Data Availability Statement

Data will be provided on reasonable request from the corresponding author.

Abstract

Background

Since the efficacy and safety of endovascular thrombectomy (EVT) in patients with acute ischemic stroke with a large infarct area is still inconclusive, we sought to compare functional and neurological outcomes with the use of endovascular thrombectomy versus medical care alone.

Methods

We searched MEDLINE (via PubMed), Embase, Cochrane Library, ClinicalTrials.gov, and the International Clinical Trials Registry Platform (ICTRP) to retrieve all the relevant randomized controlled trials (RCTs) on this topic. Review manager (RevMan) was used to perform meta-analyses using a random-effect model. Dichotomous outcomes were pooled using risk ratios (RR) with 95% confidence intervals (CIs).

Results

Our meta-analysis included 6 RCTs with a total of 1665 patients. Most studies included patients with an ASPECTS score of 3-5. Our results demonstrate that endovascular thrombectomy significantly increased the rates of functional independence ($mRS \leq 2$) (RR, 2.49; 95% CI, 1.89-3.29) and moderate neurological outcome ($mRS \leq 3$) (RR, 1.90; 95% CI, 1.50-2.40) at 90 days. The benefit of EVT for these outcomes remained the same at 1-year follow-up.. Endovascular thrombectomy was associated with increased rates of early neurological improvement (RR, 2.22; 95% CI, 1.53-3.22), excellent neurological recovery ($mRS \leq 1$) (RR, 1.75; 95% CI, 1.02-3.03), and decreased rate of poor neurological recovery

(mRS 4-6) (RR, 0.81; 95% CI, 0.76-0.86). No significant difference was found between the two groups regarding all-cause mortality (RR, 0.86; 95% CI, 0.72-1.02), decompressive craniectomy (RR, 1.32; 95% CI, 0.89-1.94), and the incidence of serious adverse effects (RR, 1.39; 95% CI, 0.83-2.32) between the two groups. Endovascular thrombectomy significantly increased the rates of any intracranial hemorrhage (RR, 1.94; 95% CI, 1.48-2.53) and symptomatic intracranial hemorrhage (RR, 1.73; 95% CI, 1.11-2.69).

Conclusion

Endovascular thrombectomy (EVT) significantly improves neurological and functional outcomes in patients with acute ischemic stroke with a large infarct area (ASPECTS 3-5) compared to medical therapy alone, with an increased risk of symptomatic intracranial hemorrhage.

Keywords: meta-analysis; endovascular thrombectomy; large ischemic stroke; mechanical thrombectomy

Introduction

Over the last decade, studies have showcased a clear benefit of endovascular thrombectomy (EVT) over medical therapy (MEDT) alone in managing acute ischemic stroke (AIS) due to large vessel occlusion (LVO) (1). Therefore, current guidelines advocate for EVT in individuals presenting with Alberta Stroke Program Early CT Score (ASPECTS) ≥ 6 (range: 0-10, inverse relation with the infarction size) (2,3). However, patients with large-core infarct (LCI) – defined as ischemic volume greater than 50 mL or 70 mL with cerebral perfusion $< 30\%$, or ASPECTS < 6 – were not considered candidates for EVT due to the potential risk of reperfusion injury, hemorrhagic conversion, and perception of negligible advantage as a notable portion of brain tissue being already infarcted in these patients (4).

The management of this patient population, constituting one-fourth of LVO cases, revolved mainly around curtailing secondary insult from raised intracranial pressure and cerebral edema in the background of large ischemic volume. Frequently applied approaches included but not limited to optimizing cerebral blood flow and diligent blood pressure monitoring, bolstering collateral circulation in at-risk tissue, seizure identification, and management, and preventing recurrent recurrence (4,5). In brief, the LCI stroke population remained underrepresented for a long time in studies assessing the benefits of EVT over MEDT.

RESCUE-Japan LIMIT trial by Yoshimura et al. was the first randomized controlled trial (RCT) to evaluate the efficacy and safety of EVT in this subset population (6). The trial reported favorable outcomes in the EVT arm compared to MEDT alone and paved the way for further studies. As a result, five more RCTs have been conducted to date (5,7–10). Several meta-analyses meticulously combine the results of published trials in the literature (1,11–13). However, these reviews do not include all trials as results from some trials, such as LASTE, were reported after publication. They do not include all trials as results from some trials, such as LASTE, were reported after publication (10). Furthermore, we also incorporated the 90-day results from the TESLA and SELECT2 trials, which helped assess the long-term efficacy of EVT (14,15).

This updated meta-analysis aims to comprehensively synthesize the latest results from all trials, offering higher-level insight into the efficacy and safety of EVT and MEDT vs. MEDT alone.

Materials and methods

This systematic review and meta-analysis followed the guidelines outlined in the Cochrane Handbook for Systematic Reviews (16) and reported according to the Preferred Reporting Items for Systematic Reviews and Meta-Analysis (PRISMA) statement (17). Ethical approval

was not required for this study. The protocol was registered with the International Prospective Register of Systematic Reviews (PROSPERO) under the identifier CRD42023492739.

Data Sources and Search Strategy

Electronic searches were conducted using various online databases from inception to December 2023. These included the Cochrane Central Register of Controlled Trials (CENTRAL), MEDLINE (via PubMed), Embase (via Ovid), ClinicalTrials.gov, and the International Clinical Trials Registry Platform (ICTRP). No geographical or language restrictions were applied during the search process. Additionally, the reference lists of the included studies and similar systematic reviews were screened to retrieve relevant articles. The detailed search strategy for MEDLINE is given in Supplementary Table 1.

Eligibility Criteria

The inclusion criteria for the study were as follows: (1) study design: randomized controlled trials (RCT); (2) population: individuals with large ischemic stroke, defined as a large vessel occlusion with an ASPECTS score of 3 to 5; (3) intervention: endovascular thrombectomy plus medical therapy; (4) control group: medical therapy alone; and (5) outcome: reporting at least 1 outcome of interest.

The exclusion criteria were as follows: (1) study designs other than RCTs, such as quasi-randomized trials, reviews, and observational studies; (2) studies conducted on animals; and (3) studies evaluating outcomes in patients who have undergone ischemic stroke with a small infarct area.

Study Selection

The literature search results were imported into Zotero, a software management tool for screening articles. After de-duplication, two authors independently conducted the initial phase of screening titles and abstracts. The full-text screening was performed on the remaining studies, and a final selection was made based on adherence to our eligibility criteria. A third author settled any disagreements regarding the selection of the studies. The selection process is presented in the form of a PRISMA flow chart.

Data collection process and data items

Two review authors extracted data from the included studies into a pre-piloted structured Excel spreadsheet. Relevant data items were extracted, including study characteristics (country, study design, total participants, intervention, main inclusion criteria, ASPECTS score, study follow-up duration, and baseline imaging), baseline characteristics (age, sex, number of patients in each group, NIHSS score, infarct core volume, ASPECTS score, and occlusion location), primary outcomes (functional Independence (mRS ≤ 2) and moderate neurological outcome (mRS ≤ 3)), and secondary outcomes (all-cause mortality at 90 days, early neurological improvement, excellent neurological recovery (mRS ≤ 1), poor neurological recovery (mRS $\leq 4-6$), any intracranial hemorrhage, symptomatic intracranial hemorrhage, decompressive craniectomy, and >1 SAE (serious adverse effect)).

Risk of Bias and Quality Assessment

The risk of bias was assessed in the included studies using the revised Cochrane Risk of Bias Tool for randomized controlled trials (RoB 2.0) (18). The domains that were evaluated included (1) risk of bias resulting from the randomization process, (2) risk of bias due to deviation from the intended intervention, (3) risk of bias due to missing outcome data, (4) risk of bias in measuring the outcome, (5) risk of bias in selecting the reported results, and (6)

other bias. For clarification, "low" indicates a low risk of bias, and "high" indicates a high risk of bias. If the study lacked information or had uncertainty over the potential for bias, the item was judged as "unclear." Any disagreements in evaluating the risk of bias were resolved through discussion to reach a consensus between the two authors. A third author served as an arbiter if needed.

Statistical Analysis

Statistical analyses were performed using the Review Manager software (version 5.3; RevMan v5.3). The DerSimonian-Laird variance estimator was used to apply a random effects model. Dichotomous outcomes were pooled using risk ratios (RR) with 95% confidence intervals (CIs). Heterogeneity was assessed using the chi-square and I-square tests. The alpha level for the chi-square test was set at 0.1, as determined by the Cochrane Handbook, and was considered to suggest statistically significant heterogeneity.

Results

Search Results and Study Selection

A total of 2077 studies were identified from various databases. Following deduplication and initial screening, 55 full-length articles were assessed for eligibility. A total of 6 RCTs were included in our systematic review and meta-analysis. The detailed screening process is illustrated in the PRISMA flowchart (Figure 1)

Characteristics of Included Studies

We included 6 RCTs in our meta-analysis (5–10). A total of 1665 patients were included, of which 945 received endovascular thrombectomy with medical therapy, and 942 received medical therapy alone. All studies except LASTE included patients having a pre-stroke mRS score of 0–1 and a stroke with a large ischemic-core volume, defined as an ASPECT score of

3 to 5. The follow-up duration was 90 days in all the studies. Reports of two studies reporting outcomes at 1-year follow-up have also been included in this systematic review. Detailed characteristics of included studies are given in Table 1

Risk of Bias and Quality of Evidence

We used Cochrane RoB2 to evaluate the risk of bias of included studies. All six RCTs were deemed to have a low risk of bias [Figure 2].

Primary Outcomes

Functional Independence (mRS \leq 2)

Our meta-analysis of 6 trials indicates that endovascular thrombectomy significantly increased the rate of functional Independence (mRS \leq 2) at 90 days (RR, 2.49; 95% CI, 1.89-3.29; Figure 3). The heterogeneity reported between studies for this outcome was low ($I^2 = 7\%$). A meta-analysis of only two trials found endovascular thrombectomy to significantly increase the rate of functional Independence (mRS \leq 2) at 1 year (RR, 3.84; 95% CI, 2.35 – 6.29; Supplementary Figure 1) with minimal heterogeneity ($I^2 = 0\%$)

Moderate Neurological Outcome (mRS \leq 3)

Endovascular thrombectomy significantly increased the rate of independent ambulation (also known as moderate neurological outcome) compared to medical therapy (RR, 1.90; 95% CI, 1.50-2.40; Figure 4). Statistical heterogeneity was found to be moderate ($I^2 = 51\%$).

A meta-analysis of only two trials found endovascular thrombectomy to significantly increase the rate of independent ambulation (mRS \leq 3) at 1 year (RR, 2.08; 95% CI, 1.56 – 2.77; Supplementary Figure 2) with minimal heterogeneity ($I^2 = 0\%$).

Secondary Outcomes

Early Neurological Improvement

Our meta-analysis found that endovascular thrombectomy increased the rate of early neurological improvement (RR, 2.22; 95% CI, 1.53-3.22; Supplementary Figure 3) with minimal statistical heterogeneity ($I^2 = 17\%$).

Excellent Neurological recovery (mRS ≤ 1)

Endovascular thrombectomy was associated with an improved rate of excellent neurological recovery (mRS ≤ 1) as compared to medical therapy alone (RR, 1.75; 95% CI, 1.02-3.03; Supplementary Figure 4). The inter-study statistical heterogeneity was estimated to be low ($I^2 = 36\%$).

Poor Neurological Recovery (mRS 4-6)

Endovascular thrombectomy was associated with a significantly decreased rate of poor neurological recovery (mRS 4-6) as compared to medical therapy alone (RR, 0.81; 95% CI, 0.76-0.86; Supplementary Figure 5) with minimal statistical heterogeneity ($I^2 = 0\%$).

All-cause Mortality

No statistically significant difference was found between the two groups regarding all-cause mortality (RR, 0.86; 95% CI, 0.72-1.02; Supplementary Figure 6) with moderate statistical heterogeneity ($I^2 = 45\%$).

Symptomatic Intracranial Hemorrhage

Endovascular thrombectomy significantly increased the rate of symptomatic intracranial hemorrhage (RR, 1.73; 95% CI, 1.11-2.69; Supplementary Figure 7). Statistical heterogeneity was found to be minimal ($I^2 = 0\%$).

Decompressive craniectomy

No statistically significant difference was found between the two groups regarding decompressive craniectomy (RR, 1.32; 95% CI, 0.89-1.94; Supplementary Figure 8).

Statistical heterogeneity between studies was low ($I^2 = 41\%$).

Any intracranial hemorrhage

Endovascular thrombectomy significantly increased the rate of any intracranial hemorrhage (RR, 1.94; 95% CI, 1.48-2.53; Supplementary Figure 9). The estimated heterogeneity was substantial ($I^2 = 72\%$).

>1 SAE

Our meta-analysis showed no significant difference in rates of serious adverse effects between the two groups (RR, 1.39; 95% CI, 0.83-2.32; Supplementary Figure 10) with substantial heterogeneity ($I^2 = 93\%$).

Discussion

Our meta-analysis included six randomized controlled trials (RCTs), which showed that endovascular thrombectomy (EVT) in combination with medical therapy significantly improves outcomes for patients suffering from large vessel occlusion strokes. EVT increases the likelihood of primary outcomes, i.e., functional independence and moderate neurological outcomes at 90 days, with maintenance of these benefits at 1-year follow-up. Moreover, our analysis indicates that EVT leads to higher rates of early neurological improvement and excellent neurological recovery while reducing the incidence of poor neurological recovery. Despite these benefits, the procedure is associated with an increased risk of symptomatic intracranial hemorrhage; however, it does not significantly affect all-cause mortality or the need for a decompressive craniotomy.

AHA/ASA recommends EVT for patients with an ASPECT score greater than 5. In contrast, those with ASPECT scores below 5 have a poor prognosis and are at risk of symptomatic intracranial hemorrhage (19). Our findings align with the HERMES meta-analysis, suggesting that a lower ASPECT score could still warrant consideration, especially in younger patients (20). There was considerable heterogeneity regarding inclusion criteria among the six trials. The trials in our study had diverse ASPECT scores and ischemic core volumes as their criteria for inclusion, with the majority having ASPECT 3-5. The LASTE trial (10) also included patients with ASPECT scores ranging from 0 to 2. The trials SELECT-2 (5) and ANGEL-ASPECT (7) have incorporated ischemic regions quantified in volumes determined using imaging with more than 50 ml and 70–100 ml, respectively. Our analysis indicated that EVT enhances functional outcomes in post-stroke patients across a wide range of stroke severities, mRS scores, and ischemic volumes.

Our results are consistent with the previous two meta-analyses (21,22), except for the incidence of symptomatic intracranial hemorrhage (sICH); our analysis revealed an increased risk of sICH. This difference can be attributed to including two latest trials, TESLA(8) and LASTE (10). The LASTE trial carried significant weight in the meta-analysis and indicated a heightened risk of sICH, likely accounting for this deviation from earlier reviews.

Considerable heterogeneity was observed in the time elapsed from stroke onset to intervention across all trials. Most trials have set 24 hours as the maximum time for intervention from the time of symptom onset. Notably, the TENSION trial included patients within 12 hours of stroke onset, while the RESCUE Japan LIMIT and LASTE trials included patients who presented within 6 hours of stroke onset. The onset-to-intervention time window is crucial for the patients because the odds of independent ambulation and discharge to home

are reduced by 8% and 10% for every 60 minutes of onset-to-intervention time extended in the early window (within 6 hours). In the late window (6–24 hours), the chances of independent ambulation and discharge to home are 1% and 2% lower for every 60-minute delay in treatment.

Hence, early treatment is more favorable for patient recovery and is associated with lower 90-day mortality (23).

ASPECT scores determine the areas with ischemia but do not precisely measure infarction volume or extent. While diagnostic imaging like CT and MRI perfusion can determine the volume of infarcted tissue, it cannot ultimately determine the actual tissue viability.

Nevertheless, EVT reperfusion of the ischemic area can be beneficial. The increased blood supply could alleviate edema and remove toxins, leading to neurological recovery regardless of the ischemia area/ volume (24,25). Further studies or imaging techniques are required to understand the pathophysiological changes following reperfusion.

The primary strength of our meta-analysis lies in the comprehensive selection of the latest randomized controlled trials (RCTs) and the meticulous adherence to appropriate inclusion and exclusion criteria. Furthermore, we also incorporated the 90-day results from the TESLA and SELECT2 trials (14,15) for our primary outcomes, aiding in the evaluation of the long-term effects of EVT. The inclusion of the latest RCTs with large sample sizes increased the statistical power of our meta-analysis.

However, there are a few limitations to the articles that we included. Firstly, all the studies were of an open-label design, which may introduce bias due to lack of blinding, potentially influencing the outcomes through placebo effects or altered reporting symptoms. Secondly,

early termination of studies or trials might have overestimated the results as premature conclusions drawn from incomplete data may inflate the perceived benefits of the treatment. Third, regional specificities observed in studies conducted exclusively in Japan and China, such as different standard doses of rt-PA and varying prevalences of intracranial artery stenosis, respectively, could limit our findings' generalizability to a global population. Additionally, exclusion criteria for patients older than or equal to 80 years used by Huo et al. (7) might affect generalizability since it excluded a significant portion of the stroke population from the results.

In addition, two studies focusing on a specific imaging technique (non-contrast CT) raised concerns about the generalizability of their results to settings where other imaging methods are commonly used (8,14). Furthermore, patient enrollment criteria based on the ASPECTS score led to the exclusion of patients with a score higher than 5 and with an infarct core volume of 70–100 ml in ANGEL-ASPECT And SELECT2 trials, resulting in potential bias in patient selection that may affect treatment outcomes. Additionally, Yoshimura et al. failed to document the causes of deaths during the study, raising questions about safety and associated risks related to the intervention (6).

Limitations in the review process include a small sample size, which might have reduced statistical power, reducing the ability to detect real differences between groups or variables being studied, resulting in false negative results and an increased risk of random error influencing the analysis. Additionally, there is moderate heterogeneity across certain aspects of our analysis, stemming from variations in study designs, patient populations, treatment protocols, or outcome measures among the included trials. This variation complicates the interpretation of specific sub-populations. Furthermore, sub-group analyses could not be

performed based on patient age, stroke severity, or the presence of comorbid conditions, without which our conclusion may overlook significant variations in treatment efficacy. Lastly, individual patient data analysis was not performed due to insufficient data.

Future research should aim to standardize inclusion criteria, particularly regarding ASPECT scores and ischemic core volumes, to enhance and improve comparability among trials and robustness of meta-analysis. Investigating the impact of different inclusion criteria on treatment outcomes could provide valuable insights into patient selection. Long-term follow-up data from trials such as TESLA and SELECT-2 contribute to understanding EVT's sustained benefits. Further studies with extended follow-up periods could elucidate EVT's durability and identify potential late complications or recurrence risks. Future trials should prioritize blinding to minimize possible bias introduced by open-label designs.

Additionally, efforts to prevent premature study termination and ensure complete data collection are essential to avoid overestimating treatment effects. Studies should strive for diverse patient populations and global representation to enhance the generalizability of findings. Addressing regional specificities, such as variations in treatment protocols and patient demographics, can facilitate more comprehensive recommendations applicable to diverse healthcare settings.

Overall, while the current evidence supports the efficacy of EVT in ischemic stroke with large infarct areas, ongoing research is essential to optimize patient selection, treatment protocols, and long-term management strategies, ensuring equitable access to effective interventions globally.

Conclusion

Our meta-analysis demonstrates that endovascular thrombectomy (EVT) significantly improves neurological and functional outcomes in patients with acute ischemic stroke with a large infarct area (ASPECTS 3-5) compared to medical therapy alone. However, our findings also indicate a higher risk of symptomatic intracranial hemorrhage associated with EVT. Further studies are needed to evaluate the efficacy of EVT in patients with low ASPECTS scores (1-3) and confirm the safety profile of EVT.

Figure 2. Quality assessment of randomized controlled trials (RCTs).

Figure 3. Forest plot of functional independence (mRS \leq 2) at 90 days follow-up.

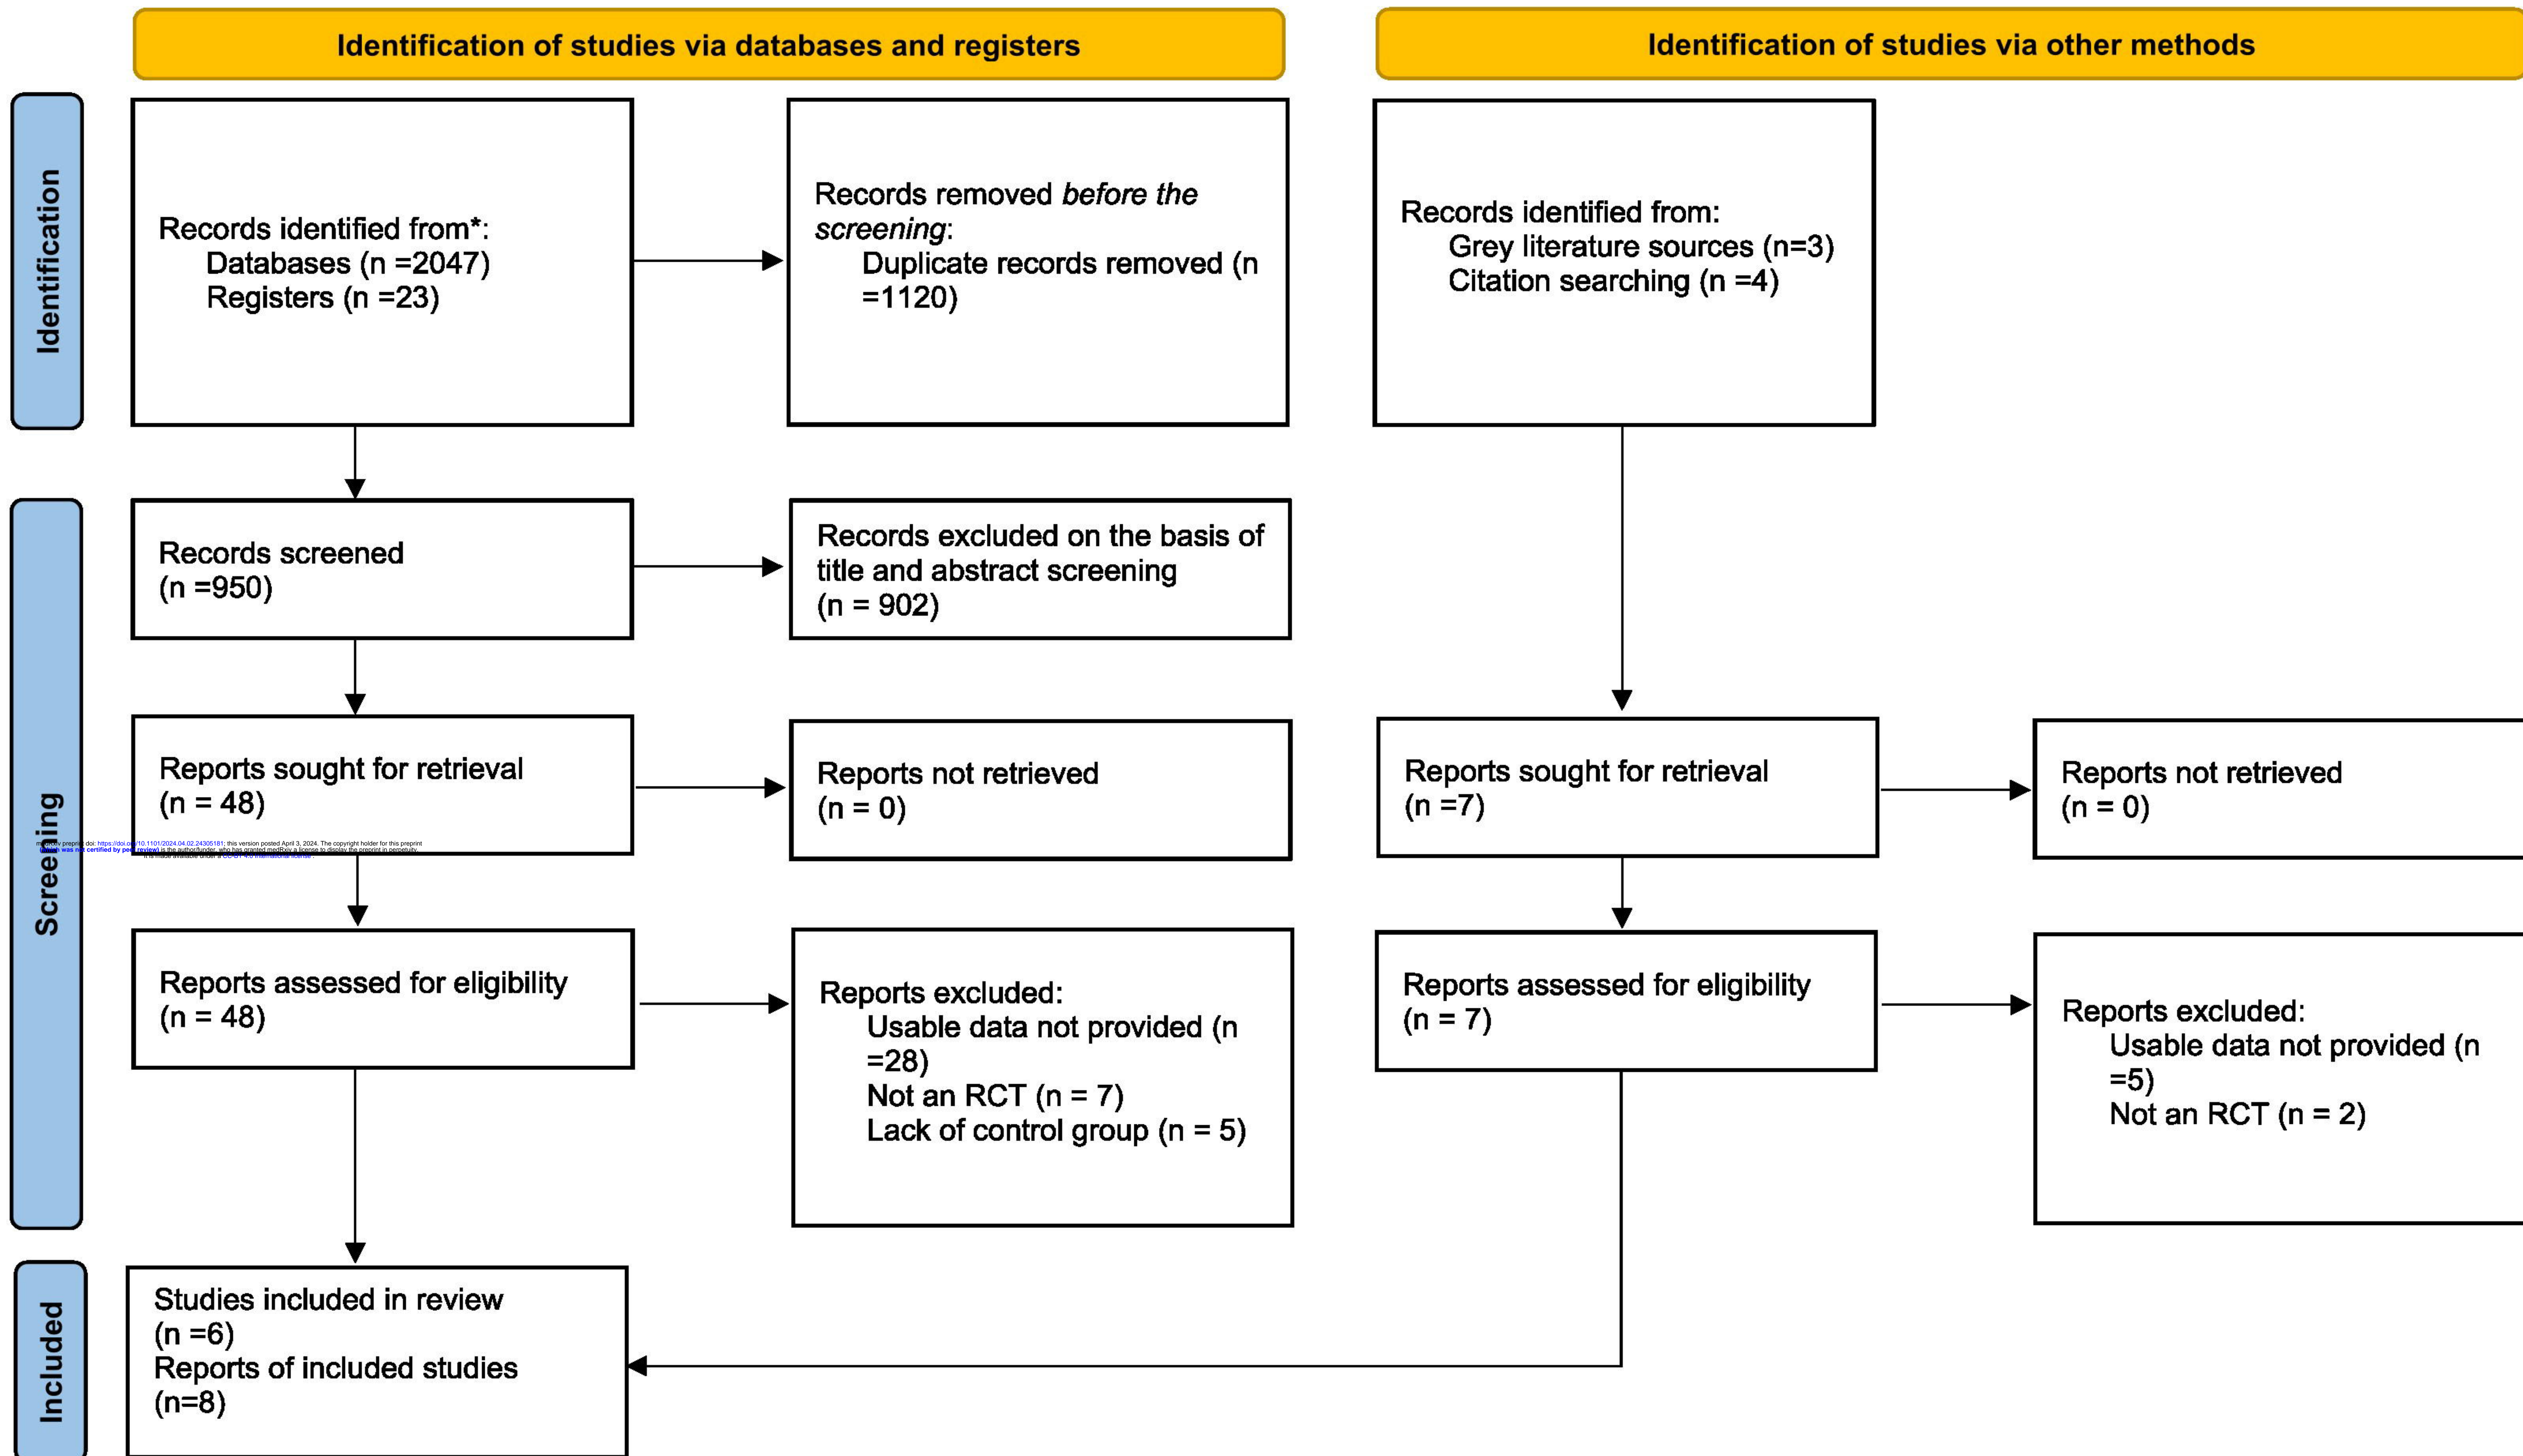

Figure 4. Forest plot of independent ambulation (mRS \leq 3) at 90 days follow-up

Table 1 Study characteristics of included studies

Study ID	Country of origin	Trial design	Study follow-up duration	Number of participants	Age (years)	Male (%)	Endovascular Intervention	Medical Intervention	ASPECTS, median (IQR)	NIHSS, median (IQR)	Infarct core volume, median (IQR)	Occlusion location, N (%)	Median pre-stroke modified Rankin Scale (IQR)	Intravenous thrombolysis administered
Yoshimura et al., 2022	Japan	Multicenter, open-label, randomized clinical trial	90 days	203 (101 vs 102)	76.6±10.0 vs 75.7±10.2	55 (54.5) vs 58 (56.9)	Stent retriever, aspiration catheter, balloon angioplasty, intracranial stent, and carotid-artery stent)	Alteplase at a dose of 0.6mg/kg of body weight	3(3-4) vs 4(3-4)	22 (18-26) vs 22 (17-26)	94 (66-152) vs 110 (74-140)	ICA: 47 (46.5) vs 49 (48.0) M1 segment: 74 (73.3) vs 70 (68.6) M2 segment: 0 vs 3 (2.9) Tandem lesion of ICA and M1 segment of the MCA: 20 (19.8) vs 20 (19.6)	0 (0-1) vs 0 (0-1)	27 (26.7) vs 29 (28.4)
Bendszus et al., 2023	Multinational (Europe and Canada)	Multicenter, blinded endpoint, open-label	90 days	253 (125 vs. 128)	73 (65-81) vs. 74 (64-80)	59 (55%) vs. 51 (48%)	Aspiration Catheter (21/121) Stent Retriever (28/121) Both aspiration catheter and stent retriever (72/121)	Standard of care (including IV thrombolysis)	3: 36/125 vs. 48/128 4: 45/125 vs. 39/128 5: 44/125 vs. 41/128	19 (16-22) vs. 18 (15-22)	-	ICA 41/125 (33%) vs. 37/127 (29%) MCA, M1 segment 83/125 (66%) vs. 88/127 (69%) MCA, M2 segment 0/125 (0%) vs. 1/127 (1%) MCA plus ACA 1/125 (1%) vs. 1/127 (1%)	0 (0-1) vs. 0 (0-1)	49 vs. 44
Huo et al., 2023	China	MC, open-label	90 days	455 (230 vs. 225)	68 (61-73) vs. 67 (59-73)	135 (58.7) vs. 144 (64.0)	Stent retriever or contact aspiration	Alteplase(0.9 mg/kg body weight) Or Urokinase (1 to 1.5 million IU))	3(3-4) vs 3(3-4)	16 (13-20) vs 15(12-19)	60.5 (29-86) vs 63 (31-86)	ICA 83 (36.1) VS 81 (36) M1 Segement 145 (63) vs 142 (63.1) M2 Segment 2 (0.09) vs 2 (0.09)	-	66 (28.7) vs 63 (28.0)

<u>Sarraj et al., 2023</u>	International (United States, Canada, Europe, Australia, and New Zealand.)	Multicentered, Open-label, Assessor-blinded	1 year	352 (178 vs 174)	66 (58.75 vs 67.5)	107 (60.0% vs 100.4%)	178 (Stent retrievers or aspiration devices, or both of, depending on the trial site.)	Tenecteplase or Alteplase	4 (3-5) vs 4 (4-5)	19 (15-23) vs 19 (15-22)	81.5 (57-118) vs 79 (62-111)	ICA: 80 (44.9) vs 66 (37.9) M1 Segment: 91 (51.1) vs 100 (57.5) M2 Segment: 7 (3.9) vs 8 (4.6)	-	37 (20.8) vs 30 (17.3)
<u>TESLA, 2023</u>	United States	Multicentered, Open-label, Blinded endpoint, Phase III trial	1 year	300 (152 vs 148)	66 (54.74 vs 67.5)	76 (50.0% vs 84.8%)	Stent retriever Aspiration catheter Combined approach (stent retriever with local aspiration)	IV Alteplase	4 (3-5) vs 4 (3-5)	19 (15-23) vs 18 (14.5-21)	166 (103-261.5) vs 171 (93.5-235)	ICA: terminus 33 (21.7) vs 24 (16.2) MCA M1: 119 (78.3) vs 124 (83.8)	0-1 vs 0-1 119 (78.3)- 33 (21.7) vs 112 (75.7)- 36 (24.3)	31 (20.4) vs 30 (20.3)
<u>LASTE, 2024</u>	Europe, United States	Multicentered, Open-label, blinded endpoint	90 days	324 (159 vs 165)	73 (66.79 vs 74.80)	80 (51.6% vs 88.3%)	-	-	0-2: 73 (45.9%) vs. 70 (42.4%) ≥2: 86 (54.1%) vs. 95 (57.6%)	21 (18-24) vs. 21 (18-24)	-	ICA: 69 (43.3%) vs. 74 (44.8%) M1/M2: 90 (56.6%) vs. 91 (55.2%)	-	55 (34.6%) vs. 58 (35.2%)

PRISMA 2020 flow diagram for new systematic reviews which included searches of databases, registers and other sources

Risk of bias domains

		D1	D2	D3	D4	D5	Overall
Study	ANGEL-ASPECT						
	LASTE						
	RESCUE-Japan LIMIT						
	SELECT2						
	TENSION						
	TESLA						

Domains:

D1: Bias arising from the randomization process.

D2: Bias due to deviations from intended intervention.

D3: Bias due to missing outcome data.

D4: Bias in measurement of the outcome.

D5: Bias in selection of the reported result.

Judgement

 Low
