33

34

35 Abstract

36 Background: Dengue is a significant global public health concern that poses a threat to
37 Africa. Particularly, African countries are at risk of viral introductions through air travel
38 connectivity with areas of South America and Asia that experience frequent explosive
39 outbreaks. Limited reporting and diagnostic capacity hinder a comprehensive assessment of
40 continent-wide transmission dynamics and deployment of surveillance strategies in Africa.
41 This study aimed to identify African airports at high risk of receiving dengue infected
42 passengers from Asia, Latin America and other African countries with high dengue
43 incidence.

44

45 Methods: The risk of dengue introduction into Africa from countries of high incidence in
46 Africa, Latin America and within Africa was estimated based on origin-destination air travel
47 flows and epidemic activity at origin. We produced a novel proxy for local dengue epidemic
48 activity using a composite index of theoretical climate-driven transmission suitability and
49 population density, which we used, along with travel information in a risk flow model, to
50 estimate importation risk.

51

52 Findings: We find that countries in East Africa face higher estimated risk of importation from
53 Asia and other East African countries, whereas for West African countries, larger risk of
54 importation is estimated from within the region. Some countries with high risk of importation
55 experience low local transmission suitability which likely hampers the chances that
56 importations lead to local transmission and establishment. Conversely, Mauritius, Uganda,
57 Ivory Coast, Senegal, and Kenya are identified as countries susceptible to dengue
58 introductions during periods of persistent transmission suitability.

59

60 Interpretation: Our work improves data driven allocation of surveillance resources, in regions
61 of Africa that are at high risk of dengue introduction and establishment, including from
62 regional circulation. This will be critical in detecting and managing imported cases and can
63 improve local response to dengue outbreaks.

68

69 **Research in context**

70 **Evidence before this study**

71 Despite the significant global burden of dengue virus, Africa remains relatively understudied
72 due to limited reporting and diagnostic capabilities. We searched PubMed for articles in
73 English published on and before May 6, 2024, that included “Dengue OR dengue”, “Africa”,
74 and "importation OR imported". Few studies have investigated the introduction of dengue
75 into African countries. Limited evidence includes phylogeographic studies describing a
76 potential introduction of dengue from Brazil into Angola in 2013 and evidence of multiple
77 historical introductions of dengue from Asia to Africa over several years. Before our study,
78 none had employed a modelling framework to investigate the continental risks of importing
79 dengue via viremic travellers into African countries from other regions of high dengue
80 incidence.

81

82 **Added value of this study**

83 This study provides a novel approach to assessing the risk of dengue importation into Africa,
84 integrating climate-dependent transmission suitability and air travel data. By identifying
85 high-risk regions and highlighting the complex interplay between travel patterns, population
86 density, and climatic factors, our findings enhance the understanding of ongoing dengue
87 dynamics in Africa. This information enables targeted allocation of surveillance resources,
88 improving preparedness and response to potential dengue outbreaks in susceptible regions.

89

90 **Implications of all the available evidence**

91 The integration of transmission suitability as a proxy for local epidemic activity and air travel
92 data into a risk flow metric provides valuable insights into the risk of dengue importation into
93 African airports from high-incidence countries. These findings have implications for tailored
94 surveillance and prevention strategies in high-risk regions, facilitating early detection and
95 management of potential imported dengue outbreaks in Africa.

96

97 Introduction

98 Dengue is an arthropod-borne virus with four main serotypes and is a member of the genus
99 *Flavivirus* of the family *Flaviviridae* (1,2). It is thought to cause between 5.2 million and 390
100 million infections around the world every year, mostly transmitted by *Aedes aegypti* and *Ae.*
101 *albopictus* mosquitoes (3,4). Approximately half of the global human population is estimated
102 to currently live in areas that are environmentally suitable for dengue transmission (3,5,6).
103 Dengue is now endemic in more than 100 countries, with reported outbreaks predominantly
104 in Central America, South America, and Southeast Asia, and has recently established
105 epidemic cycles in parts of Africa and North America (6–8).

106

107 Despite the widespread distribution of mosquito vectors in Africa (9) and favourable
108 transmission conditions characterised by high temperatures and increased urbanisation
109 (7,10,11), severe gaps exist in our understanding of the transmission intensities of the virus
110 on the continent. Limited diagnostic capacity and reporting on dengue incidence make it
111 difficult to assess the true burden of dengue in Africa (3,5). Similarity of symptoms with
112 other febrile illnesses such as malaria also play a role in underdiagnosis (12,13). Consensus
113 of evidence studies have reported that dengue transmission is endemic in 34 countries in the
114 African region (14,15). It is therefore speculated that dengue is more widespread in Africa
115 than previously thought. In 2023 alone, 16 countries in Africa reported large dengue
116 outbreaks (16).

117

118 Risk assessment for dengue in Africa has to consider several factors. Given frequent
119 explosive dengue outbreaks in South America and Asia, African countries are, for instance, at
120 risk of constant viral introductions through air travel connectivity. Once introduced, dengue
121 can theoretically spread rapidly in large parts of Africa due to the presence of suitable
122 vectors, appropriate environmental conditions and limited population immunity. Many initial
123 dengue infections are also prone to be asymptomatic, which can lead to underreporting and
124 unnoticed spread (1). While primary dengue infections are rarely fatal, secondary infections
125 with a different dengue virus serotype can be highly problematic, potentially causing severe
126 dengue fever (17). Even in countries where dengue is thought to be endemic, the importation
127 of dengue genetic variants either from high incidence South American or Asian countries can
128 exacerbate the burden of disease, favour serotype diversity and seed new explosive outbreaks.

129

130 The potential for dengue importation into a given location via viremic travellers is a function
131 of transmission occurring in the origin country and the volume of travellers from such
132 country to the destination country of interest. It is well documented that increased
133 international travel and trade have facilitated dengue's global spread and mixing of viral
134 serotypes and genotypes (10,6,18,19). The influence of human mobility on pathogen spread
135 has previously been characterised e.g. for influenza (20,21), Zika (22) and more recently, and
136 very extensively, for SARS-CoV-2 (23,24). Human mobility also plays a key role in shaping
137 individuals' interactions with disease-carrying vectors and consequently affecting viral
138 transmission (25,26). Understanding the combination of factors driving dengue introduction
139 and onward transmission is crucial for effective surveillance, prevention, and control in
140 Africa in the absence of antiviral treatment, adequate diagnosis, and widespread vaccine
141 cover. This study aimed to identify African airports at high risk of receiving dengue infected
142 passengers from Asia, Latin America and other African countries with high dengue
143 incidence. In doing so, it identifies potential high risk areas and optimal periods (at a monthly
144 scale) during which enhanced disease surveillance could contribute more to local public
145 health.

146 Methods

147 2.1 Data

148 2.1.1 Air Travel

149 The air travel flow data used in this study was obtained from the International Air Transport
150 Association (IATA). It comprises the number of origin-destination passenger tickets and
151 accounts for any connections at intermediate airports for the year 2019. We opted for the year
152 2019 to reflect a recent customary year of travel preceding disruptions due to the COVID-19
153 pandemic. The data comprises monthly passenger volumes from 14 high incidence countries
154 outside of Africa and 18 countries within the African continent that reported dengue outbreak
155 in the last 10 years (selection described further down) to 54 African countries, encompassing
156 all commercial airports (n = 197) in both the source and destination regions.

157 2.1.2 Transmission Suitability Estimate

158 We sourced spatio-temporal estimates of climate-based transmission suitability of dengue
159 (referred to as index P) developed and made accessible by estimates from (7) Nakase et al.
160 (2023; <https://doi.org/10.6084/m9.figshare.21502614>). The index used in this study quantifies
161 the transmission capacity of a single adult female mosquito throughout its lifetime in a
162 completely susceptible host population, incorporating factors such as infectious periods and
163 oviposition. For a more detailed explanation and validation of the P index, see (7), which
164 provides an in-depth analysis and evidence supporting model, including spatio-temporal
165 validation with regional dengue data from Brazil and Thailand. The index P metric utilises
166 local temperature and humidity time series (spatial pixel resolution used was $0.25^\circ \times 0.25^\circ$
167 ($\sim 28 \text{ km}^2$) as primary inputs, which enables its application to any location with available
168 climate data. For more detailed discussions on how climatic factors like temperature and
169 rainfall affect mosquito biology and dengue transmission, see e.g. (27–29).

170

171 We post-processed raw climate-based transmission suitability P estimates to define periods of
172 *persistence suitability*. Since P measures the number of hosts a single infected female may
173 transmit DENV to during its infectious lifespan, a threshold of $P > 1$ represents the potential
174 for epidemic expansion (i.e. single infected mosquitoes would transmit to more than one
175 host). Following this rationale, periods of persistence suitability are then defined as the
176 months where $P > 1.0$.

177 2.1.3 Population Density

178 Population density at a given location significantly influences dengue transmission due to its
179 role in determining the availability of human hosts for mosquito biting and thus the virus. To
180 consider population density, we extracted the population count of each district within
181 countries from the Gridded population of the World, using administrative (level 1) boundary
182 data from the GADM database (30). To calculate the population density of a province, we
183 aggregated the population count values of grid cells intersecting the province boundary and
184 divided by the respective areas

185 2.2 Transmission suitability as a proxy for case counts

186 To address the challenge of missing or insufficient dengue case data, we explored the
187 possibility of using climate-based transmission suitability (index P) as a proxy. To assess the

188 viability of replacing dengue case data with transmission suitability, we conducted a
189 preliminary correlation test between transmission suitability and monthly dengue cases for
190 countries in which monthly dengue case data was available (see supplementary figure S1,
191 p.1). Moreover, using transmission suitability instead of case data would allow for a more
192 fine scaled understanding of dengue activity in a country, surpassing the resolution typically
193 available at the national level.

194

195 For this study, we considered countries outside of Africa with large outbreaks of dengue in
196 2019 as flagged by the European Centre for Disease Prevention and Control (ECDC)
197 (accessed on 10th May 2023; <https://www.ecdc.europa.eu/en/dengue>). These were
198 predominantly in Latin America and Asia. Monthly dengue case data from these countries
199 were then extracted from public health organisations such as the Pan American Health
200 Organisation (PAHO; www3.paho.org), from governmental health reports or bulletins and
201 from statistical bureau websites (governmental reporting websites, WHO reports, etc). The
202 inclusion criteria for countries of high dengue incidence used in this study was based on the
203 availability of monthly case data in 2019 as it allowed for reliable testing of the transmission
204 suitability proxy and use of travel data for the same year. This resulted in a final selection of
205 14 countries of high dengue incidence in Latin America and Asia, namely: Brazil, Bolivia,
206 Peru, Sri Lanka, Vietnam, Malaysia, Columbia, Thailand, Nicaragua, India, Bangladesh,
207 Cambodia, Singapore and Belize. We also extracted province-level case data where openly
208 available. In the correlation coefficient computation we also incorporated data from two
209 African countries, Burkina Faso and Mauritius, for which monthly data for the year 2019
210 were available.

211

212 We use the Spearman's Rank correlation coefficient to examine the relationship between
213 transmission suitability and monthly dengue case counts for 16 countries. Following the
214 methodology used by (7), we computed correlation coefficients between case counts and
215 transmission suitability with various month lags (month+0, month+1 and month +2). We
216 found (see supplementary figure S1, p.1) a significant positive correlation between
217 transmission suitability and dengue cases for most countries, with the highest association at a
218 lag of one month (12 out of 16 countries), corroborating previous analyses (7). The strength
219 of the association ranged from -0.204 to 0.954. For some countries ($n = 3$), we found a weak
220 correlation which could be caused by several factors, such as: i) limited case data obscuring
221 seasonal patterns, which results in poor alignment with the index, ii) the national-level index

222 failing to accurately reflect the overall case distribution if cases are concentrated in specific
 223 regions. Correlation between case data and transmission suitability was also calculated at
 224 higher resolution (State level) for Brazil, and the strongest relationship was also found at a
 225 one month lag (see supplementary figure S2, p.2). Thus, for the rest of the presented analyses,
 226 transmission suitability with a one-month lag was used. Subsequently, we included 18
 227 African countries that have experienced a dengue outbreak in the past decade as reported in
 228 the WHO Afro reports. The 18 countries were: Angola, Benin, Burkina Faso, Chad,
 229 Comoros, Ethiopia, Ghana, Guinea, Kenya, Mali, Mauritania, Mauritius, Niger, Nigeria,
 230 Senegal, Tanzania, Togo and Sao Tome and Principe.

231
 232 While the transmission suitability index serves as a valuable indicator of dengue risk in a
 233 given region, its standalone consideration provides only an answer to whether climate is
 234 suitable for transmission. Additional factors, such as the presence of the host and vector, are
 235 crucial for a more accurate assessment. Specifically, *Aedes* mosquito density data, along with
 236 host density and various other environmental factors (e.g. precipitation, vector habitat
 237 distribution, etc) that influence the spatial distribution of vectors, remain relevant for a
 238 complete understanding of the biological system. The main reason why such actors are often
 239 left out of modelling approaches is the lack of sufficient data with adequate spatio-temporal
 240 resolution. In this study, advancing on others based solely on climate-based suitability for
 241 vectors or viral transmission, we address one extra factor by incorporating human population
 242 density alongside the transmission suitability index. Using Spearman's Rank correlation
 243 coefficient, we also examine the correlation between dengue cases and the composite index at
 244 a provincial level (see supplementary figure S3, p.3). We thus define a composite index (\square):

$$\square_{\square} = \square_{\square_{\square}} \square_{\square_{\square}} (\square_{\square_{\square}} \square) \\ * \square_{\square_{\square}} \square_{\square_{\square}} (\square_{\square_{\square}} \square)$$

246 which captures the combined influence of the transmission suitability and the population
 247 density at the district level, by multiplying both elements (see supplementary figure S4 and
 248 S5, p.4).

249
 250

251 2.3 Risk Flow Metric

252 The importation risk to each airport (destination) in each African country was estimated as
253 the probability of importing a case from each state (origin) within each country of high
254 incidence, accounting for the origin–destination travel flows and their different, estimated
255 transmission suitability from the originating states. For cross-country comparisons, we
256 aggregated the resulting risk of introduction from each airport to the country level, and for
257 visualisation purposes, we calculated the average risk across each airport over the 12-month
258 period (January - December 2019).

259

260 The methodology was adapted from (31) and is as follows:

261 Risk flow ($r_{i\alpha}$) from origin state i to destination airport α is calculated by:

$$r_{i\alpha} = \frac{t_i n_i A_{i\alpha}}{\sum_j t_j n_j}$$

262

263 where λ_i is the combined transmission suitability and population density of state i , $t_{i\alpha}$ is the
264 travel flux from the origin state i , $\lambda_{i\alpha}$ is the probability of a traveller flying from i to α ,
265 conditioned on travelling internationally from i (by construction, $\sum_{\alpha} \lambda_{i\alpha} = 1$). The
266 denominator accounts for the transmission suitability in various states and the potential risk
267 associated with travellers from different origin states. It is constructed as the sum product of
268 all transmission suitability and travel flows originating from each individual state (denoted by
269 j). This normalisation process ensures that the impact of each state's transmission suitability
270 and travel flow is proportionally represented in relation to the collective risk from all origin
271 states.

272

273 The total risk of case importation to destination α is then given by

$$R_{\alpha} = \sum_i r_{i\alpha}$$

274 This risk is normalised such that $\sum_{\alpha} R_{\alpha} = I$.

275

276 To summarise and compare the overall introduction risks of dengue into African countries
277 from high incidence countries in Asia and South America, we aggregated the risk originating
278 from Asia, South America and Africa separately by summing it across all airports to the

279 district level and then calculating the average value over all months. We then computed the
280 proportions of risk coming from Asia, South America and Africa for each district. To further
281 explore the dynamics between introduction risk and the local transmission suitability, we
282 applied cosine similarity, a measure of synchrony between two time series. Cosine similarity
283 helped us evaluate how closely the temporal patterns of introduction risk align with local
284 transmission suitability. The cosine similarity ranges between 0 and 1, with 0 being less
285 synchronous and 1 being highly synchronous.

286

287 Additionally, in aggregating the risk for destination countries, we conducted a secondary
288 computation of risk emphasising the locations characterised by persistence suitability (see
289 section 2.1.2). This was done by excluding any estimate of risk that occurred outside of times
290 of persistence suitability (i.e. when index $P \leq 1$) in respective destination locations. In other
291 words, we filter only for estimated risks that are most likely to lead to onward transmission
292 and local outbreaks. We term this introduction suitability while we term the risk based on the
293 non-filtered values the raw introduction risk. It is important to note that the resulting risk
294 values should not be interpreted in absolute terms but rather as indicators of the direction and
295 timing of risk introduction, highlighting where and when the risk is coming in.

296 Results

297 **Dengue introduction risks from high incidence Asian and South American countries** 298 **into Africa**

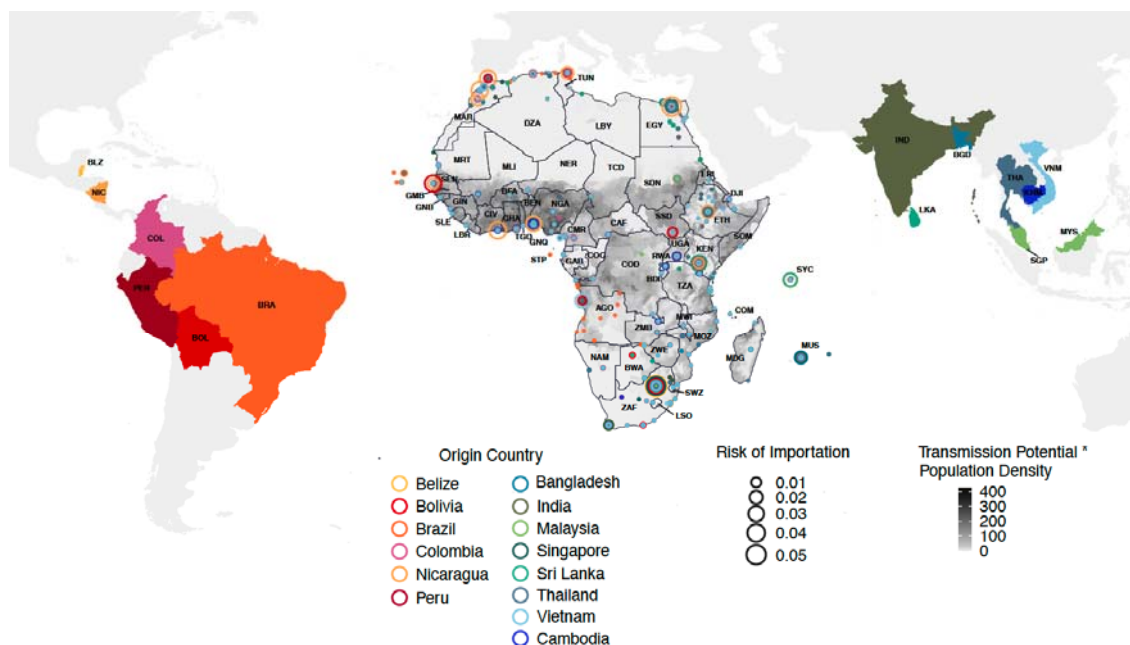

299 Several countries in Africa are estimated to have high transmission suitability for dengue and
300 simultaneously high population density, indicating elevated potential for local transmission
301 following viral introductions (Supplementary Figure S4, p.4). At the same time, certain
302 countries on the continent are receiving variable, and sometimes high volumes of
303 international passengers from various Asian and South American countries (Supplementary
304 Figure S6, p.5). In 2019, over 504 million travellers entered the African continent from the 14
305 high-incidence countries. Of the total number of travellers, 39% originated from Southeast
306 Asia, 34% from South Asia and 27% from South America (Supplementary Figure S6, p.5).
307 The months with the highest travel volume entering the African continent from these places
308 were November, December, and January.

309

310 The total risk flow of dengue from countries with high incidence rates, from Asia and South
311 America showed that South Africa and Egypt were the countries at higher risk of dengue
312 importation, generally considered as popular tourist destinations receiving large volumes of
313 vacationers, followed by Kenya, Angola, Morocco, Seychelles and Mauritius (Figure 1).
314 Egypt is exposed to significant risk primarily originating from Asia, specifically its biggest
315 risk coming from Malaysia. Kenya, Mauritius, Tanzania, and Uganda exhibit an elevated risk
316 of introduction from India. Risks from Singapore were also high, especially towards
317 Mauritius, South Africa and Egypt. Risks from Vietnam are relatively low across the entire
318 continent, with the most significant potential impact observed in South Africa and Angola.
319 Additionally, Morocco and Nigeria are identified as regions with a considerable risk of
320 disease introduction from Nicaragua.

321

322 Results revealed a general trend that countries in the southern and eastern African region are
323 faced with higher risks of dengue importation from Asia, whereas central, western and a
324 portion of northern African countries face higher risk of introduction from South America.
325 South Africa is estimated to receive large introduction risks from both origin regions. When
326 considering the raw risks of introductions overlaid onto the local transmission suitability
327 index across Africa, it becomes clear that high risk of introduction is not necessarily linked to
328 high transmission suitability (Figure 1). For instance, the high risks of introduction into South
329 Africa may not necessarily translate to transmission locally due to very low dengue
330 transmission suitability.

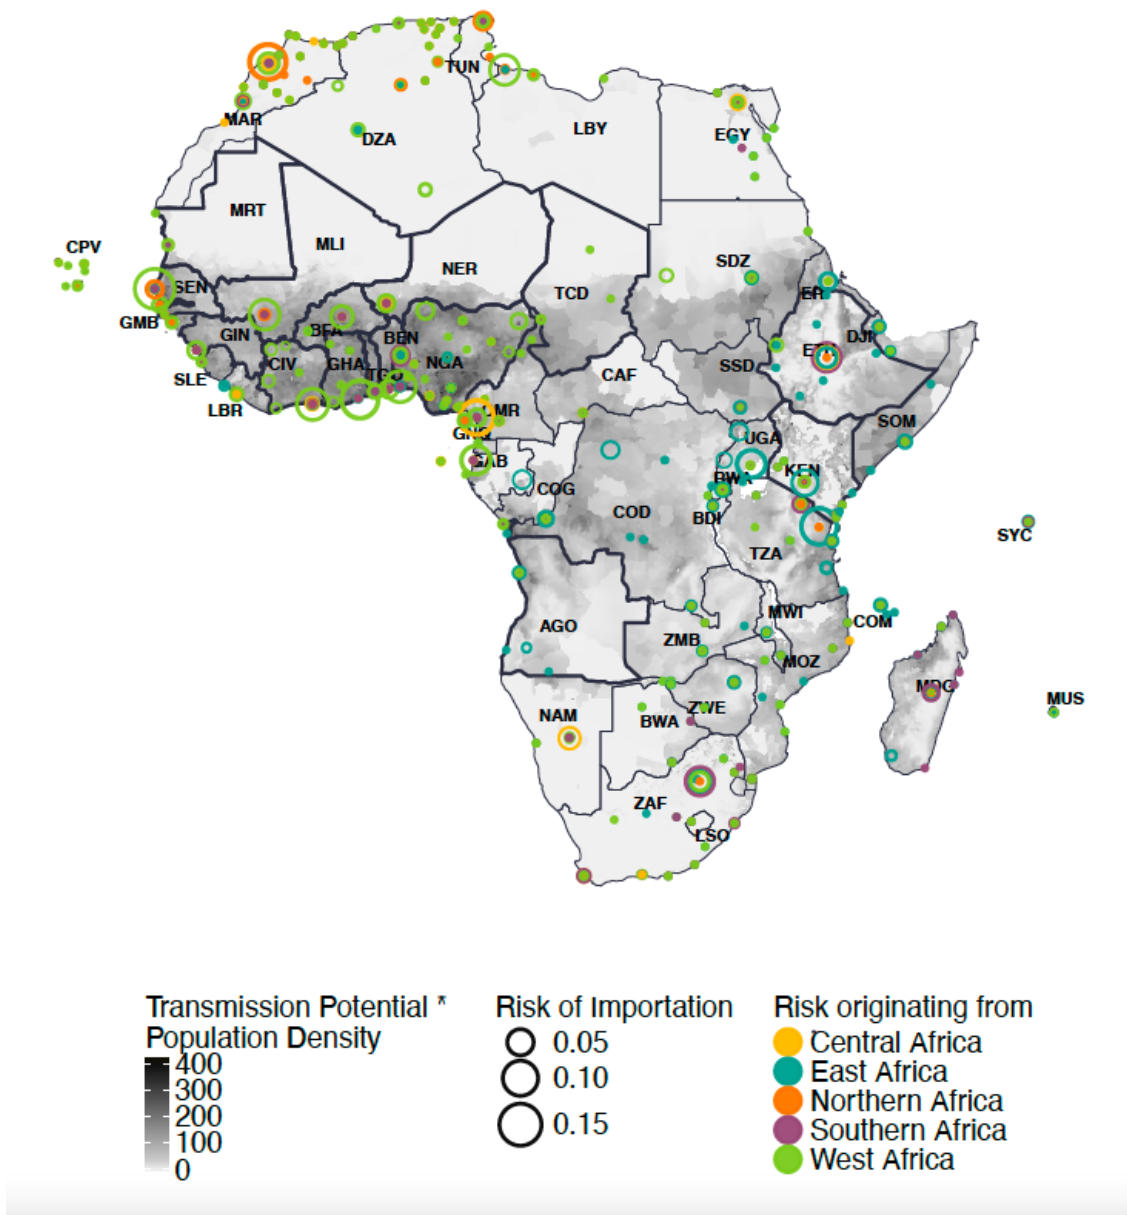

331

332 **Figure 1. Mean risk of dengue introduction into African countries in 2019 from 14**
333 **countries in Asia and Latin America.** The risk of dengue introduction into African
334 countries from 14 origin countries in Asia and Latin America is represented by circles on the
335 African continent. The size of the circles represent the size of the risk averaged over the 12
336 months for each airport in Africa. The colour of the circles represents the country from which
337 the risk is coming from and the fill colour of those countries are consistently matched. The
338 fill colour of the African continent represents the index of transmission suitability multiplied
339 by population density to highlight the hotspots of high transmission at the destination.

340

341 **Dengue introduction risks within Africa**

342 The analysis of dengue introduction risk into African countries from other African countries
343 with dengue circulation revealed significant regional patterns. We identified that countries in
344 West Africa and East Africa exhibit higher importation risks, particular from regional
345 transmission, compared to other regions (Figure 2). High importation risks are estimated into
346 countries such as Kenya, Tanzania, Cameroon and Gabon. A notable pattern is that the
347 importation risk within the East African region primarily originates from within the region
348 itself, a trend also observed for West Africa. In contrast, countries in Northern Africa, such as
349 Libya and Tunisia and those in Southern Africa, such as South Africa, exhibit lower dengue
350 importation risks from the African continent itself.

351

352 **Figure 2: Mean risk of dengue introduction into African countries in 2019 from 18**

353 **African countries with Dengue circulation.** Originating African countries considered here

354 are Chad, Sao Tome and Principe (Central Africa), Comoros, Ethiopia, Kenya, Tanzania

355 (East Africa), Benin, Burkina Faso, Ghana, Guinea, Mali, Niger, Nigeria, Senegal, Togo

356 (West Africa), Angola, Mauritius (Southern Africa) and Mauritania (Northern Africa). The

357 risk of dengue introduction into African countries is represented by circles on the African

358 continent coloured by the corresponding region of the originating African country. The size

359 of the circles represent the size of the risk averaged over the 12 months for each airport in

360 Africa. The border for African countries considered as originating locations in the study are

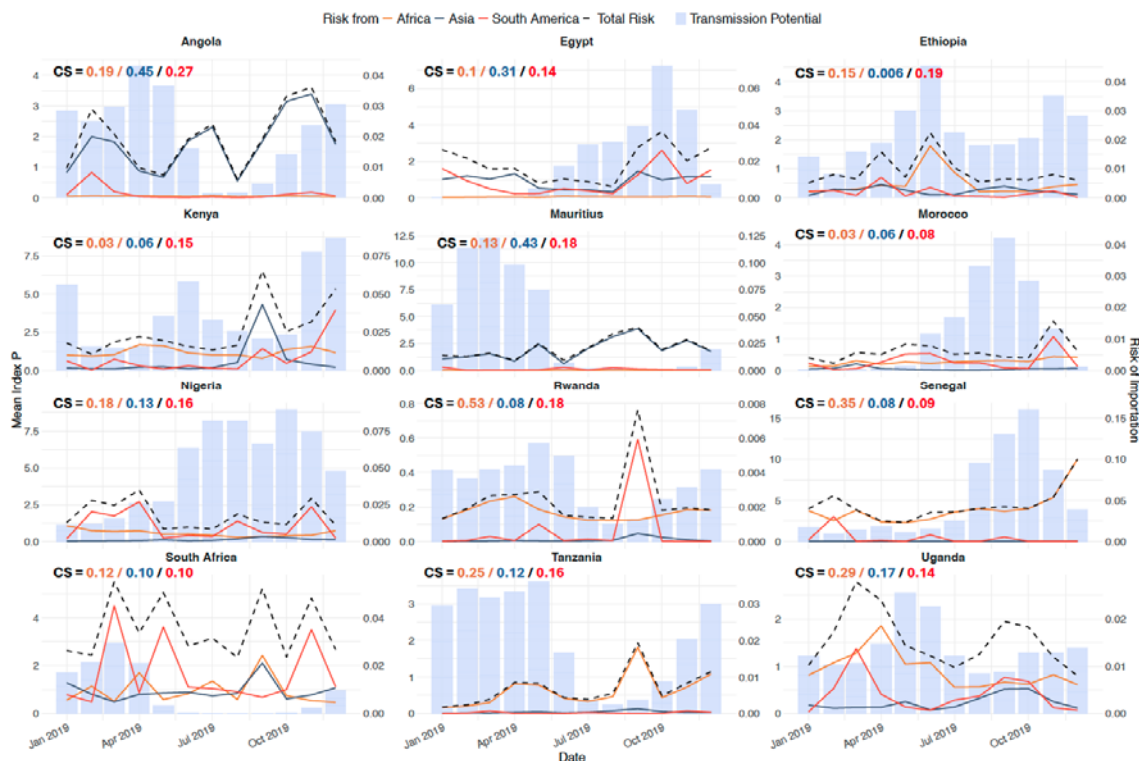

361 outlined in black. The fill colour of the African continent represents the index of transmission
362 suitability multiplied by population density to highlight the hotspots of high transmission at
363 the destination.

364

365 **Spatiotemporal variation in risks of introduction and local transmission suitability**

366 In addition to quantifying the risk of dengue introductions from countries of high incidence in
367 Asia and South America we evaluated the timing of these introductions and whether they
368 would arrive at periods of high local transmission suitability in Africa. For this, the monthly
369 introduction risk was mapped to local transmission suitability at the airport level in Africa.
370 Egypt was estimated to be at high risk of dengue introduction during the second half of the
371 year from both Asia and South America (Figure 3). This temporal pattern aligns with a
372 concurrent period of heightened transmission suitability within the country, which could
373 indicate a higher likelihood of viral introductions leading to onward transmission. To
374 quantify the synchrony between the estimated viral importation risk and the local
375 transmission suitability, we computed the cosine similarity (CS) between the different time-
376 series, which revealed a CS of 0.311 for estimated risks from Asia and 0.147 from Latin
377 America into Egypt (see Supplementary Table S1, p.10). In fact in 2023, Egypt experienced a
378 large dengue outbreak around September to November (32), which coincides with peaks in
379 estimated risk and transmission suitability. Angola and Ethiopia both were estimated to have
380 a continuous risk of disease introduction from Asia throughout the year. However, in Angola,
381 the transmission suitability was predicted to decline during the months of July, August, and
382 September. Mauritius was also estimated to be at high risk of introduction from Asia. The
383 cosine similarity between the risk of introduction and transmission suitability for Mauritius
384 was 0.437 for Asia and 0.183 for South America. On the other hand, we observed high risks
385 of dengue introduction into South Africa but, in general, the country exhibited a low
386 transmission suitability throughout the year, indicating these potential introductions as likely
387 impasses for transmission. In Nigeria, the majority of the high risk of introduction from South
388 America were estimated to occur during periods of lower local transmission suitability.
389 Angola and Mauritius were identified as being at high-risk of suitable introductions, given the
390 combination of high and synchronous risk of introduction from Asia (see Supplementary
391 Table S1, p.1).

392

393

394 **Figure 3. Time-varying risk of introduction into selected African countries in 2019.** The
 395 blue, red and orange lines represent the risk of importation from Asia, South America and
 396 Africa, respectively, and the dotted line represents the total risk of importation from both
 397 continents and African countries across the year. The risk of importation was aggregated at
 398 the national level by summing the individual risks from all airports within each African
 399 destination country. The blue bars represent the time-varying transmission suitability index.
 400 The CS value represents the cosine similarity between the two timelines, where a value of 0
 401 indicates low synchrony and a value of 1 indicates high synchrony. Here, we demonstrate
 402 countries that had the most synchronicity between transmission suitability and risk of
 403 introduction - see supplementary S7, p.6 for additional countries.

404

405

406 **Overall introduction suitability in Africa**

407 We then integrated the risk of dengue importation from 14 countries outside of Africa with
 408 that from 18 African countries to gain a clearer understanding of the proportion of
 409 importation risk originating from within the African continent compared to that from external
 410 sources. We filtered for risk estimates that are most likely to lead to onward transmission:
 411 introduction suitability risk, that is, risks that occur during periods of persistence suitability

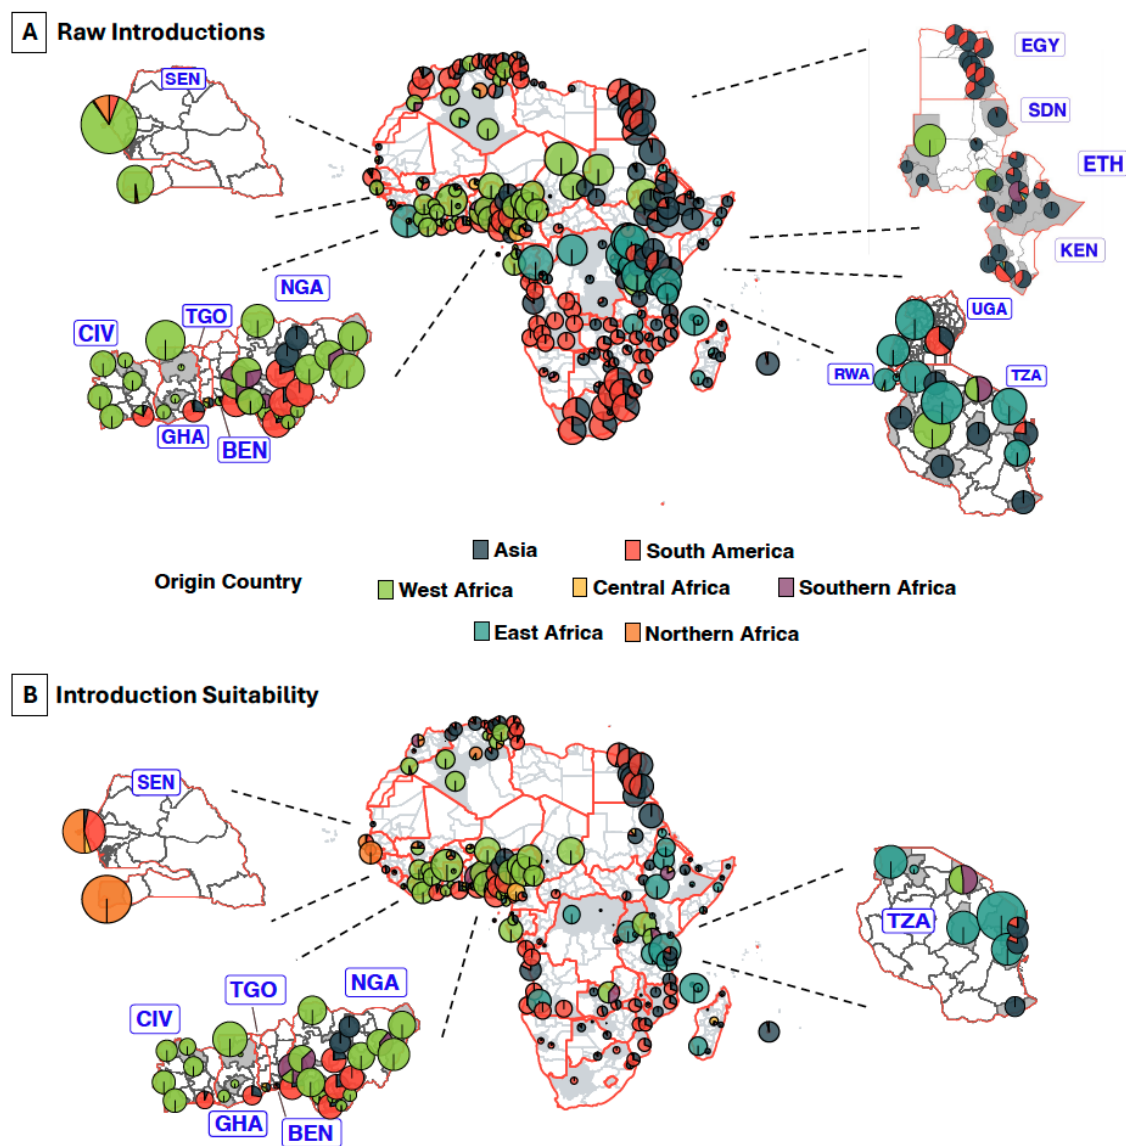

412 (P>1). Figure 4A illustrates the aggregated raw risk of dengue introduction throughout the
413 year 2019 across individual provinces or districts (administrative level 1) within each African
414 country, and aggregated as originating either from Latin America, Asia, West, East, Central,
415 Northern or Southern Africa. Conversely, Figure 4B presents the aggregated introduction
416 suitability of dengue into Africa. Notably, in South Africa, where the transmission suitability
417 (P) remains consistently below 1 throughout the year, the risk of dengue evolving into an
418 outbreak from an introduction is negligible.

419

420 In our analysis, a noteworthy shift in risk proportionality emerged when focusing on
421 introduction suitability compared to raw risk. For example, in the case of Dakar in Senegal,
422 initially, 87.7% of the total risk was attributed to West African region, followed by 3.9%
423 from South America and 6% from Northern Africa. However, when looking at periods of
424 persistence suitability for Senegal, the risk distribution shifted and the proportion of risk
425 attributed to Northern African regions, rose to 50.4%, followed by South America with
426 41.5%. This outcome underlines the importance of understanding not only the geographic
427 origin of importation risks but also the specific temporal and spatial context in which the
428 potential introductions can occur. Focusing on introduction suitability risk, countries in the
429 West and East African regions exhibited significant risks of dengue importation. Notably, the
430 highest risks for these countries were associated with regions within Africa itself (Figure 5).

431

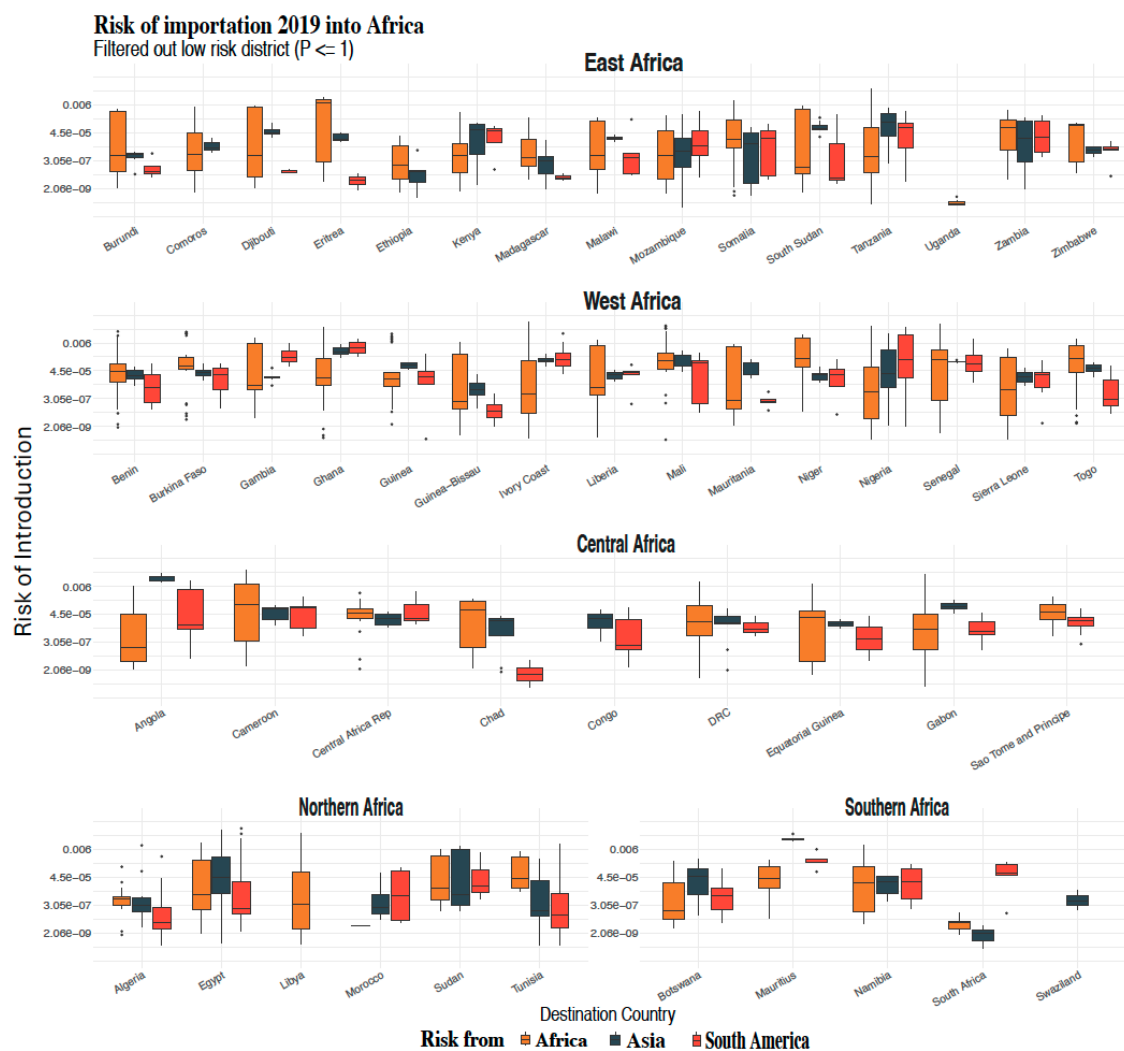

432

449

450 Discussion

451 In this study, we investigated the temporal and spatial intersections between high risk of

452 introduction and heightened local transmission suitability of dengue in African countries. The

453 exploration of dengue introduction into Africa is imperative due to the potential implications

454 for onward transmission. To this end, we constructed an importation suitability map to depict

455 the spatial and temporal hotspots of dengue introduction and establishment into Africa from
456 high incidence countries in Asia, Latin America, and regionally from other African countries.

457

458 We identified that the heterogeneity of the risk across Africa is dependent on the distribution
459 of dengue activity across different provinces or states in the countries of high incidence and
460 their connection to destination airports in Africa (see supplementary figure S8, p.9). Further,
461 we found that seasonal variation plays a crucial role. For example, in India, major outbreaks
462 tend to occur after the monsoon season and thus have a higher transmission suitability during
463 these seasons (monsoon season spans from June to September) (33–35) and thus we also
464 estimate a higher risk of dengue importation from India to African countries following the
465 monsoon season (see supplementary figure S8, p.9).

466

467 This research presents an alternative risk assessment by considering modelled dengue
468 transmission suitability (7) rather than reported incidence, compared to other studies using
469 case incidence which might suffer from substantial underreporting (36–39). The correlation
470 analyses revealed a robust association between transmission suitability and dengue cases for
471 countries where high resolution spatiotemporal case records were available, with a significant
472 correlation observed at a one-month lag (see supplementary figure S1, p.1). Our findings are
473 consistent with previous research, demonstrating that 96% of municipalities in Brazil and
474 95% of provinces in Thailand exhibited incidence dynamics with 0-3 months time delays
475 relative to estimated transmission suitability (7). Our correlation further supports the utility of
476 using transmission suitability as a proxy for local dengue circulation.

477

478 Increased international travel and trade have facilitated the global spread of dengue from
479 endemic to non-endemic regions, by enabling the movement of infected individuals and
480 mosquito vectors between regions (6–8,10). The risk flow results presented here highlight the
481 substantial risks of dengue introduction into certain parts of the African continent from Asia,
482 South America, or regionally from other African countries through human mobility. We show
483 that the risk of importation to African countries is highly heterogeneous. The results produced
484 by our model suggest that major airports in South Africa, Egypt, Morocco, Kenya, Seychelles
485 and Mauritius, are potential hotspots for the importation of dengue-infected travellers from
486 high-incidence countries. However, the analysis also revealed important geographical
487 nuances: for example, the broader Eastern African region, and parts of Southern and Africa,
488 are confronted with elevated risks of dengue importation from Asia, while Central, and

489 segments of Northern and Southern Africa are more susceptible to introductions from South
490 America (albeit often not suitable introductions). This is consistent with a recent
491 phylogeographic study which found that all four dengue serotypes were introduced on
492 multiple occasions to Africa, primarily from South or Southeast Asia since the 1940s (40).
493 This highlights the significance of our study in obtaining high-resolution and recent temporal
494 and spatial trends for the vulnerability of Africa to dengue introductions.

495

496 In contrast, our analysis of the risk of importing dengue from within the continent reveal
497 areas of the continent where a substantial portion of the risks tends to come from within the
498 region, underscoring the importance of intra-continental transmission dynamics. This is
499 estimated to be the major driver of cross-country introduction in West Africa, and to a lesser
500 extent in East Africa. This is supported by recent phylogeographic reconstructions which
501 showed frequent introductions and reintroductions of the dengue virus within the western
502 African region, as well as similar patterns in the eastern part of the continent (40,41). While
503 Asia represents the second largest contributor to dengue risk, particularly impacting the East,
504 West and Central African regions, the internal risk within Africa remains a primary concern.
505 To put this in context, Africa exhibits relatively similar or closely aligned spatial
506 characteristics in transmission suitability across its regions and therefore, it is expected that
507 intra-continental risk remains predominant. This spatial similarity reinforces the
508 interconnectedness of African regions in the context of disease transmission dynamics. On
509 the other hand, there is also a substantial contribution from Asia particularly in East Africa,
510 and towards the island nation of Mauritius, indicating that these countries are vulnerable to
511 introductions both from within the continent and from Asia.

512

513 It remains crucial not to disregard regions with high population density but that currently
514 express low transmission suitability, such as Ethiopian highlands or high altitude regions of
515 Tanzania. Despite their dense population, these regions have historically shown low
516 transmission suitability values. However, with the potential impacts of future global climate
517 change, these areas may become increasingly susceptible to local dengue outbreaks. By
518 integrating appropriate travel models, this approach can be adapted to predict dengue risk
519 under various climatic conditions, providing valuable insights for future public health
520 planning.

521

522 To translate the high risks of introduction into the notion of introduction suitability, that is
523 considering potential introductions that are highly likely to cause onward transmission in the
524 destination countries, it was important to understand the specific temporal and spatial patterns
525 of the risk flow estimates. The temporal analysis of estimated importation risks and local
526 transmission suitability revealed the optimal times to conduct increased surveillance, as the
527 times when the risks of introduction and the potential for transmission are simultaneously
528 high. Therefore, the temporal synchrony between estimated introduction risks and
529 transmission suitability has important implications for which viral introductions are predicted
530 to have the ability to contribute to local outbreak risks.

531

532 Epidemiological and genomic surveillance are critical public health measures to mitigate
533 disease burden, and also to understand the spread and evolution of pathogens. At present,
534 there is no approved antiviral treatment for dengue and supportive care is the only option
535 (17–19). However, two dengue vaccines have shown great promise (Takeda and Butantan
536 vaccines) (20). Genomic surveillance can provide critical information about viral
537 transmission landscape prior to upcoming dengue vaccine rollouts. To determine the optimal
538 locations for conducting genomic surveillance in Africa, it is also important to have a
539 quantitative understanding of the actual risk of a dengue virus epidemic at country level,
540 particularly given limited resources to implement surveillance programs. This study's
541 findings point to the fact that emphasis should be placed on targeted monitoring during
542 periods when the likelihood of risks escalating into an outbreak is higher, and within areas
543 prone to introductions during time of persistence suitability. In turn, in light of introduction
544 risks, genomic surveillance for dengue enables public health officials to monitor the
545 circulating serotypes while remaining vigilant for the emergence of novel strains or
546 genotypes. In the particular case of dengue, introductions could lead to outbreaks with
547 worsened disease outcomes in a population that has already been exposed to a different
548 serotype of the virus, and depending on the temporal sequence of serotype circulation. This is
549 a growing concern in Africa and elsewhere given the number of countries in which dengue is
550 now well established and serotype co-circulation is becoming universal. Importantly, our
551 modelling approach can also be used for other continents, namely Europe and North America
552 where dengue epidemic activity is increasing.

553

554 This study should be interpreted in light of several limitations. First, this study presents
555 relative introduction and establishment risks calculated from ecological, statistical, and

556 mathematical models but does not present direct estimates of the number of expected
557 introductions. Further, due to paucity of genomic and traveller testing data the models
558 presented here have yet to be validated. In countries that perform disease surveillance of
559 incoming travellers, the history of travel of positive dengue cases could serve as validation
560 data to this type of modelling study. Rapidly expanding volume of available dengue genomes
561 will soon make it possible to reconstruct high resolution transmission dynamics to validate
562 introduction models presented here. Additionally, the measure of transmission suitability
563 used for the source locations does not account for specific control measures in place,
564 potentially impacting the accuracy of the estimated dengue incidence. It also does not take
565 into account the presence and abundance of mosquito vectors. Despite this limitation, the
566 chosen transmission suitability index P seems to produce realistic estimates for dengue
567 incidence in source locations, considering variations in testing and reporting practices
568 globally. Thirdly, while our findings are founded upon the current travel networks, it is
569 imperative to acknowledge the dynamic nature of travel patterns. Given the expansive reach
570 of air travel and the transformative impact observed during the COVID-19 pandemic, we
571 must remain vigilant to the possibility of shifts in dengue introduction risks. This is
572 particularly relevant as more areas are becoming suitable for transmission of dengue.
573 Furthermore, the connectivity between African countries is only captured here through air
574 travel data, while the true connection between neighbouring countries would also be
575 dependent on road travel networks and information about the porosity of borders, data which
576 is much more difficult to obtain. Finally, models like the one employed in this study rely on
577 air travel data and do not account for the role of trade in moving infected mosquitoes between
578 countries (e.g. in tyres); this should be considered in future work.

579

580 In conclusion, this study provides valuable insights into the complex dynamics of dengue
581 importation risks into Africa, while making a distinction as to the source of those potential
582 introductions. The incorporation of estimated transmission suitability for dengue and
583 population density in risk assessment enhances the accuracy of predictions. The temporal and
584 spatial analyses highlight specific regions and times that warrant intensified surveillance and
585 public health interventions given the likelihood of potential introductions that would lead to
586 local outbreaks. These findings contribute to a more nuanced understanding of global dengue
587 dynamics, and importantly focus on informing further surveillance on the Africa continent
588 and globally.

589 Data Availability Statement

590 Proprietary air travel data are commercially available from the International Air Transport
591 Association (<https://www.iata.org/>) databases. Transmission suitability (index P) estimates
592 are available at <https://doi.org/10.6084/m9.figshare.21502614>. Risk estimates computed from
593 this study can be found at:
