage microbiome over a year-long field trial conducted
80 in six campus dormitories. Including COVID-19-negative sewage samples as a control allows for
81 identifying specific changes attributable to viral presence, facilitating the establishment of
82 correlations between the sewage microbiota and COVID-19 prevalence in human communities.
83 Essentially, this investigation seeks to address the knowledge gap regarding the interplay
84 between SARS-CoV-2 and the sewage microbiome, offering valuable insights into the potential
85 utility of wastewater-based epidemiology for monitoring and assessing COVID-19 prevalence.

86 **Materials and Methods**

87 **Raw Sewage Sampling and Sample Processing**

88 Raw wastewater was systematically collected from six student residence halls on the University
89 of Tennessee, Knoxville campus, as illustrated in Figure 1. Each of these residential dormitories
90 accommodated a population of over 400 students, and a detailed summary of their characteristics
91 is presented in Table 1. Sampling was from access points to the main sewage pipe in the
92 basement of the building or at the first access point to a raw sewer manhole immediately outside
93 the building, specifically before the convergence or merging with other sewer conduits. This
94 sampling initiative occurred from September 14, 2020, to October 11, 2021.

95 Grab samples (>50 ml) were collected at the manhole using a stainless-steel telescopic rod pole
96 swivel dipper water swing sampler. Alternatively, samples were obtained from the valve by
97 submerging a sterile Nalgene bottle into the flowing sewage. Sampling commenced at 8:00 am,
98 and all collected samples were promptly transported to the BSL-2 laboratory in a cooler with ice.
99 The transit time was kept to less than 3 h to ensure immediate processing.

100 Upon reaching the laboratory, sewage samples underwent pasteurization for 2 h at 60°C.
101 Following pasteurization, centrifugation at 5,000 x g for 10 min occurred, and subsequent
102 filtration was carried out through sequentially sized 0.45 µm and 0.22 µm nitrocellulose filters.
103 These filters were individually placed in DNA LoBind tubes and stored at -80°C until DNA
104 extraction. Concentration was achieved using an Amicon Ultra-15 filtration device, with
105 centrifugation at either 4,000 x g for 30 min (Swing-arm rotor) or 5,000 x g for 20 min (Fixed-
106 angle rotor) at room temperature. The resulting concentrated solution, approximately 250 µL,
107 was carefully transferred to 2 mL DNA LoBind tubes.

108 RNA extraction was performed using the Qiagen viral RNA Mini Kit, following the instructions
109 of the manufacturer, yielding 60 µL of extracted RNA, with a negative control using
110 DNase/RNase-free water. Subsequently, the RNA samples were stored at -80°C and subjected to
111 RT-qPCR analysis within 24 h following extraction (Ash et al. 2023, Li et al. 2023).

112 **RT-qPCR**

113 To quantify the concentrations of SARS-CoV-2 and PMMoV RNA in each sample, we
114 employed RT-qPCR. Specifically, we measured SARS-CoV-2 N1 using the TaqPath 1-Step RT-
115 qPCR Master Mix, CG (Thermo Fisher Scientific) on an Applied Biosystems QuantStudios 7 Pro
116 Real-Time PCR System instrument. Each 20 μL reaction mixture comprised 5 μL of 4X Master
117 Mix (Thermo Fisher Scientific), 0.25 μL of a 10 $\mu\text{mol/L}$ probe, 1 μL each of 10 $\mu\text{mol/L}$ forward
118 and reverse primers, 7.75 μL of nuclease-free water, and 5 μL of nucleic acid extract. After
119 accurate pipetting of reagents into 96-well plates, a 10-second vortex mixing step followed. The
120 RT-qPCR cycling conditions included an initial uracil-DNA glycosylase incubation for 2 min at
121 25°C, reverse transcription for 15 min at 50°C, activation of the Taq enzyme for 2 min at 95°C,
122 and a two-step cycling process involving 3 sec at 95°C and 30 sec at 55°C, repeated for a total of
123 45 cycles. A positive test result was determined by the presence of an exponential fluorescent
124 curve intersecting the threshold within 40 cycles (cycle threshold [Ct] <40).

125 The quantification of PMMoV was executed using the TaqPath 1-Step RT-qPCR Master Mix,
126 CG (Thermo Fisher Scientific) on a QuantStudios 7 Pro instrument. Each reaction was composed
127 of 20 μL , including 5 μL of 4X Master Mix from Thermo Fisher Scientific, 0.5 μL of 10 $\mu\text{mol/L}$
128 probe, 1.8 μL each of 10 $\mu\text{mol/L}$ forward and reverse primers, 8.9 μL of nuclease-free water, and
129 2 μL of nucleic acid extract. The reagents were meticulously transferred into 96-well plates using
130 pipettes and subsequently mixed by vortexing for 10 sec. The thermocycling conditions utilized
131 in this study were as follows: incubation of uracil-DNA glycosylase for 2 min at 25°C, reverse
132 transcription carried out for 15 min at 50°C, activation of the Taq enzyme for 10 min at 95°C,
133 and a two-step cycling process consisting of 30 sec at 95°C followed by 1 min at 60°C, repeated
134 for a total of 40 cycles.

135 In each RT-qPCR run, one positive PMMoV control and negative controls, comprising
136 Mastermix and DNase/RNase-free water, were incorporated. The RT-qPCR reactions were
137 carried out in triplicate, and the criteria for classifying a sample as positive included the
138 requirement that all replicates produced positive results, with each individual replicate falling
139 within the linear range of the standard curve. The N1 standard curve demonstrated a high level of
140 efficiency, with a value of 94.669% ($R^2 = 1$). The quantification of SARS-CoV-2 RNA was
141 determined by calculating the average of three replicates of viral copies. The outputs of RT-

142 qPCR were converted into units of copies per liter. In this study, the detection limit for SARS-
143 CoV-2 and PMMoV was established at 20 and 10 copies per liter, respectively.

144 **DNA Isolation, 16S rRNA Gene Amplification, Sequencing**

145 Before inclusion in the kit, quarter-sections of 0.45 μm and 0.22 μm nitrocellulose filters were
146 prepared by flame-sterilizing a blade and using ethanol for sterilization. Genomic DNA
147 extraction was then performed using the FastDNA Spin Kit for Soil (BIO101, Vista, CA, USA),
148 strictly following the guidelines of manufacturer. Subsequent DNA purification utilized the
149 SELECT-A-SIZE DNA Clean & Concentrator Kits (Zymo Research, Irvine, CA). The quality of
150 the extracted DNA was assessed by determining the 260/280 and 260/230 ratios on a NanoDrop
151 spectrophotometer (Thermo Fisher Scientific, Waltham, MA).

152 After confirming successful DNA extraction, Polymerase Chain Reaction (PCR) was conducted
153 on 1–10 μL of the extracted DNA. DNA libraries were prepared following the methodology
154 outlined by Caporaso et al. (2012). PCR amplification of the V4 region employed Phusion DNA
155 polymerase (Master Mix; Thermo Fisher Scientific, Waltham, MA) and universal primers 515f
156 and barcoded 806r, designed to anneal to both bacterial and archaeal sequences. A 12-bp barcode
157 index on the reverse primer facilitated multiplexing for sequencing analysis.

158 Subsequently, amplicon quality and size were assessed using an Agilent Bioanalyzer (Agilent
159 Technologies Santa Clara, CA). Following the protocol of manufacturer, the DNA amplicons
160 were pooled and quantified with a NEBNext Library Quant Kit for Illumina (New England
161 Biolabs, Ipswich, MA). Sequencing was performed using a MiSeq V2 kit on an Illumina MiSeq
162 platform (Illumina, San Diego, CA).

163 Digital sequence data from the MiSeq underwent processing through the QIIME2 (v1.9) pipeline
164 on a Linux Server (Caporaso et al. 2010). DADA2 within QIIME2 was employed for denoising,
165 and fast-join facilitated the joining of paired-end sequences. Subsequent demultiplexing
166 excluded sequences with a Phred score below 20, and UCHIME identified and removed chimeric
167 sequences. Genus-level identification of sequences utilized the Silva database, with operational
168 taxonomic units (OTUs) determined and sample populations normalized by total sequence count
169 to ascertain the relative abundance of each OTU.

170 **Data Analysis**

171 Statistical analyses were conducted using R version 4.2.3. Initially, samples were processed by
172 rarefying OTU tables to the lowest library size across all samples in each student residence hall.
173 Subsequently, we computed common α -diversity metrics (Observed, ACE, Shannon, Simpson,
174 InvSimpson, Fisher, Coverage, and PD) and β -diversity metric (Bray-Curtis) using the R
175 phyloseq package. To assess differences in α -diversity metrics between groups, linear regression
176 was employed, with semesters included as covariates. For the evaluation of differences in β -
177 diversity metrics between groups, nonmetric-multidimensional scaling (NMDS) was utilized,
178 and p values for the comparison between groups were determined using permutational
179 multivariate ANOVA models, which included semesters as covariates. A Pearson Correlation
180 analysis was undertaken to explore the correlations between various parameters, including the
181 relative abundance of enteric pathogen and potential pathogens, the relative abundance of enteric
182 pathogen and potential pathogen in positive and negative SARS-CoV-2 samples, as well as the
183 relative abundance of potential pathogen in positive and negative SARS-CoV-2 sewage samples.

184 **Results**

185 **Concentration of SARS-CoV-2 in Raw Sewage**

186 The 174 raw sewage samples included in this study were collected from 6 different dormitories
187 in the same sewage network across the University of Tennessee, Knoxville (Figure 1). Figure 2
188 depicts the concentrations of SARS-CoV-2 from September 2020 to October 2021 within various
189 high-density student residence halls. Over the sampling period, SARS-CoV-2 concentrations
190 were consistently measured at different levels in the respective halls: 3.09 ± 3.46 log₁₀ copies/L
191 in D1, 2.02 ± 2.19 log₁₀ copies/L in D2, 2.80 ± 3.26 log₁₀ copies/L in D3, 2.97 ± 3.61 log₁₀
192 copies/L in D4, 2.94 ± 3.30 log₁₀ copies/L in D5, and 2.36 ± 2.71 log₁₀ copies/L in D6.

193 Furthermore, the positive rates, calculated by dividing the number of positive samples by the
194 total number of samples and multiplying by 100%, varied across the halls. Specifically, the
195 positive rates were 70% in D1, 39% in D2, 52% in D3, 20% in D4, 68% in D5, and 37% in D6
196 (Table 2). These results provide valuable insights into the dynamics of SARS-CoV-2
197 concentrations and positivity rates within high-density student residence halls during the
198 specified timeframe.

199 **Characteristics of the predominant flora in different dormitories.**

200 **Characterization on phylum, family, and genus level.**

201 The sequences extracted from the samples underwent comprehensive analysis, resulting in the
202 classification of data into 56 phyla, 145 classes, 315 orders, 548 families, and 1170 genera.
203 Figure 3 illustrates the relative abundances of the top 10 phyla across six dormitories, revealing
204 notable variations. The phylum Bacteroidetes was identified as the most abundant across all
205 sampling sites, with relative abundance ranging from 46.1% to 26.9%. Firmicutes emerged as the
206 second most abundant phylum in dormitories 1, 2, 3, and 4, with relative abundance varying
207 from 35.2% to 14.8%. Meanwhile, Proteobacteria emerged as the second most abundant phylum
208 in dormitories 5 and 6, with relative abundance ranging from 41.3% to 25.4%. Additionally, it
209 was observed that dormitories 2 and 3 have the same four highest abundance phyla of
210 Bacteroidetes, Firmicutes, Proteobacteria, and Spirochaetota. Similarly, Dormitories 5 and 6
211 have the same four highest abundance phyla of Bacteroidetes, Proteobacteria, Firmicutes, and
212 Campilobacterota.

213 Figure 4 highlights the 10 most dominant families, showcasing significant differences among the
214 six dormitories. Paludibacteraceae and Spirochaetaceae emerged as the most dominant families,
215 with varying relative abundance in D1, D2, and D3. Interestingly, Bacteroidaceae took
216 precedence in D4, D5, and D6, with distinct relative abundance up to 12.6%.

217 The relative abundances of the top 50 genera detected in all dormitory samples are shown in
218 Figure 5. Moreover, many typical gut bacteria were also found at very high levels in the sewage
219 such as Bacteroides, Acinetobacter, Prevotella, Pseudomonas, Blautia, Faecalibacterium,
220 Ruminococcus, Dorea, and others, corresponding to ranks 1, 8, 10, 11, and 21 within the top 50
221 genera in Figure 5 (Furet et al. 2009, Cai et al. 2014, Bäckhed et al. 2015, Do et al. 2019).
222 Among the top 50 genera, 14 genera (33.52%) were identified as potential pathogens, including
223 Bacteroides, Arcobacter, Treponema, Aeromonas, Acinetobacter, Prevotella, Pseudomonas,
224 Erysipelothrix, Faecalibacterium, Flavobacterium, Ruminococcus, Bifidobacterium, Laribacter,
225 and Streptococcus (Cai and Zhang 2013, Cai et al. 2014, Do et al. 2019, Oluseyi Osunmakinde et
226 al. 2019, Poopedi et al. 2023).

227 In the examination of the top 50 genera, dormitories D1 to D6 exhibited varying relative
228 abundance of potential pathogens, with 13 (40%), 12 (23%), 11 (18%), 12 (28%), 14 (45%), and
229 14 (41%) genera recognized as such, respectively (Figure 5). Notably, a substantial number of
230 these potential pathogens displayed an increased relative abundance in samples from D1, D5,
231 and D6 compared to other sites. Among the detected enteric pathogens in the top 50 genera were
232 *Arcobacter*, *Aeromonas*, and *Laribacter*, with total relative abundances of 13.61%, 2.37%,
233 5.45%, 5.64%, 20.82%, and 9.01% from D1 to D6, respectively. *Arcobacter* and *Aeromonas*
234 were identified across all six dormitories, while *Laribacter* was exclusively found in D3, D5, and
235 D6. Furthermore, an observation revealed a correlation between the relative abundance of enteric
236 pathogen and potential pathogens (Pearson Correlation = 0.842, $p = 0.018$). Additionally,
237 *Mycobacterium*, the most prevalent respiratory tract-associated pathogen, contributed from
238 0.02% to 0.15% of the total bacterial community across all six dormitories, respectively.

239 **Diversity of bacterial communities**

240 The analysis of the microbiota communities within the collected wastewater samples revealed
241 significant distinctions across all sampled locations (Figure 6). At the species level, dormitory 6

242 (D6) exhibited the highest count of exclusive taxa, totaling 1206, while the other dormitories (D1
243 to D5) displayed varying counts of exclusive taxa, ranging from 546 to 1081 species. It is
244 noteworthy that a core microbiome consisting of 286 bacterial species was consistently observed
245 across all sampled dormitories.

246 Considerable distinctions were identified in microbiota communities within the collected
247 wastewater from all sampled locations, as illustrated in Figure 6. Notably, at the species level,
248 D6 demonstrated the highest count of exclusive taxa, totaling 1206. Conversely, the other
249 dormitories (D1 to D5) exhibited diverse counts of exclusive taxa, with 1081, 764, 856, 546, and
250 755 species, respectively. Notably, a core microbiome was observed with 286 bacterial species.

251 Alpha diversity analysis was employed to assess the diversity and richness of bacterial
252 communities within the microbiome of six dormitories (Figure 7). A comprehensive comparison
253 among the six dormitories was conducted using linear regression models, with semester serving
254 as a covariate. The results showed statistically significant differences in bacterial diversity across
255 the dormitories.

256 Figure 8 depicts the clustering of beta diversity, assessed through Bray-Curtis distance metrics,
257 among the six dormitories. A permutational multivariate ANOVA model, which included
258 semester as a covariate, demonstrated significant differences in the measured β -diversity metrics
259 between groups ($p < 0.05$).

260 **Characteristics of the predominant flora in positive and negative samples**

261 **Characterization on phylum, family, and genus level**

262 The microbial composition of various sampling sites was analyzed to determine the abundance
263 of specific phyla and family, with a focus on the impact of COVID-19 status on the results.
264 These results showed that the microbial composition of different dormitory locations remains
265 consistent at the top 10 dominant phyla and family, regardless of the COVID-19 status (Figure 9,
266 10).

267 The current study, encompassing multiple dormitories, unveiled several noteworthy distinctions
268 in the relative abundances of microbial families (Figure 11). Dormitory 1 showed a distinction
269 between the families Lachnospiraceae and Streptococcaceae. Similarly, dormitory 3 exhibited
270 significant differences in the relative abundances of Arcobacteraceae, Peptostreptococcaceae,

271 Rhodocyclaceae, and V2072-189E03 between COVID-19 positive and negative samples. In
272 dormitory 4, Peptostreptococcales-Tissierellales displayed significant variation in relative
273 abundances between the two sample groups. In dormitory 5, Desulfovibrionaceae demonstrated a
274 significant difference in relative abundances based on COVID-19 status. Lastly, in dormitory 6,
275 significant differences were observed in the relative abundances of Aeromonadaceae and
276 Paludibacteraceae between COVID-19 positive and negative samples. These findings underscore
277 the potential impact of COVID-19 on specific microbial families within the microbiota of
278 different dormitories, providing valuable insights into the nuanced variations in microbial
279 composition associated with the viral infection.

280 The LEfSe analysis was employed to discern and differentiate the microbiome composition
281 between samples that tested positive and negative for COVID-19 across the six dormitories
282 (Figure S1). Interestingly, no universal biomarkers were identified across all six dormitories.
283 Instead, distinct biomarkers were exclusively found in dormitories 3, 4, and 5, suggesting unique
284 microbial signatures associated with COVID-19 status in these specific dormitory environments.

285 The present study aimed to analyze the relative abundance of potential pathogen in both SARS-
286 CoV-2 positive and negative samples of the top 50 genera (Figure 12). As depicted in Table 2,
287 the results revealed a noteworthy correlation between the relative abundance of potential
288 pathogen in positive and negative samples, with a Pearson Correlation coefficient of 0.918 ($p =$
289 0.010). Additionally, the study found a significant correlation between the relative abundance of
290 enteric pathogen and potential pathogen in positive SARS-CoV-2 samples (Pearson Correlation
291 = 0.817, $p = 0.024$), irrespective of relative abundance of potential pathogen in negative SARS-
292 CoV-2 samples.

293 **Diversity of bacterial communities**

294 Our study conducted a comprehensive analysis of samples from different locations, with a
295 specific focus on viral quantification to distinguish the differences between exclusive and shared
296 species in wastewaters tested for SARS-CoV-2. We found that samples testing positive for
297 SARS-CoV-2 demonstrated a higher diversity of taxa compared to their negative counterparts
298 (Figure 13). The analysis highlighted that exclusive species were most prominently represented
299 in positive samples for SARS-CoV-2 collected from D1 at 31.87%, while D3 exhibited the
300 lowest representation at 18.99%. Conversely, negative samples for SARS-CoV-2 were

301 associated with exclusive bacterial species in wastewater collected from D3 (18.24%), with D1
302 displaying the lowest representation at 8.49%. Despite the SARS-CoV-2 status, the analysis
303 further indicated a low representativity for exclusive bacteria found in other dormitories.

304 An observation revealed a correlation between the positive rate of sampling sites and the relative
305 abundance of exclusive species in positive samples (Pearson Correlation = 0.771, $p = 0.036$).
306 Additionally, the presence of 1033, 914, 954, 671, 1071, and 917 taxa in both SARS-CoV-2
307 positive and negative samples from D1 to D6, respectively. These findings collectively
308 contribute to our understanding of the microbial dynamics associated with SARS-CoV-2 in
309 wastewater samples across different dormitory locations.

310 The α -diversity of the microbiome across all locations exhibited a general trend of being higher
311 in negative samples compared to positive samples. Specifically, the observed species index
312 showed a significant difference in D5 and D6 ($p < 0.05$, Figure 14), as determined through linear
313 regression models that incorporated semester as a covariate. Notably, significant differences in
314 the measured β -diversity metrics were discerned in D3 and D6 between groups ($p < 0.05$ for the
315 Bray-Curtis indices, using permutational multivariate ANOVA with semester as a covariate), as
316 illustrated in Figure 15.

317 **Discussion**

318 The identified variations at the phylum, family, and genus levels across the six dormitories shed
319 light on the geographic differences in bacterial composition in this study (Figure 3, 4, and 5).
320 The analysis revealed two clusters of community types, as illustrated in Figure 3. Dormitories 2,
321 3, 1, and 4, organized by the closer relationship of bacterial phyla in each building, exhibited
322 similar dominance patterns in these phyla, while D5 and D6 exhibited comparable compositions.
323 The spatial arrangement depicted in the map (Figure 1) highlights that D1, D2, and D4 are in
324 proximity, D5 and D6 are likewise nearby, and D3 is closer to D5 and D6. This spatial variation
325 suggests a potential impact of geographic factors on the microbial composition in different
326 dormitories. This observation aligns with the study by Fierer et al. (2022) finding five clusters of
327 17 different locations, revealing no strong relationship with the distance between sampling
328 locations.

329 The significant alpha and beta diversity further underscore pronounced geographical variations
330 in microbial communities in this study, aligning with Fierer et al. (2022) findings. Their
331 emphasis on independently considering spatial variations when assessing the wastewater
332 microbiome highlights the need to account for the influence of location on microbial diversity.
333 Their research identified geographic variations in bacterial composition unrelated to sewer
334 material, sewer depth, or resident human population on the campus. They attributed these
335 variations to sample pH, with total suspended solids concentrations and sample volume playing a
336 lesser role. This pH correlation aligns with studies by Fujii et al. (2012) and Lindström et al.
337 (2005), which demonstrated the close association between pH and shifts in bacterial community
338 composition in aquatic environments. Despite the detected variations in bacterial composition
339 across dormitories in our study, the pH did not exhibit significant changes. Future research could
340 explore specific factors such as organic carbon or nutrient concentrations to better understand the
341 observed geographic variations in microbial communities.

342 The analysis of the microbial community in raw sewage yielded results consistent with previous
343 research, indicating the influence of the human gut bacterial community on the bacterial profile
344 in raw sewage. Specifically, the phyla Bacteroidota was identified as the most abundant and
345 variable across samples, aligning with findings from Arumugam et al. (2011). However, a study
346 by Cai et al. (2014) reported Firmicutes as the most dominant phylum in influent samples,

347 asserting its alignment with the human microbiome composition. The findings of may clarify this
348 discrepancy Turnbaugh et al. (2006) and Clemente et al. (2012), indicating that the gut
349 microbiota typically showcases dominance of bacteria, particularly from the Bacteroidota and
350 Firmicutes divisions. Furthermore, Huttenhower et al. (2012) revealed that gut microbiota
351 relationships were characterized by inverse associations with Bacteroidota, varying from
352 dominance in some subjects to a minority in others with a greater diversity of Firmicutes. These
353 nuanced observations highlight the intricate dynamics of the human gut microbiota and
354 underscore the pivotal roles played by Bacteroidota and Firmicutes in shaping microbial profiles
355 observed in raw sewage.

356 The primary objective of our study was to investigate potential changes in wastewater
357 microbiomes during the pandemic, considering the influence of the human gut bacterial
358 community on the bacterial profile in raw sewage. This investigation was prompted by existing
359 literature highlighting significant alterations in fecal microbiomes among individuals with
360 COVID-19 (Gu et al. 2020, Zuo et al. 2020, Yeoh et al. 2021). The significant differences in
361 bacterial composition observed across the six dormitories prompted a recommendation for
362 separate analyses of the 16S rRNA data for each dormitory. This approach aims to mitigate
363 biases that may arise when combining data from diverse dormitory settings. The prominent
364 representation of exclusive species in positive samples for SARS-CoV-2 were found across all
365 six dormitories supports the findings of Gallardo-Escárate et al. (2021). Moreover, the observed
366 trend of higher α -diversity in the microbiome of negative samples compared to positive samples
367 across some locations echoes the results reported by Gu et al. (2020) and Yeoh et al. (2021), who
368 documented a significant decrease in gut microbiota diversity and abundance in COVID-19
369 patients relative to healthy individuals.

370 The observed correlation between the relative abundance of enteric pathogen and potential
371 pathogens at sampling sites adds a significant layer of understanding in the context of COVID-
372 19, particularly highlighting the notable association between the relative abundance of enteric
373 pathogen and potential pathogen in positive SARS-CoV-2 samples. The presence of three enteric
374 genera, namely, *Arcobacter*, *Aeromonas*, and *Laribacter*, in our study, commonly residing in the
375 human intestines and potentially utilizing pathogenic mechanisms to induce gastrointestinal tract
376 infections, emphasizes the relevance of these microbes in the sewage context during the
377 pandemic. Notably, the *Aeromonas* genus ranked as the third leading cause of diarrhea after

378 *Campylobacter* and *Salmonella* [OB], exhibited a notably high abundance exclusively in D5
379 (9.09%) and D6 (6.14%) compared to other dormitories, where the abundance ranged from
380 0.66% to 1.14%. Additionally, two *Arcobacter* species, *A. butzleri*, and *A. cryaerophilus*, are
381 considered emerging pathogens posing threats to human health, adding depth to discussing
382 potential pathogenic risks in the sewage microbiome. Additionally, the genus *Laribacter*,
383 represented by the species *L. hongkongensis*, known for its associations with traveler
384 gastroenteritis and diarrhea (Beilfuss et al. 2015), further contributes to understanding the
385 microbial landscape in the context of COVID-19.

386 In the context of the ongoing discourse surrounding COVID-19, an emerging respiratory
387 infectious disease, the investigation into the presence of *Mycobacterium*, a medically significant
388 respiratory tract-associated pathogen, within sewage systems has garnered attention. Notably,
389 this scrutiny extends across six dormitories, revealing a discernibly lower total abundance of
390 *Mycobacterium* in sewage than the prevalent genera identified in the samples. The quantification
391 of *Mycobacterium* in our samples aligns with findings from previous studies, providing a basis
392 for comparative analysis. Cai and Zhang (2013) reported an overall abundance of
393 *Mycobacterium* in influent and effluent samples that remained below the threshold of 0.02%.
394 Numberger et al. (2019) the genus *Mycobacterium* was observed exclusively in October effluent
395 samples with a relative abundance of less than 0.02%. The 16S rRNA gene sequences analysis in
396 our work determined the presence of the bacterial genera but not species. These genera may
397 contain both pathogenic and non-pathogenic species. Therefore, the identification of pathogens
398 requires further study.

399 Our study did not unveil a significant universal biomarker distinguishing positive from negative
400 SARS-CoV-2 sewage samples across all sampling locations. This contrasts with the findings of
401 Gu et al. (2020), who identified five biomarkers to differentiate between COVID-19 patients and
402 healthy individuals. It is essential to note that the absence of SARS-CoV-2 detection in certain
403 patients may not necessarily signify a complete recovery of their gut microbiota. The restoration
404 of microbial communities may require an extended period, even when SARS-CoV-2 is not
405 detectable. This aligns with the observations of Zhang et al. (2023), who documented persistent
406 dysbiosis for months after the clearance of the virus. Individuals recovered from COVID-19,
407 when compared to healthy controls, exhibited reduced bacterial diversity and richness at 3
408 months. This reduction was accompanied by a lower abundance of beneficial commensals and a

409 higher abundance of opportunistic pathogens. Hence, the significant correlation in the relative
410 abundance of potential pathogen between positive and negative SARS-CoV-2 sewage samples in
411 our study may be attributed to the lingering effects of microbial dysbiosis observed in COVID-
412 19 recovery.

413 **Conclusion**

414 In conclusion, our study provides valuable insights into the raw sewage microbiota as a
415 reflection of the gut microbiota during the COVID-19 pandemic and its potential association
416 with fecal SARS-CoV-2 shedding. The observed significant differences in raw sewage microbial
417 communities across all sampling sites and the prominent representation of exclusive species in
418 positive samples for SARS-CoV-2 emphasize the potential of sewage microbiota as an indicator
419 of viral shedding. Positive samples for SARS-CoV-2 exhibited a significant reduction in
420 bacterial diversity, highlighting the impact of the virus infection on microbial composition.
421 These findings introduce a novel and targeted approach for modulating sewage microbiota,
422 specifically linked to gastrointestinal manifestations, as a strategy for monitoring and predicting
423 the presence of SARS-CoV-2 in raw sewage.

424 While our analysis did not uncover a significant universal biomarker distinguishing positive and
425 negative SARS-CoV-2 raw sewage samples, the observed noteworthy correlation in the relative
426 abundance of potential pathogens between these samples suggests a potential connection to the
427 enduring effects of microbial dysbiosis during the recovery phase of COVID-19. Moreover, the
428 identified correlation between the relative abundance of enteric pathogens and potential
429 pathogens at sampling sites adds a significant dimension to our understanding of COVID-19,
430 particularly in the context of the substantial correlation in positive SARS-CoV-2 samples. These
431 findings underscore the importance of monitoring enteric pathogens in raw wastewater
432 surveillance systems to comprehend the potential spread of COVID-19 and other infectious
433 diseases. Such insights carry crucial implications for public health monitoring and management
434 strategies.

Sampling site	Sampling Point	Gender	Student Number
D1	Direct Dispense from the valve	Male	387-504
D2	Direct Dispense from the valve	Female	469-531
D3	Direct Dispense from the valve	Mix	254-279
D4	Direct Dispense from the valve	Mix	529-637
D5	Direct Dispense from the valve	Mix	10-672
D6	Direct Dispense from the valve	Mix	580-672

599 Table 1. Demography data for D1, D2, D3, D4, D5, and D6.

600

601 Table 2. Raw wastewater data information for D1, D2, D3, D4, D5, and D6.

Dorms	pH	Positive Rate	Relative abundance of potential Pathogen		602
			Positive SARS-CoV-2 Sample	Negative SARS-CoV-2 Sample	
D1	6.71-9.08	70.00%	40.04%	40.35%	
D2	6.83-8.27	39.00%	21.80%	29.37%	
D3	6.51-8.97	52.00%	17.58%	13.88%	
D4	6.27-9.01	20.00%	30.63%	24.11%	
D5	6.38-8.95	68.00%	43.49%	45.17%	
D6	5.72-8.63	37.00%	41.30%	45.64%	

603 **Figure Legends**

604 Figure 1. Map of the sampling locations on the University of Tennessee-Knoxville campus.

605 Figure 2. Experimental design and sampling points/times for microbiome sequencing. SARS-
606 CoV-2 concentrations are indicated as yellow lines. The yellow points at 10 copies/L represent
607 negative samples. The sequencing runs are indicated as black points. The virus load was
608 estimated by qPCR in untreated wastewater from different dormitories: D1, D2, D3, D4, D5, and
609 D6. The study was conducted from Sep 2020 to Oct 2021.

610 Figure 3. Relative abundances of the top 10 dominant phyla in 6 dormitories.

611 Figure 4. Relative abundances at family levels for six dormitories.

612 Figure 5. Relative abundances of top 50 genera.

613 Figure 6. Venn diagram of exclusives and shared bacteria among the 6 dormitories.

614 Figure 7. Diversity index in 6 dormitories. The box-and-whisker plots show the mean (diamond),
615 median (middle bar), first quartile (lower bar), third quartile (upper bar), minimum observation
616 above the lowest fence (lower whisker), and maximum observation below the upper fence (upper
617 whisker) of common α -diversity metrics for each group. The P values for the comparison
618 between groups using linear regression models including semester as covariate is also shown.

619 Figure 8. The scatter plots show each participant's microbial community composition (small
620 circles) by group, as well as each group's centroid (large circles) and 95% CI ellipses. The
621 scatter plots were generated using Principal Coordinates Analysis (PCoA) ordination based on
622 common β -diversity metrics. For ease of visualization, only 2 dimensions were used. The P
623 values for the comparison between groups using permutational multivariate ANOVA models
624 including semester as covariate is also show.

625 Figure 9. Relative abundances of the top 10 dominant phyla in 6 dormitories with positive and
626 negative SARS-CoV-2 samples.

627 Figure 10. Relative abundances of the top 10 dominant family in 6 dormitories with positive and
628 negative SARS-CoV-2 samples.

629 Figure 11. Significant changes at family levels with positive and negative SARS-CoV-2 samples
630 in 6 dormitories.

631 Figure 12. Relative abundances of top 50 genera and potential pathogens with positive and
632 negative SARS-CoV-2 samples in 6 dormitories. The genera are listed from the highest relative
633 abundance (top) to the least relative abundance (bottom). The pathogens are marked with an
634 orange box around their name.

635 Figure 13. Venn diagram of exclusives and shared bacteria with positive and negative SARS-
636 CoV-2 samples in the 6 dormitories.

637 Figure 14. Diversity index with significant difference between the positive and negative SARS-
638 CoV-2 samples in 6 dormitories. The box-and-whisker plots show the mean (diamond), median
639 (middle bar), first quartile (lower bar), third quartile (upper bar), minimum observation above the
640 lowest fence (lower whisker), and maximum observation below the upper fence (upper whisker)
641 of common α -diversity metrics just for significant group. The P values for the comparison
642 between groups using linear regression models including semester as covariate is also shown.

643 Figure 15. The scatter plots show each participant's microbial community composition (small
644 circles) by D4 and D6, as well as their centroid (large circles) and 95% CI ellipses. The scatter
645 plots were generated using Principal Coordinates Analysis (PCoA) ordination based on common
646 β -diversity metrics. For ease of visualization, only 2 dimensions were used. The P values for the
647 comparison between groups using permutational multivariate ANOVA models including
648 semester as covariate is also shown.

649 Figure S1. Histograms of linear discriminant analysis (LDA) effect size (LEfSe) comparison
650 between positive and negative SARS-CoV-2 samples microbiota at the genus level in D3, D4
651 and D5. Log-level changes in LDA score are displayed on the x axis
