20 Abstract

21 Respiratory syncytial virus (RSV) causes a large burden of respiratory illness, globally. It has two subtypes, 22 RSV A and RSV B, but little is known regarding the predominance of these subtypes during different 23 seasons and their impact on morbidity and mortality. Using molecular methods, we quantified RSV A and 24 RSV B RNA in wastewater solids across multiple seasons and metropolitan areas to gain insight into the 25 predominance of RSV subtypes. We determined the predominant subtype for each group using the 26 proportion of RSV A to total RSV (RSV A + RSV B) in each wastewater sample ($P_{A,WW}$), and conducted a 27 comparative analysis temporally, spatially and against clinical specimens. A median $P_{A,WW}$ of 0.00 in the 28 first season and 0.58 in the second season indicated a temporal shift in the predominant subtype. Spatially, 29 while we observed dominance of the same subtype, $P_{A,WW}$ was higher in some areas ($P_{A,WW} = 0.58$ to 0.88). 30 The same subtype predominated in wastewater and clinical samples, but clinical samples showed higher 31 levels of RSV A (RSV A positivity in clinical samples = 79%, median $P_{A,WW} = 0.58$). These results suggest 32 that wastewater, alongside clinical data, holds promise for enhanced subtype surveillance.

33

34 Importance. Respiratory syncytial virus (RSV) causes a large burden of respiratory illness, globally. It has 35 two subtypes, RSV A and RSV B, but little is known regarding the predominance of these subtypes during 36 different seasons and their impact on morbidity and mortality. The study illustrates that information on 37 subtype predominance can be gleaned from wastewater. As a biological composite sample from the entire 38 contributing population, wastewater monitoring of RSV A and B can complement clinical surveillance of 39 RSV.

41 **1. Introduction**

42 Respiratory syncytial virus (RSV) is a leading cause of lower respiratory tract infection across all age 43 groups. Infants, young children, and older adults are the groups with highest risk of developing severe complications from an RSV infection¹. An RSV infection typically causes flu-like symptoms such as 44 congestion, cough and fever, and can cause bronchiolitis and pneumonia in severe cases². Each year in the 45 46 United States, RSV causes between 58,000 to 80,000 children hospitalizations, and 6,000 to 10,000 older 47 adults deaths^{3,4}. It is estimated that over 100,000 deaths of children under the age of five are attributed to RSV annually globally⁵. The true burden of RSV, however, is substantially underestimated, as such an 48 49 estimate relies on clinical testing of patients, often only including patients with more severe symptoms 50 that have access to and seek medical treatment. Most older children and adults infected with RSV are 51 excluded from these estimates, as they often only experience mild symptoms⁶. An RSV infection can also 52 be asymptomatic which also contributes to the incomplete understanding of the true burden⁷. 53 RSV is an enveloped, single stranded, negative sense RNA virus that infects humans, and has two subtypes, RSV A and RSV B⁸. The major difference between subtypes is the variation in the G 54 glycoprotein (G protein) that makes up part of the envelope⁹. The pharmaceutical interventions available 55 56 to combat RSV, such as prophylactic treatments and the recently approved vaccines, consider their difference in structure and can be cross-reactive for both subtypes $^{10-12}$. Regardless, these are only 57 58 available to a limited section of the population (e.g. individuals older than 60 years old, pregnant individuals, and infants younger than 19 months)^{13–17} and have even encountered supply issues^{18,19}. 59 60 Despite the known structural differences between RSV subtypes, the variability in subtype predominance 61 remains poorly understood. The predominant subtype during an outbreak is often not characterized, as routine surveillance of RSV typically does not include subtype monitoring²⁰. Studies show that although 62 63 co-circulation of both subtypes is expected, typically one subtype predominates in a particular season²¹.

64 Some epidemiological studies have found that seasons in which RSV A dominated started earlier in the

winter, peaked faster, and lasted longer than seasons in which RSV B dominated²², while others found no
difference between RSV A- and RSV B-dominated seasons²³. There is also a limited understanding of the
difference in virulence between subtypes. Several epidemiological studies found that RSV A was
associated with a more severe disease than RSV B, while others reported the opposite or found no
difference between them¹⁰. Understanding how subtype predominance varies could aid in discovering
potential differences in infection dynamics and virulence caused by each subtype, and could contribute to
a better understanding of RSV spread.

72 Wastewater may represent a means for understanding the variability in RSV subtype circulation.

73 Wastewater has recently emerged as a tool for monitoring the disease levels of a community contributing

to it, as concentrations of viral genetic material in wastewater have been shown to correlate with

positivity rates or clinical case rates for a number of different viruses^{24–27}. Several studies have measured

76 RSV RNA wastewater concentrations^{25,28–35}, with only three of them measuring RSV subtypes using

77 PCR-methods^{25,29,30}, and one using a sequence-based methods³². Overall, there is limited research

78 investigating the variability of RSV subtype predominance in wastewater. While some epidemiological

studies have studied variations in subtype dominance 22,23,36,37, their scope has been confined to clinical

80 samples, typically encompassing individuals with severe RSV cases. This limitation is crucial when

81 considering that the majority of individuals infected with RSV do not seek medical treatment³⁸.

82 Wastewater data bypasses biases inherently included in clinical case data and, thus, could be used to

83 understand variations in RSV subtype predominance at a broader population scale.

The goal of this study is to investigate temporal and spatial variations in the predominant RSV subtype detected in wastewater solids samples. This investigation involves measuring concentrations of both RSV A and RSV B in wastewater solids samples across multiple seasons and metropolitan areas, determining the predominant subtype for each, and conducting a comparative analysis temporally, spatially and against clinical data.

89 2. Materials and Methods

90 Study Design

98

- 91 This study was carried out at different wastewater treatment facilities across the United States (Table 1),
- 92 comprising 240 wastewater solids samples in total. The samples in this study are part of a larger
- 93 wastewater surveillance effort which measures total RSV (RSV A + RSV B) routinely in wastewater
- 94 solids³⁹, and were selected due to their high total RSV concentration (more information in SI). For each
- 95 wastewater solids sample, we measured the concentrations of both RSV A and RSV B using digital
- 96 droplet reverse transcription polymerase chain reaction (RT-PCR), and calculated the main outcome of
- 97 this study the proportion of RSV A to total RSV (P_{A,WW}):

$$P_{A,WW} = C_{RSVA} / (C_{RSVA} + C_{RSVB})$$
(1)

- 99 where C_{RSVA} is the concentration of RSV A, and C_{RSVB} is the concentration of RSV B in the sample in
- 100 units of copies/g dry weight. A proportion greater than 0.5, for example, indicates that RSV A is the
- 101 predominant subtype for that sample. Equation 1 assumes that $C_{RSV Total} = C_{RSV A} + C_{RSV B}$ in each
- sample. Shedding of RSV A and RSV B by infected individuals into the wastewater stream is assumed to
- 103 be similar due to the lack of information in the literature⁴⁰.

Table 1. Characteristics of wastewater treatment plants (WWTPs) included in the study, number of samples per
 WWTP, sample type, and the evaluations in which they were considered. Settled solids were collected directly from
 the primary clarifier ("primary clarifier"), or were collected from a raw influent sample ("influent") and allowed to
 settle for 10-15 minutes in the laboratory, and later aspirated into a falcon tube using a serological pipette.

WWTP Name	Closest Metropolitan Area	Population Served	Number of samples (Sample dates)	Sample Type	Evaluation
Palo Alto Regional Water Quality Control Plant (PA)	Santa Clara County, CA	236,000	40 (Nov 2021 - Feb 2022) 40 (Nov 2022 - Feb 2023)	Primary clarifier	Temporal, Spatial, Clinical

City of Sunnyvale Water Pollution Control Plant (SV)	Santa Clara County, CA	153,000	40 (Nov 2021 - Feb 2022) 40 (Nov 2022 - Feb 2023)	Primary clarifier	Temporal, Spatial, Clinical
City of Garland Rowlett Creek WWTP (GR)	Dallas, TX	200,000	20 (Nov 2022 - Feb 2023)	Primary clarifier	Spatial
Duck Creek WWTP (DC)	Dallas, TX	186,000	20 (Nov 2022 - Feb 2023)	Primary clarifier	Spatial
RM Clayton Water Reclamation Center (RM)	Atlanta, GA	294,660	20 (Nov 2022 - Feb 2023)	Influent	Spatial
South River Water Reclamation Center (SR)	Atlanta, GA	105,160	20 (Nov 2022 - Feb 2023)	Influent	Spatial

108 Temporal Evaluation

109 We compared P_{A,WW} between two different RSV seasons (2021-2022 and 2022-2023) using wastewater 110 solids samples collected from two WWTPs in the Santa Clara County, CA area (PA and SV). Samples 111 from Season 1 (2021-2022) were collected between November 15, 2021 and February 28, 2022, and samples from Season 2 (2022-2023) were collected between November 1, 2022, and February 28, 2023 112 113 (Table 1). The WWTPs included in this evaluation are located 20 kilometers (km) from each other and 114 have neighboring sewersheds (Figure 1). In a secondary evaluation, we compared results between these 115 WWTPs within each season to determine if samples from the WWTPs, located in close proximity (~20 116 km apart with neighboring sewersheds), yield similar results. 117 Spatial Evaluation

- 118 We compared P_{A,WW} between WWTPs located across the United States using wastewater solids samples
- 119 collected during a single RSV season (2022-2023). Wastewater solids samples were collected between
- 120 November 1, 2022 and February 28, 2023 from three United States areas: Santa Clara County, CA,
- 121 Dallas, TX, and Atlanta, GA (Table 1). These areas were selected as they are considered some of the most
- 122 populous metropolitan cities in the United States⁴¹, and each have two WWTPs with neighboring

123 sewersheds. Each metropolitan area was represented by two different WWTPs located within 20 km from each other and with neighboring sewersheds. The distances between each metropolitan area were 124 125 approximately 1,000 km, 2,000 km, and 3,000 km (Figure 1). Note that the samples from Santa Clara 126 County, CA used for this analysis were the same ones used for the temporal variation analysis described 127 above.

128

129

130 131 Figure 1. Wastewater treatment plants included in this study. Distance (km) between each of the three metropolitan 132 areas evaluated (A). Distance (km) between both WWTPs selected to represent each area and their corresponding 133 sewersheds: Santa Clara County, California (B), Dallas, Texas (C), and Atlanta, Georgia (D). WWTPs shown in 134 Figure 1B are part of all three evaluations, and WWTPs shown in Figures 1C-1D are only included in the spatial 135 evaluation. This figure was generated using QGIS; map layer from OpenStreetMap (openstreetmap/org/copyright).

136 Clinical Evaluation

137 We compared the relative proportion of RSV A identified using wastewater solids ($P_{A,WW}$) to the fraction

138 of clinical specimens collected from individuals residing within and adjacent to the sewersheds in Santa

139 Clara County, CA identified as subtype A ($F_{A, Cl}$). A total of 80 wastewater solids samples and 602 140 clinical samples were included in this evaluation (Table 1), and all were collected in the 2022-2023 RSV 141 season. The wastewater solids samples were already described as those used in the temporal evaluation 142 study. Clinical samples, collected between October 1, and December 31, 2022, were processed by the 143 Stanford Clinical Virology Laboratory (Palo Alto, CA). The laboratory receives samples from patients in 144 the Santa Clara, CA area, including patients living and/or working within the sewershed of the selected 145 WWTPs. This study was conducted with Stanford Institutional Review Board approval (protocol 62834), 146 and individual consent was waived. 147 Using the total number of clinical samples subtyped, we calculated the fraction of clinical specimens 148 identified as subtype A to the total number identified as RSV positive (F_{A, Cl}): 149 $F_{A,CL} = N_{RSV,A} / N_{RSV}$ (2) 150 151 152 where N_{RSVA} is the number of samples that were positive for RSV A, and N_{RSV} is the total number of 153 samples that were subtyped and found positive for either RSV A or RSV B, $N_{RSV} = N_{RSVA} + N_{RSVb}$. 154 $F_{A, Cl}$ was compared to $P_{A,WW}$. 155 Wastewater solids storage and freeze-thaw cycles impact assessment 156 Concentrations of pepper mild mottle virus (PMMoV) and total RSV were measured in all wastewater 157 samples immediately after they were collected with no storage (Table S1). To assess the impact of storage 158 and freeze-thaw cycles in our samples, a subset of randomly selected samples (n = 30) from Sunnyvale 159 (SV) and Palo Alto (PA) WWTPs were measured a second time for PMMoV after two freeze-thaw 160 cycles. For all samples (n = 240), the sum of RSV A and RSV B concentrations taken after two freeze-161 thaw cycles were compared against the measurements of total RSV in fresh samples.

162 Statistical Analysis

163 The median $P_{A,WW}$ of wastewater solids samples were used to compare the predominant subtype between

- 164 different groups in the statistical analyses. Non-parametric methods were employed as the wastewater
- 165 data were found to be not normally distributed (Shapiro-Wilk test, W=0.90, p=9.1 x10⁻¹²). A Kruskal-
- 166 Wallis test was used to test the null hypothesis that the P_{A,WW} was not different between groups, and a
- 167 post-hoc test (Conover-Iman test) was used to compare the P_{A,WW} between groups.
- 168 A bootstrap method was implemented to compare the F_{A, Cl} to the P_{A,WW}. A synthetic dataset consisting of
- 169 zeros and ones was generated using the total number of clinical samples subtyped (N_{RSV}) and the total
- 170 number of samples identified as subtype A ($N_{RSV A}$). Next, a collection of 1000 F_{A, Cl} was established by

171 randomly selecting, with replacement, from the synthetic list and calculating it using equation 2. From the

172 collection of 1000 F_{A, Cl}, a subset of 80 were randomly selected (equivalent to the number of wastewater

173 solids samples), and subsequently used in the Kruskal-Wallis and post-hoc analyses⁴³.

174 Lastly, three supplementary statistical analyses were performed. Two Kruskal-Wallis tests were

175 conducted to compare fresh sample measurements of RSV and pepper mild mottle virus (PMMoV) with

176 measurements from samples subjected to storage and freeze-thaw cycles to assess the impact of storage

177 on measurements in the wastewater samples. Additionally, Kendall's τ was used to test the null

178 hypothesis that total RSV (RSV A +RSV B) concentration levels and P_{A,WW} are statistically independent.

179 Two hypotheses were tested (two tests: Kruskal-Wallis test and post-hoc test) for each comparison

180 (temporal, spatial or clinical)] and three hypotheses were tested for the supplementary analysis, for a total

181 of 9 hypothesis tests. A p value of 0.006 (0.05/9) for alpha = 0.05 was used to adjust for multiple

182 comparisons (Bonferroni correction). Statistical analysis was completed using R version 4.3.0 within

183 RStudio version 2021.09.1. Wastewater solids data from this study is available at the Stanford Digital

184 Repository⁴⁴.

185 **Procedures**

186 Wastewater solids sample collection and pre-analytical processing. Wastewater solids were either grab 187 samples of settled solids from the primary clarifier, or 24-hr composite raw influent samples in which 188 solids were allowed to settle for 10-15 minutes in the laboratory, and aspirated into a falcon tube using a 189 serological pipette (Table 1). Samples were collected in sterile bottles by WWTP staff, immediately 190 stored at 4°C, delivered to the laboratory, and processed within 6 hours upon arrival. Samples were 191 dewatered by centrifugation and resuspended in DNA/RNA shield (Zymo Research, Irvine, CA) spiked 192 with bovine coronavirus vaccine (BCoV, Zoetis, Calf-Guard Cattle Vaccine) to a final concentration of 75 193 mg/ml to minimize inhibition of measurements in solids⁴⁵. Resuspended solids were homogenized and 194 centrifuged, and the supernatant was withdrawn for nucleic-acid extraction. A 0.5 g to 1 g aliquot of the 195 dewatered solids was oven dried to measure its dry weight for its use in the dimensional analysis. Detailed description of the pre-analytical processing can be found elsewhere^{46,47} including in detailed protocols on 196 197 protocols.io⁴⁷.

198 Wastewater solids RNA extraction and quantification. RNA extraction from the supernatant was 199 performed using the Chemagic Viral DNA/RNA 300 kit H96 for the Perkin Elmer Chemagic 360 (Perkin 200 Elmer, Waltham, MA). Extract was further purified using the Zymo One-Step PCR inhibitor removal 201 columns (Zymo Research, Irvine, CA). Nuclease-free water served as a negative extraction control, and 202 BCoV served as a process control. RNA extracts were immediately processed (no storage or freeze-thaw) 203 for quantification of BCoV, pepper mild mottle virus (PMMoV), and total RSV (RSV A + RSV B). 204 Additional aliquots of RNA extracts were stored at -80°C (for 0-700 days) and later subjected to two 205 freeze-thaw cycles for RSV A and RSV B measurements. Although PMMoV was already measured using 206 fresh samples, they were measured again on a subset of the stored and freeze thawed samples to assess the 207 impact of storage and freeze-thaw cycles in our samples (as described in the Study Design section).

208 RNA extracts were used as template neat using one-step RT-ddPCR Advanced Kit for Probes. RSV A 209 and RSV B were measured in a duplex assay using methods described below, and PMMoV, BCoV and 210 total RSV were measured in fresh samples using methods described in detail in other publications³⁹. 211 Primers and probes were purchased from Integrated DNA Technologies (IDT, Coralville, IA). Primers 212 and probe sequences and corresponding thermal cycling conditions were selected from published assays (Table S1)^{25,48–50}. The fluorescence signal was analyzed in the HEX channel for RSV A and the FAM 213 214 channel for RSV B (Table S1). Nuclease-free water served as a negative PCR control, and gene blocks 215 (Integrated DNA Technologies (IDT), Coralville, IA) served as positive controls for all targets. Non-216 infectious intact RSV A virus (NATRSVA-STQ, Zeptomatrix, Buffalo, NY) and non-infectious intact 217 RSV B virus (NATRSVB-STQ, Zeptomatrix, Buffalo, NY) were used as additional positive controls for 218 RSV A and RSV B, correspondingly, RNA target concentrations were measured via digital droplet RT-219 PCR (RT-ddPCR) using an Automated Droplet Generator (Bio-Rad, Hercules, CA), C1000 Touch (Bio-220 rad) thermocycler, and a QX200 Droplet Reader (Bio-Rad). Droplets were analyzed using QuantaSoft and 221 QuantaSoft Analysis Pro software. Each sample had three replicate wells. Replicate wells were merged, 222 and were required to have at least 10,000 droplets post-merger. A sample was required to have three or 223 more positive droplets across three merged wells to be scored as positive for a target. The lower detection 224 limit for the RSV A and RSV B assays was approximately 2,200 gc/g dry weight, assuming three positive 225 droplets across merged wells. A detailed description of RNA extraction of resuspended solids, 226 quantification using digital RT-ddPCR, and dimensional analysis used to convert concentrations per reaction to copies per gram of dry weight is described in detail in other publications^{46,51} and on 227 protocols.io^{52,53}. 228

Clinical samples RNA extraction and quantification. RSV-positive respiratory samples, including
 nasopharyngeal, mid-turbinate, and anterior nasal swabs in viral transport media, as well as
 bronchoalveolar lavage fluid, were extracted on the PerkinElmer Chemagic 360 instrument using the
 Chemagic viral DNA/RNA 300 Kit H96 according to the manufacturer's recommendations. Samples were

233	extracted from 300 μ L and eluted in 60 μ L. Samples were identified as positive for either RSV A or RSV
234	B using reverse-transcription qPCR (RT-qPCR). The primer and probe sequences were adapted from the
235	assay described by Wang et al. 2019 ⁵⁴ , and modified to include RNAse P primers and probe to serve as an
236	internal control (Table S2).
237	RT-qPCR was performed using Invitrogen Superscript III Platinum One-Step qRT-PCR kit (Invitrogen,
238	Carlsbad, CA) on the Bio-rad CFX-96 instrument (Bio-rad, Hercules, CA). Each 25 µL reaction
239	contained 12.5 μ L of 2X Buffer, 0.5 μ L of enzyme mix, 2 μ L of primer/probe mix, and 10 μ L of eluate.
240	Cycling conditions were as follows: hold at 52°C for 15 min, 94°C for 2 min, then 45 cycles of 94°C for
241	15 sec, 55°C for 40 sec, and 68°C for 20 sec. The fluorescence signal was analyzed in the FAM (A), Cy5
242	(B), and HEX (internal control: RNase P) channels. Thresholds were set at 3000, 1000, and 200 relative
243	fluorescence units (RFU), respectively. Any exponential amplification curve crossing either the FAM or
244	Cy5 RFU thresholds were interpreted as positive for the corresponding target. Samples were considered
245	to have failed extraction or contain inhibitory substances if RNase P did not amplify at a cycle threshold
246	value \leq 35 cycles. Samples were considered to be untypable if both RSV A and RSV B were not detected.

247 **3.** Results and Discussion

248 QA/QC.

249 Results are reported as suggested by the Environmental Microbiology Minimal Information (EMMI)

250 guidelines (Figure S3-S4)⁵⁵. Negative and positive PCR and extraction controls yielded negative and

251 positive results, respectively. Median BCoV recovery in fresh samples was around 100% (median =

252 110%, IQR = 69%), and PMMoV was stable across fresh samples (median = $1.16 \times 10^9 \text{ gc/g}$, IQR = 1.19

253 $x10^9 \text{ gc/g}$).

254 A comparison of total RSV and PMMoV concentrations reported in this study to concentrations measured

in samples with no storage and no freeze-thaw cycles showed an effect on target quantification. The

256 median ratios of RSV and PMMoV in stored to fresh samples were 1.29 (IQR = 0.62, n = 240) and 0.40

257 (IQR = 0.41, n = 30), respectively. Although the ratios show less than an order of magnitude difference 258 between measurements in fresh and stored samples, we found that fresh sample measurements for both 259 RSV and PMMoV were significantly different from measurements from those measurements in stored 260 samples (Kruskal-Wallis test, RSV comparison p=1.60 x 10^{-3} ; PMMoV comparison p= 1.69 x 10^{-10}). This 261 suggests that storage and freeze thaw might have had an impact on target measurements.

262 We found no significant correlation between concentrations of total RSV and $P_{A,WW}$ (Kendall's τ test, $\tau =$

263 0.09, z = 2.05, p=0.04). This suggests that the levels of total RSV RNA detected in wastewater are not

reflective of the predominance of a specific subtype.

265 **Overall Wastewater and Clinical Samples Results.**

All wastewater solids samples were positive for RSV A and/or RSV B, with the exception of three
samples that were non-detects for either RSV A or RSV B. Median RSV A concentration across all

- 268 wastewater samples (n = 240) was 1.31×10^4 gc/g dry weight (IQR = 4.07 \times 10^4 gc/g), and median RSV B
- 269 concentration was $1.90 \times 10^4 \text{ gc/g}$ dry weight (IQR = $2.54 \times 10^4 \text{ gc/g}$) (Figure S1). Overall median P_{A,WW}
- across all seasons and all wastewater treatment plants was 0.47 (IQR = 0.74, n = 237) (Figure S2). A total

of 593 of 602 RSV-positive clinical samples were identified as either RSV A or RSV B, and 9 samples

- 272 were considered untypable. We identified the predominant RSV subtype across multiple wastewater
- treatment plants and conducted a comparative analysis temporally, spatially, and against clinical
- specimens.

275 Temporal Evaluation.

The median $P_{A,WW}$ was significantly larger in Season 2 (2022-2023) than Season 1 (2021-2022) for both wastewater treatment plants (Palo Alto Regional Water Quality Control Plant [PA] and City of Sunnyvale Water Pollution Control Plant [SV]) (Conover-Iman test, exact p-values shown in Table S3-S4). The combined median $P_{A,WW}$ from both WWTPs for Season 1 was 0 (PA median = 0.0, IQR = 0.11, n = 40; SV median = 0.0, IQR = 0.16, n = 40), while combined median $P_{A,WW}$ for Season 2 was 0.58 (PA median

- = 0.53, IQR = 0.21, n = 40; SV median = 0.61, IQR = 0.21, n = 40) (Figure 2, Table S3-S4). The results
 confirm a change in the predominant subtype between two consecutive RSV seasons. RSV B was the
 predominant subtype during 2021-2022 with limited RSV A circulation, while in the following season
 (2022-2023), RSV A dominated with RSV B also circulating.
- 285 Our results align with epidemiological studies that have also reported shifts in subtype predominance
- 286 between seasons^{23,36,56}. Observing these results in wastewater solids, which capture contributions from
- 287 individuals with a wider spectrum of disease severity than clinical data, suggests that changes in subtype
- dominance between seasons are also observable at the population level. Tracking subtype predominance
- in wastewater each season could enhance our understanding of RSV dynamics at the population level,
- 290 particularly when subtype monitoring is not integrated into routine clinical surveillance²⁰.
- 291 Wastewater treatment plants with neighboring sewersheds (PA and SV) showed similar subtype patterns.
- 292 For both seasons studied, we found no significant difference in the median $P_{A,WW}$ between each
- 293 wastewater treatment plant (Conover-Iman test, exact p-values shown in Table S3-S4). This result
- suggests that if resources are constrained, monitoring one geographic area may provide insights into
- subtype predominance dynamics in adjacent areas.

Figure 2. Proportion of RSV A to total RSV ($P_{A,WW}$) for the temporal evaluation comparing Palo Alto Regional Water Quality Control Plant (PA) and City of Sunnyvale Water Pollution Control Plant (SV) for Season 1 (2021-2022) and Season 2 (2022-2023). Each box plot is made up of the 25th quartile, median, and 75th quartile proportion of RSV A total RSV for each WWTP per season, and length of each whisker 1.5 times the interquartile range(IQR). Boxplots are overlaid with jittered data points from each group.*= Statistically Significant per post-hoc (Conover–Iman) test with a significance level p= 0.006 accounting for the Bonferroni Correction.

303 Spatial Evaluation.

- 304 Across the three metropolitan areas evaluated during the 2022-2023 season, RSV subtype A
- 305 predominated (Santa Clara County, CA median = 0.58, IQR = 0.26, n = 80; Dallas, TX median = 0.88,
- IQR = 0.34, n = 39; Atlanta, GA median = 0.68, IQR = 0.74, n = 38) (Figure 3). However, the levels at
- 307 which RSV A was found varied. We found that P_{A,WW} was significantly higher in Dallas, TX than in Santa
- 308 Clara County, CA and Atlanta, GA, but was similar between Santa Clara County, CA and Atlanta, GA
- 309 (Conover-Iman test, exact p-values shown in Table S3-S4).
- 310 Our results, showing dominance of the same RSV subtype across the three metropolitan areas, are
- 311 consistent with epidemiological studies using clinical samples that have found geographic clustering of

viral lineages in large geographical areas (e.g., Australian states)³⁶, and that have concluded that variants
are restricted to a local level (i.e., country-wide rather than global)³⁷.

314 Despite sharing a predominant subtype, we observed a lack of association between geographic proximity

and levels of one specific subtype. The areas closest to each other (~1,000 km and ~2,000 km apart) were

316 found to have different $P_{A,WW}$, and the two areas with furthest distance from each other (~3,000 km apart)

317 were found to follow similar subtype patterns. Factors beyond physical distance — such as

318 environmental, demographic and transit accessibility factors — may play a crucial role in shaping the

319 levels of subtype dominance. For instance, local climate, minimum temperature, precipitation, and

320 population density have been shown to influence RSV dynamics including onset and timing of peak

321 infectivity^{57,58}, and urban public transportation systems have been shown to facilitate transmission of

322 respiratory illnesses⁵⁹. The three metropolitan areas included in this study experience similar temperate

323 climates with mild winters, but experience different levels of precipitation^{60,61}, have different population

densities⁶², and have varying levels of public transportation usage⁶³ which could have contributed to the

325 difference in $P_{A,WW}$.

Figure 3. Proportion of RSV A to total RSV ($P_{A,WW}$) for the spatial evaluation comparing wastewater solids samples from Santa Clara County, CA, Dallas, TX, and Atlanta for Season 2 (2022-2023). Each box plot is made up of the 25th quartile, median, and 75th quartile proportion of RSV A total RSV for two WWTPs per area, and length of each whisker 1.5 times the interquartile range(IQR). Boxplots are overlaid with jittered data points from each group.*= Statistically Significant per post-hoc (Conover–Iman) test with a significance level p= 0.006 accounting for the Bonferroni Correction.

333 Clinical Evaluation.

334 During the 2022-2023 season, 79% (470/593) of the clinical RSV-positive samples were subtyped as

335 RSV A (bootstrapping $F_{A, Cl}$ median = 0.79, IQR = 0.03, n = 80). Wastewater solids samples had a median

- 336 $P_{A,WW}$ of 0.58 (IQR = 0.26, n = 80). Therefore, subtype A dominated in both sample types. However, we
- found the levels of subtype A in clinical samples was significantly higher than in wastewater solids
- 338 samples (Conover-Iman test, $p=3.88 \times 10^{-26}$) (Table S3-S4).
- 339 To our knowledge, this is the first study to confirm that wastewater data reflects the same RSV subtype
- 340 dominance as clinical data. Our results highlight the validity of wastewater as an appropriate
- 341 epidemiological tool to monitor subtype predominance within a community. The discrepancies in specific
- 342 subtype levels observed between clinical and wastewater solids samples may stem from the broader
- 343 representation in wastewater, encompassing mild and asymptomatic cases. Clinical samples, in contrast,

might have a larger representation of pediatric infections when considering that children under two are
 less likely contributors to wastewater solids samples. Wastewater data, in combination with clinical data,

could help to provide a comprehensive understanding of the RSV burden.

347 Limitations and Future Work.

348 This study has several limitations. First, this study was conducted during atypical RSV periods due to the 349 COVID-19 pandemic and the implementation of nonpharmaceutical interventions. While both seasons 350 began earlier in the year than prepandemic levels, the 2021-2022 season lasted longer, and the 2022-2023 351 season exhibited a higher peak number of cases compared to typical RSV epidemics⁶⁴. Another limitation 352 is that we were not able to account for any potential impact of the newly approved vaccines or 353 prophylactic antibody on RSV dynamics, as they were approved for public usage in certain populations subsequent to the 2022-2023 season^{14,16}. Additionally, the temporal evaluation was conducted using data 354 355 from only two RSV seasons, and the spatial evaluation was limited to three metropolitan areas. A wider 356 range of seasons across a more extensive array of metropolitan areas would enhance our conclusions 357 regarding spatial-temporal subtype predominance. Due to the nature of this retrospective study, another 358 limitation is that wastewater solids samples used to detect RSV subtypes were subjected to storage and 359 freeze thaw which might have had an impact on target measurements. An additional limitation is that the 360 clinical data might also include individuals residing outside the sewershed from the selected WWTPs 361 which could potentially bias the clinical evaluation results. Lastly, although wastewater captures a larger 362 percent of the population infected with RSV than clinical data, it is likely that children under the age of 363 two contribute minimally to wastewater solids samples; therefore, wastewater provides a comprehensive 364 yet incomplete picture of the burden.

365 Despite the aforementioned limitations, the findings in this study suggest that future work regarding RSV
 366 subtype variability in several areas is warranted. Future studies could conduct finer-scale temporal
 367 evaluations of subtype predominance variability in wastewater, examining potential differences in onset

368 and peak timings between seasons dominated by different subtypes. Spatial evaluations could consider 369 differences in environmental and/or demographic conditions between areas studied that might influence 370 subtype predominance such as climate, precipitation, population density, public transportation usage and 371 other factors. Investigations comparing subtype predominance in wastewater to clinical data could include 372 patient characteristics, distinguishing between pediatric and non-pediatric cases, as well as in-patient vs 373 outpatient cases, to determine the different factors that affect subtype dominance in each signal. Lastly, 374 wastewater monitoring could be integrated into long-term epidemiological studies investigating 375 variability, infection dynamics, virulence characteristics of RSV subtypes, or be used to investigate the 376 effectiveness of the newly approved vaccines at the population level. Wastewater could provide a vital 377 comprehensive picture of cases ranging in severity, and combined with clinical data, could be robust tools 378 to better understand these complex issues.

379 4. Conclusions

380 This study presents an analysis of RSV subtypes in wastewater across multiple seasons, metropolitan 381 areas, and in comparison to clinical specimens. We found that the predominant RSV subtype varied 382 temporally, but remained consistent spatially and between wastewater and clinical samples. Temporal 383 evaluation revealed a shift in the predominant subtype between consecutive seasons. Spatially, while we 384 observed dominance of the same subtype across metropolitan areas, the levels of one specific subtype 385 varied, indicating that factors beyond geographic proximity may influence levels of subtype prevalence. 386 When comparing wastewater samples to clinical samples, we found that the same subtype dominated in 387 both sample types, but presence of a specific subtype was higher in clinical samples. Our findings suggest 388 that wastewater, in conjunction with clinical data, holds promise for enhanced subtype surveillance, 389 understanding subtype dynamics, and controlling RSV spread. Future research in RSV subtype 390 predominance can investigate finer-scale temporal variations, study characteristics beyond physical 391 distance, incorporate patient characteristics into clinical-wastewater comparisons, and implement 392 wastewater monitoring into epidemiological studies.

393 5. Supporting Material

394 Additional details about the methods and results used in this study (Tables S1-S4 and Figures S1-S4).
