Abstract

Immune dysfunction is implicated in the aetiology of psychiatric, neurodevelopmental, and neurodegenerative conditions, but the issue of causality remains unclear impeding attempts to develop new interventions. We have tested evidence for causality for 735 immune response-related biomarkers on 7 neuropsychiatric conditions, using cutting-edge genomic causal inference methods (Mendelian randomization and genetic colocalization) applied to genomic data on protein and gene expression across blood and brain. We provide robust evidence of causality for 21 biomarkers, including two previously unreported (*LATS1*, and *FCN1*), confirming a role of both brain specific and systemic immune response in the pathogenesis of several neuropsychiatric conditions especially schizophrenia, Alzheimer's disease, depression, and bipolar disorder. Furthermore, 18 of the identified biomarkers are therapeutically tractable, including *ACE*, *TNFRSF17*, and *CD40*, with drugs approved or in advanced clinical trials, offering an opportunity for repurposing existing drugs for neuropsychiatric indications.

Introduction

Psychiatric, neurodevelopmental, and neurodegenerative conditions (henceforth, neuropsychiatric conditions) are among the leading causes of disability worldwide^{1,2}. These conditions are typically chronic, and affect mood, perception, cognition, and behaviour. Biological pathways contributing to these conditions are poorly understood, impeding attempts to identify effective new interventions³. For example, approximately one in three individuals with depression or schizophrenia do not respond to current medications which primarily target monoamine neurotransmitters⁴. This suggests that the current one-size-fits-all approach to treatment for these conditions may not be tenable. Therefore, identifying biological pathways underpinning neuropsychiatric conditions to help prioritise novel intervention targets remains a key priority for mental health research⁵.

Over the last two decades immune dysfunction has emerged as a promising mechanistic candidate for several neuropsychiatric conditions. For example, immune activating drugs induce depressive symptoms in hepatitis C patients⁶ and healthy volunteers⁷. Meta-analyses of case-control studies confirm atypical levels of cytokines in blood plasma and cerebrospinal fluid of individuals with schizophrenia, depression, and bipolar disorder^{8,9}. Neuroimaging with positron emission tomography shows evidence of neuroinflammation in acute depression¹⁰. Nationwide cohort studies indicate associations between autoimmune conditions, infections and neuropsychiatric conditions, such as schizophrenia^{11,12}, attention deficit hyperactivity disorder (ADHD)¹³, Alzheimer's disease¹⁴, and depression¹⁵.

However, inferring causality remains an important outstanding issue because the observed associations could be result of residual confounding or reverse causation. Mendelian randomisation (MR), a genetic causal inference method that can minimise these limitations by using genetic variants regulating levels/activity of biomarkers as proxies¹⁶⁻¹⁸, has provided some evidence for a potential causal effect of IL-6 and CRP in depression and schizophrenia^{19,20}. RCTs suggest that broad spectrum anti-inflammatory drugs improve mood and psychotic symptoms in people with depression²¹ and schizophrenia²², but recent RCTs of monoclonal antibodies targeting specific cytokine pathways have yielded null findings²³⁻²⁵. This highlights the need for strengthening causal inference using complementary techniques and data sources to inform appropriate selection of therapeutic target/agent in future trials. Furthermore, as existing studies have typically focused on a small number of immunological biomarkers, a comprehensive approach allowing investigations across hundreds of available biomarkers is necessary to obtain a more complete understanding of the role of immune dysfunction in neuropsychiatric conditions.

We examined the causal influence of 735 genetically proxied immunological biomarkers on seven major neuropsychiatric conditions (schizophrenia, bipolar disorder, depression, anxiety, ADHD, autism, and Alzheimer's disease), using cutting-edge genomic causal inference methods, MR and genetic colocalisation. We harnessed quantitative trait loci (QTL) data, capturing protein abundance (pQTL) and protein-coding gene expression (eQTL) in blood and brain, to gain mechanistic insights into potential systemic (blood) and brain-specific effects. We conducted a series of sensitivity analyses to examine the robustness of our findings, including the possibility of reverse causation. We used a systematic three-tier approach to appraise evidence of causality, by grouping biomarkers based on increasingly stringent criteria. Evidence of causality was complemented by the assessment of therapeutic tractability of identified causal biomarkers to inform future translation.

Materials & Methods

Please see Figure 1 for an overview.

Genome-wide association studies (GWAS) of immunological biomarkers

Blood plasma derived protein abundance (blood pQTLs)

We used data from the largest genomic investigation of the human plasma proteome conducted in 34,557 European ancestry participants (discovery sample) of the UK Biobank (UKB)²⁶ cohort, comprising 2,941 GWAS for 2,923 unique proteins assayed using the Olink Explore 3072 platform. Of these, we selected all proteins included in the Olink Inflammation panels I & II (n=735), which represent the most comprehensive collection of immunological biomarkers currently available (Supplementary Table 1). These 735 proteins formed the basis of our subsequent data extraction strategy from GWAS on blood and brain protein coding gene expression, and brain protein abundance. Details on the Olink Explore panels, assaying and genotyping in UKB can be found in the original publication²⁶.

Blood cell derived protein coding gene expression (blood eQTLs)

We used data from the eQTLGEN Phase I²⁷ study of blood-cell derived gene expression in a sample of 31,684 individuals. The study assessed the expression of 19,942 genes, including 561 immunological protein coding genes present in the Olink Inflammation panels I & II.

Brain tissue derived protein abundance (brain pQTLs)

To gain insights into potential brain specific effects, we additionally looked up the proteins of interest in BrainQTL, the most comprehensive investigation of the brain proteome currently available²⁸. It includes levels of 7,376 proteins in the dorsolateral prefrontal cortex (DLPFC) of 330 individuals from the Religious Orders Study (ROS) and Memory and Ageing Projects

(MAP). Brain pQTLs were available for 299 immunological proteins present in the Olink Inflammation panels I & II.

Brain tissue derived protein coding gene expression (brain eQTLs)

We used the latest meta-analysis of brain cortex gene expression (MetaBrain²⁹) conducted in 6,601 RNA-seq samples (N=2,970) and covering 18,396 genes. This includes GWAS summary data for the expression of 715 genes encoding 715 proteins of interest in the brain cortex. Although MetaBrain provided data across different brain regions, the sample sizes were relatively small, and for this reason we used data for brain cortex rather than other brain regions (e.g., hippocampus, N= 168).

Further details on the study samples, genotyping and QTL analyses from UKB, eQTLGEN, BrainQTL, and MetaBrain, can be found in the original publications^{26–29}.

GWAS of neuropsychiatric conditions

We used the latest (at the time of analysis) available GWAS summary data on seven neuropsychiatric conditions. Specifically, two neurodevelopmental: autism³⁰ (Ncases= 18,381, Ncontrols= 27,969), attention deficit hyperactivity disorder (ADHD)³¹ (Ncases= 38,691, Ncontrols= 186,843); four psychiatric: anxiety³² (Ncases= 7,016, Ncontrols= 14,745), depression³³ (Ncases= 294,322, Ncontrols= 741,438), bipolar disorder³⁴ (Ncases= 41,917, Ncontrols= 371,549), schizophrenia³⁵ (Ncases= 76,755, Ncontrols= 243,649); and one neurodegenerative condition: Alzheimer's disease³⁶ (Ncases= 71,880, Ncontrols= 383,378). Details on the study samples, phenotype definition and genotyping can be found in the original publications^{30–36}.

Two-sample Mendelian randomization (MR)

MR utilises the special properties of germline genetic variants to strengthen causal inference within observational data¹⁶. Here we implemented MR as an instrumental variables analysis using common genetic variants as instruments. The method can yield unbiased causal effect estimates under assumptions that the instruments should satisfy: (1) they must be associated with the exposure, (2) they must not be associated with any confounders of the exposure outcome associations, (3) they should operate on the outcome entirely through the exposure (i.e., no horizontal pleiotropy)³⁷.

For the present study, we performed two-sample MR, in which instrument-exposure and instrument-outcome effect sizes and standard errors were extracted from separate GWAS conducted in independent samples but representative of the same underlying population³⁸.

Instrument selection

For each exposure (immunological protein abundance, protein-coding gene expression), we used as genetic instruments common genetic variants that met the genome-wide significance threshold ($p \leq 5 \times 10^{-8}$) and were independent ($r^2 < 0.01$; 10,000 kb). We assessed the strength of each instrument by estimating their F-statistic ($F \geq 10$ indicates adequate instrument strength)³⁹. Genetic instruments with an F-statistic < 10 were excluded to minimise weak instrument bias. As instruments, we selected a total of 1,791 plasma pQTLs for 644 unique proteins; 1,474 blood cell-derived eQTLs for 501 protein coding genes; 32 DLPCF pQTLs for 32 proteins; 627 brain cortex eQTLs for 421 protein-coding genes.

For blood pQTLs (UKB) and eQTLs (eQTLGEN), both *cis* and *trans* genetic instruments were available. Genetic instruments were categorised as *cis*-acting when they were located within proximity (± 1 Mb) to the gene regulatory region, and as *trans*-acting when located outside this window. Common genetic variants acting in *cis* to the protein-encoding gene are more likely to influence mRNA expression and protein levels (thus being less pleiotropic)⁴⁰. On the other hand, *trans*-acting variants, are more likely to be pleiotropic due to their distance from the protein-encoding gene, but their inclusion can potentially increase the proportion of variance explained in the exposure, increasing the statistical power for MR analyses^{40,41}.

For brain pQTLs and eQTLs only *cis*-acting variants were used, because the BrainQTL study reported *cis*-pQTLs only. The MetaBrain study reported only the statistically significant *trans*-eQTLs, without information on the respective regions around them, rendering genetic colocalization analyses for the *trans*-acting variants impossible (details on genetic instruments used across analyses in Supplementary Tables 2-5).

Statistical Analyses

For each exposure, genetic instrument effect sizes and standard errors were extracted from each neuropsychiatric condition GWAS, and the variant-exposure, variant-outcome alleles were harmonised to ensure that effect sizes correspond to the same allele. If the exposure had only one associated variant, Wald ratio was used to generate causal effect estimates, and two-term Taylor expansion was used to approximate standard errors^{29,42}. When more than one variant were available for an exposure, inverse variance weighted (IVW)⁴³ regression was used. For IVW effect estimates, we also estimated Wald ratio estimates for each genetic instrument, to gain greater insight into the potential effects of individual variants (although these Wald ratio estimates were not prioritised in subsequent causal evidence appraisal, considering that the available multi-variant instruments for the respective IVW were likely to provide more reliable causal evidence). Details on the Wald ratio and IVW

methods can be found in Supplementary Note 1. We used the Benjamini-Hochberg method⁴⁴ to control false discovery rate (FDR) across our analyses (FDR<5%). In addition, we appraised findings using a strict Bonferroni-corrected p-value threshold 1.8×10^{-06} (0.05/27,468).

Genetic colocalisation

Colocalisation analysis can complement MR by elucidating a distinct aspect of the identified causal relationship between an exposure and an outcome⁴⁵. Specifically, colocalisation allows the assessment of the hypothesis that any identified causal effects are driven by the same causal variant influencing both exposure and outcome, instead of distinct causal variants that are in linkage disequilibrium (LD) with each other⁴⁶. In practice, the approach harnesses SNP coverage within the same specified locus for two traits of interest and tests whether the association signals for each trait at the locus are suggestive of a shared causal variant⁴⁶.

Considering that genetic instruments used in our analyses comprised either single variants (MR Wald ratio estimates) or multiple *cis* and/or *trans* variants (MR IVW estimates), we followed three distinct approaches for variant selection for colocalisation analyses to help prioritise (where possible) variants with the highest biological relevance for the exposure of interest. Specifically, when the instrument consisted of variants of which at least one was *cis*, the *cis* variant(s) was tested for colocalisation. If the instrument consisted of multiple *trans* variants, we used the *trans* variant with the smallest p-value for colocalisation. Finally, if the instrument was a single variant, the variant was tested for colocalisation regardless of whether it was *cis* or *trans*.

We extracted regions within ± 500 KB around the instrumented variant and implemented the algorithm described by Robinson *et al*⁴⁷ to perform pairwise conditional and colocalisation (PWCoCo) analysis, which assesses all conditionally independent signals in the exposure dataset region against all conditionally independent signals in the outcome data. Genotype data from mothers in the Avon Longitudinal Study of Parents and Children (ALSPAC) cohort⁴⁸ were used as the LD reference panel (N= 7,733; for ALSPAC cohort details and available genotype data see Supplementary Note 2). We ran these analyses using the default settings, as suggested by the authors in the original publications^{41,46}. Evidence of colocalisation was considered if there was an H4 posterior probability of both traits having a shared causal variant ≥ 0.8 , as proposed by the authors of the method.

Steiger filtering

We performed Steiger filtering to assess whether causal effect estimates were influenced by reverse causation⁴⁹. The method assesses whether the genetic variants proxying the

exposure explain more variance in the outcome, which, if true, suggests that the primary phenotype influenced by the variant is the outcome rather than the exposure.

Drug target prioritisation and validation

We used a three-tier system to prioritise evidence of causality for the biomarkers, and to explore their potential as drug targets. Tier A included findings that had evidence which passed the Bonferroni threshold ($\leq 1.8 \times 10^{-06}$), passed Steiger filtering, and passed colocalisation ($H4 \geq 0.8$). Tier B included findings that passed the FDR threshold ($< 5\%$), passed Steiger filtering, and passed colocalisation ($H4 \geq 0.8$). Additionally, for both Tiers A and B, the biomarker had to be proxied by a genetic instrument which was either a *cis* variant or in the case of multiple available variants, it included at least one *cis* variant. Tier C included findings where the MR estimates were from *trans* variants but fulfilled the same requirements as Tier B.

When there was Tier A, B or C evidence for a biomarker across different QTLs (eQTL & pQTL) and tissue types (brain & blood), we performed genetic colocalisation analyses using PWCoCo between the QTLs of the biomarker. This approach allowed us to investigate whether the effects on the outcome were driven by the same underlying variant across QTLs and tissue types, which increases reliability of that molecular marker's relationship with the condition⁵⁰.

We looked up potential therapeutic tractability of the identified Tier A, B or C biomarkers using small molecule, antibody binding, and/or any other treatment modality⁵¹ in the Open Targets Platform (<https://platform.opentargets.org/>). The Open Targets Platform is a freely available online resource for drug target identification and prioritisation that integrates genetic and genomic data with existing evidence on protein structure and function, and information on approved drugs, and ongoing clinical trials^{51,52}. Open Targets have categorised target tractability based on eight buckets/groups for small molecules and nine buckets/groups for antibodies (see https://github.com/chembl/tractability_pipeline_v2). In order to aid interpretation, we categorised tractability into three mutually exclusive groups, in line with previous work⁵³: Group 1. Strong druggability evidence: buckets 1, 2 & 3 for small molecules, antibodies, other modalities; Group 2. Likely or potentially druggable: buckets 4-8 for small molecules, 4 & 5 for antibodies; Group 3: Little or unknown druggability: remaining buckets. Data retrieved on 04/12/2023.

Enriched pathways and phenotypes for the identified causal biomarkers

To aid the interpretation of our findings and elucidate potential biological pathways underlying the identified causal biomarkers, we performed gene-set enrichment analyses using GeneNetwork⁵⁴. Developed by the MetaBrain consortium, GeneNetwork allows

enrichment analyses using terms available on the Gene Ontology (GO), KEGG and Reactome pathway resources, as well as the Human Phenotype Ontology (HPO) database. We used the GeneNetwork browser (analyses conducted on 12/12/2023) and entered in the analyses the biomarkers that satisfied the Tier A, B and C criteria for each neuropsychiatric condition. These analyses were conducted only for neuropsychiatric conditions with at least five identified causal biomarkers (satisfying Tier A, B, or C criteria).

Bi-directional two-sample MR

To assess reverse causation, we tested the causal effects of genetic liability to each neuropsychiatric condition on circulating immunological proteins. Genetic instruments for each condition were extracted from the respective GWAS using a p-value threshold of $\leq 5 \times 10^{-08}$ ($r^2 < 0.01$; 10,000 kb). The only exceptions were autism and anxiety, for which a p-value threshold of $\leq 5 \times 10^{-07}$ was used as there were insufficient instruments at the genome-wide significance threshold (2 and 1 instrument respectively). Details on the instruments for each neuropsychiatric condition can be found in Supplementary Table 7. Genetic instruments were then extracted from the GWAS of the immunological proteins (735 proteins)²⁶ and their alleles were harmonised. Causal effects were estimated using the IVW approach (Supplementary Note 1)⁴³. Due to the number of tests conducted (7 phenotypes*735 immunological biomarkers available in UKB) we used Bonferroni correction ($p \leq 9.7 \times 10^{-06}$).

Software

Analyses were carried out using the computational facilities of the Advanced Computing Research Centre of the University of Bristol (<http://www.bris.ac.uk/acrc/>). Blood plasma pQTL data and blood cell derived eQTL data were extracted and processed using the `gwasvcf` package version 1.0 in R (<https://github.com/MRCIEU/gwasvcf>)⁵⁵. Two-sample MR, Steiger filtering, and bi-directional MR analyses were conducted using functions from the `TwoSampleMR` R package version 0.5.6 (<https://github.com/MRCIEU/TwoSampleMR>)⁵⁶ and the `mrpipeline` R package (<https://github.com/jwr-git/mrpipeline>). The PWCoCo algorithm was implemented using the Pair-Wise Conditional analysis and Colocalisation analysis package v1.0 (<https://github.com/jwr-git/pwcoco>)⁴⁷. Pathway and phenotype enrichment analyses were conducted using the GeneNetwork browser v2.0 (<https://www.genenetwork.nl/>)⁵⁴.

Data availability

Across all analyses published summary-level data were used and no patient identifiable information was included. UKB blood pQTL data can be accessed through the portal: <http://ukb-ppp.gwas.eu>. deCODE blood pQTL data can be accessed through the platform:

<https://www.decode.com/summarydata/>. Brain pQTL data can be accessed through the Synapse portal: <https://www.synapse.org/#!Synapse:syn24172458>. Blood eQTL data can be accessed through <https://www.eqtngen.org/phase1.html>. Brain cortex eQTL data can be accessed through the MetaBrain platform: <https://www.metabrain.nl/>. GWAS data on ADHD, autism, anxiety, bipolar disorder, and schizophrenia can be accessed at: <https://pgc.unc.edu/for-researchers/download-results/>. GWAS data on depression can be accessed at: <https://ipsych.dk/en/research/downloads/>. GWAS data on Alzheimer's disease can be accessed at: https://ctg.cncr.nl/software/summary_statistics.

Code availability

A version of the code at time of publication will be available at the study-dedicated GitHub repository.

Results

Immunological drivers for neuropsychiatric conditions

In total, we found evidence for 270 potentially causal relationships corresponding to 122 unique immunological biomarkers that passed the FDR<5% (Supplementary Table 7). Among these 21 unique biomarkers met our strict Tier A, B or C criteria for causal evidence. One biomarker met the most stringent Tier A criteria (i.e., passed the stringent Bonferroni threshold: 1.8×10^{-06} , Steiger filtering, was supported by evidence of colocalisation, and the instrument consisted of *cis* variants). Twenty-one biomarkers (4 unique proteins and 17 genes) met Tier B criteria (i.e., passed the FDR threshold, Steiger filtering, were supported by evidence of colocalisation, and the instruments consisted of *cis* variants). Six effects corresponding to 4 unique proteins met Tier C criteria (genetic instrument consisted of *trans* variants and fulfilled the Tier B requirements). Schizophrenia (n=64), depression (n=33), bipolar disorder (n=31) and Alzheimer's disease (n=23) had the highest number of potentially causal immunological markers after FDR correction.

Condition specific findings

Neurodevelopmental conditions

For autism, we identified 14 potentially causal immunological biomarkers after FDR correction, two of which met Tier B/C criteria. The effect of genetically proxied expression of *ANXA1* in blood tissue (FDR= 0.002; $H_4 > 0.8$) fulfilled the Tier B criteria. Genetically proxied levels of *CEBPA* in blood fulfilled the Tier C criteria (FDR=0.01, $H_4 > 0.8$). For ADHD, 9 potentially causal immunological biomarkers were identified after FDR, of which genetically proxied expression of *GCHFR* in blood fulfilled the Tier B criteria (FDR=0.006; $H_4 > 0.8$). The results are visualised in Figures 2, 3, and detailed MR and colocalisation findings are available in Supplementary Tables 7 and 8.

Psychotic and affective disorders

We found 64 potentially causal immunological biomarkers for schizophrenia after FDR correction, of which 8 met the Tier B criteria. Specifically, we found evidence of causal effects for genetically proxied expression of *ACE* in blood (FDR=0.008; $H_4 > 0.8$) and brain cortex (FDR=0.002; $H_4 > 0.8$), genetically proxied expression of *PDIA3* (FDR= 3×10^{-05} ; $H_4 > 0.8$) in blood, genetically proxied expression of *TNFRSF17* (FDR=0.02; $H_4 > 0.8$), *CD40* (FDR=0.004; $H_4 > 0.8$), *SERPINI1* (FDR=0.05; $H_4 > 0.8$), *EVI5* (FDR=0.003, $H_4 > 0.8$) in brain cortex, and genetically proxied levels of *RABEP1* (FDR= 0.01; $H_4 > 0.8$), and *DNER* (FDR=0.008; $H_4 > 0.8$) in blood. Furthermore, a blood *trans* pQTL of *BTN2A1* (FDR= 2×10^{-15} ; $H_4 > 0.8$) and a blood *trans* pQTL of *MYOM3* (FDR=0.01, $H_4 > 0.8$) fulfilled the Tier C criteria. See Figure 4, Supplementary Tables 7 and 8.

Among the 33 potentially causal immunological biomarkers identified for depression, genetically proxied expression of *AMN* (FDR=0.03, $H_4 < 0.8$) and *EP300* (FDR= 2×10^{-06}) in blood and genetically proxied expression of *FCN1* (FDR=0.02, $H_4 > 0.8$) and *LATS1* (FDR=0.006; $H_4 > 0.8$) in the brain cortex fulfilled the Tier B criteria. In addition, genetically proxied levels of *BTN2A1* in blood (FDR= 4×10^{-06} ; $H_4 > 0.8$) fulfilled the Tier C criteria. See Figure 5, Supplementary Tables 7 and 8.

For bipolar disorder, we found 31 potentially causal biomarkers. Among these, genetically proxied levels of *CD40* (FDR=0.01; $H_4 > 0.8$) in blood and genetically proxied expression of *CD40* in the brain cortex (FDR=0.002, $H_4 > 0.8$), as well as genetically proxied expression of *DNPH1* (FDR=0.04; $H_4 > 0.8$) in blood fulfilled the Tier B criteria. Genetically proxied levels of *BTN2A1* in blood (FDR= 3×10^{-05} , $H_4 > 0.8$) fulfilled the Tier C criteria (Figure 6, Supplementary Tables 7 and 8).

No estimated causal effects of genetically proxied immunological biomarkers on anxiety surpassed the FDR threshold (<5%; Supplementary Tables 7 and 8).

Alzheimer's disease

We identified 23 potentially causal biomarkers for Alzheimer's disease. Among these, genetically proxied expression of *CR1* (FDR= 4×10^{-14} ; $H_4 > 0.8$) in the brain cortex fulfilled the Tier A criteria. In addition, genetically proxied expression of *ACE* in blood (FDR= 0.006; $H_4 > 0.8$) and brain (FDR=0.001; $H_4 > 0.8$) as well as genetically proxied levels of *APOE* in blood (FDR= 3×10^{-06} ; $H_4 > 0.8$) fulfilled the Tier B criteria. Genetically proxied levels of *KLRB1* (FDR=0.001, $H_4 > 0.8$) fulfilled the Tier C criteria (Figure 7, Supplementary Tables 7 and 8).

Drug target identification, prioritisation, and validation

In total, 18 unique biomarkers meeting our strict Tier A, B or C criteria for causal evidence are therapeutically tractable (Table 1). Notably, *ACE*, which had Tier B evidence for both

schizophrenia and Alzheimer's, has approved drugs for cardiovascular indications. *CD40* (Tier B evidence for both schizophrenia and bipolar disorder) has drugs in clinical trials. Furthermore, *TNFRSF17* (Tier B evidence for schizophrenia) has approved drugs. See Supplementary Table 9 for details on drugs approved or in clinical trials for *ACE*, *CD40* and *TNFRSF17*.

Importantly, the effects of *ACE* on schizophrenia and Alzheimer's were supported by both blood and brain eQTLs. The effects of *CD40* on bipolar disorder were supported by a blood pQTL and a brain eQTL. The brain eQTL was also causal for schizophrenia (Figure 8a). We performed colocalisation analyses between the blood and brain eQTLs for *ACE* as well as the blood pQTLs and brain eQTL for *CD40*. We found evidence suggesting that the effects of *ACE* were driven by a shared underlying variant ($H4=0.91$; Figure 8b), whereas the effects of *CD40* were driven by distinct causal variants ($H3=0.99$).

Enriched pathways and phenotypes for the identified causal biomarkers

Analyses were conducted for schizophrenia and depression, as these had enough (≥ 5) causal biomarkers satisfying the Tier A, B, or C criteria. For schizophrenia, 10 biomarkers were entered in GeneNetwork. The strongest evidence of enrichment ($p \leq 2 \times 10^{-05}$) was for reactome pathways belonging to the "metabolism of RNA" superpathway, which has been implicated in a number of neurological conditions⁵⁷. We also found strong enrichment for HPO developmental phenotypes related to fetal abnormalities including congenital malformation of the great arteries ($p=3 \times 10^{-04}$) and thickened nuchal skin fold ($p=2 \times 10^{-03}$). For depression, the strongest evidence of enrichment ($p \leq 6 \times 10^{-04}$) was for reactome pathways belonging to the "DNA repair" superpathway. This superpathway has been implicated in cancer⁵⁸. Similarly, there was strong evidence of enrichment for HPO cancer phenotypes. See Supplementary Table 10 for all enrichment findings, and Figure 9 for the five most significantly enriched pathways and phenotypes for schizophrenia and depression related biomarkers.

Evidence of reverse causation

In bidirectional MR analyses, none of the estimated causal effects of genetic liability to autism, ADHD, schizophrenia, bipolar disorder, or anxiety on levels of immunological proteins, surpassed the Bonferroni correction threshold ($p \leq 9.7 \times 10^{-06}$). However, we found evidence of causal effects of genetic liability to depression on levels of *CXCL17* ($p=5 \times 10^{-08}$), *PRSS8* ($p=7 \times 10^{-07}$) and *TNFRSF13B* ($p=8 \times 10^{-06}$). Similarly, we found that genetic liability to Alzheimer's disease had causal effects on levels of *APOA2* ($p=8 \times 10^{-09}$), *APOE* ($p=1 \times 10^{-18}$), *APOF* ($p=6 \times 10^{-12}$), *ENPP7* ($p=5 \times 10^{-07}$), *IL32* ($p=3 \times 10^{-11}$), *C1orf56* ($p=5 \times 10^{-15}$), *SMPDL3A* ($p=1 \times 10^{-07}$), *VNN1* ($p=5 \times 10^{-06}$). See Supplementary Table 11.

Discussion

Recent decades have seen limited progress in new therapeutics for neuropsychiatric conditions. Despite converging evidence implicating immune dysfunction in several neuropsychiatric conditions, the success of immunotherapy clinical trials remains elusive. One key barrier is the lack of a clear understanding of causality to inform appropriate selection of therapeutic target/agent. In this study, using cutting-edge genomic causal inference methods applied to largescale proteomic and gene expression data from blood and brain, we have assessed evidence for causality for the largest available selection of immune-response related biomarkers in relation to seven neuropsychiatric conditions. We provide robust evidence for causality for 21 immunological biomarkers confirming that both brain specific and systemic immune response contribute to pathogenesis of neuropsychiatric conditions, especially schizophrenia, Alzheimer's disease, depression, and bipolar disorder. Our work highlights the potential opportunity for repurposing existing drugs for neuropsychiatric indications.

Novel immunological biomarkers

Among putative causal biomarkers identified, two related to depression are novel. Specifically, *LATS1* (6q25.1) and *FCN1* (9q34.3) are part of a broad network of genes related to type I interferon (IFN-I) signalling^{59,60}, which is implicated in inhibition of viral infections and tumour growth suppression⁶¹. Our finding is consistent with induction of depression in hepatitis C patients following treatment with interferon alpha⁶, which binds to and activates IFN-1 receptors. The potential IFN-1 mediated tumour related effect of these genes are in line with our gene-set enrichment findings indicating significant enrichment for cancer-related phenotypes. Of note, our results correspond to *LATS1* and *FCN1* expression in brain cortex, not blood. IFN-I type signalling in brain has been implicated in brain aging, Alzheimer's disease, and multiple sclerosis^{62,63}. Therefore, the possibility of distinct tissue/organ specific effects of these genes for different conditions requires further investigation.

From causal biomarkers to drug targets for neuropsychiatric conditions

Identifying causal immunological biomarkers for neuropsychiatric conditions is a pivotal step toward developing new or repurposing existing interventions. We found that 18 of the identified biomarkers are potentially druggable. Three of the identified biomarkers, *ACE* (effects on schizophrenia & Alzheimer's), *CD40* (effects on schizophrenia & bipolar), *TNFRSF17* (effects on schizophrenia) have drugs approved or in advanced clinical trials for several indications including cardiovascular and autoimmune conditions, which provides an opportunity for drug repurposing. However, there are important considerations regarding

therapeutics development which we discuss below using our findings for schizophrenia (for which we identified the highest number of causal biomarkers) as an example.

Pathways from transcription to translation

The effects on schizophrenia for more than half of the 10 immunological biomarkers with Tier B or C evidence for causality identified were through genetic variants linked to gene expression (*TNFRSF17*, *CD40*, *SERPINI1*, *EVI5*, *ACE*, *PDIA3*) but not respective protein abundance. This could be a result of limited statistical power, as the brain pQTL dataset had a total sample size of 330 individuals. However, another potential explanation may be alternative splicing events. Alternative splicing has a central role in the pathway from transcription to translation as it results in the production of multiple proteins via different signalling pathways⁶⁴. Alternative splicing events may play an important role in schizophrenia aetiopathogenesis⁶⁵. Therefore, further studies with larger sample sizes for brain pQTL and studies using genomic data on alternative splicing (sQTLs) are required.

Tissue specific effects

Half of the identified biomarkers had effects on schizophrenia via gene expression in the brain cortex (*TNFRSF17*, *CD40*, *SERPINI1*, *EVI5*, *ACE*), suggesting that both systemic and brain-specific immunological processes are important for its aetiopathogenesis⁶⁶. Particularly for *ACE*, the identified MR effects were supported by both blood and brain cortex eQTLs and the estimates were directionally consistent across both tissues. Furthermore, colocalisation analyses suggested that the effects were likely to be driven by the same underlying variant, increasing the confidence regarding a causal role of *ACE* in schizophrenia. Now interventional studies are required to assess the therapeutic potential of targeting *ACE* for schizophrenia. Epidemiological studies suggest associations of immune-mediated respiratory and gastrointestinal conditions with schizophrenia (e.g., asthma⁶⁷, inflammatory bowel disease⁶⁸). As *ACE* is expressed primarily in lung and small intestine⁶⁹, our findings also highlight the potential relevance of the lung-brain or gut-brain axis for schizophrenia pathogenesis⁷⁰.

Effects across neuropsychiatric conditions

We found that decreased expression of *ACE* in blood and brain cortex is linked to increased risk of both schizophrenia and Alzheimer's disease. This is consistent with results from previous MR studies^{71,72}. Considering that *ACE* inhibitors are widely used for the management of hypertension, these findings require further investigation. The identified effect for Alzheimer's particularly may be a result of survival bias, considering that hypertension can lead to early mortality and therefore individuals may not live long enough to be diagnosed with the condition^{73,74}. Beyond its effects on hypertension, *ACE* inhibition in

rats leads to memory and learning impairments⁷⁵. Therefore, another possibility is that ACE inhibition does not causally influence risk to the conditions per se, but some of their common phenotypic expressions, such as cognitive decline, which is common to both schizophrenia and Alzheimer's disease. Therefore, choosing the right outcome would be as important as choosing the right drug target in future RCTs. Similarly, *CD40* expression in brain may influence risk of both schizophrenia and bipolar disorder by causally influencing psychotic symptoms, which are common to both conditions. These possibilities require further investigation.

Effects on developmental stage and progression

Our study design allowed us to investigate the causal effects of immunological biomarkers on the onset of neuropsychiatric conditions but not progression⁷⁶. Identifying actionable treatment targets can be particularly complex for conditions with neurodevelopmental origins such as schizophrenia, where pathogenic changes could take place well before the emergence of clinical symptoms⁷⁷. Our gene-set enrichment analyses show significant enrichment for early developmental phenotypes related to fetal abnormalities, suggesting that immune-mediated neurodevelopmental alterations could contribute to schizophrenia. Therefore, the question of the potential utility of the identified targets in conditions with neurodevelopmental origins remains, and requires careful consideration of conceptual, methodological, and ethical aspects.

Limitations

Our study has some methodological limitations. First, the study was conducted using GWAS data of European ancestry individuals, and therefore generalisability of our findings to other populations remains a concern. Second, although we used the largest GWAS data available the possibility of limited statistical power cannot be excluded, particularly for brain pQTL data, and the anxiety GWAS. Third, our enrichment analyses were based on a small number of causal biomarkers (10 in schizophrenia and 5 in depression), which may limit the reliability of these findings. Fourth, UKB proteomic GWAS had some sample overlap with some of the neuropsychiatric conditions, notably Alzheimer's disease (>50%), depression (34%), and bipolar disorder (14%). Sample overlap can introduce a bias toward the observational estimate⁷⁸, though this is unlikely to adversely influence hypothesis testing⁷⁹ and we observed the highest number of associations for schizophrenia which had limited overlap with the proteomic GWAS sample. Fifth, though our results are strongly suggestive of causal relationship we are unable to prove causality due to potential horizontal pleiotropy or violations of other MR assumptions such as gene-environment equivalence and consistency of treatment effects. Interventional studies are required for the ultimate proof of causal relationship, which our findings should inform.

Conclusions

Using a comprehensive analytic approach allowing the integration of genomic data on protein and gene expression across blood and brain, we identify causal effects for 21 immunological biomarkers on seven neuropsychiatric conditions. Of these, 18 are therapeutically tractable suggesting that they could be potential targets for neuropsychiatric indications. Further validation of the identified biomarkers through interventional studies and understanding the mechanisms underlying these effects are now necessary for greater insight into pathogenesis of neuropsychiatric conditions and for developing new treatments to improve the lives of people with these conditions.
