20	Abstract

21 Wastewater-based epidemiology (WBE) requires high-quality survey methods to determine the 22 incidence of infections in catchment areas. In this study, the wastewater survey methods necessary for comprehending the incidence of infection by WBE are clarified. This clarification is based on 23 24 the correlation with the number of confirmed coronavirus disease 2019 (COVID-19) cases, considering factors such as handling non-detect data, calculation method for representative values, 25 26 analytical sensitivity, analytical reproducibility, sampling frequency, and survey duration. Data 27 collected from 15 samples per week for two and a half years using a highly accurate analysis method were regarded as gold standard data, and the correlation between severe acute respiratory 28 29 syndrome coronavirus 2 (SARS-CoV-2) RNA concentrations in wastewater and confirmed COVID-30 19 cases was analyzed by Monte Carlo simulation under the hypothetical situation where the quality 31 of the wastewater survey method was reduced. Regarding data handling, it was appropriate to replace non-detect data with estimates based on distribution, and to use geometric means to 32 calculate representative values. For the analysis of SARS-CoV-2 RNA in samples, using a highly 33 sensitive and reproducible method (non-detect rates of < 40%; ≤ 0.4 standard deviation) and 34 surveying at least three samples, preferably five samples, per week were considered desirable. 35 Furthermore, conducting the survey over a period of time that included at least 50 weeks was 36 37 necessary. A WBE that meets these survey criteria is sufficient for the determination of the COVID-19 infection incidence in the catchment area. Furthermore, WBE can offer additional insights into 38 infection rates in the catchment area, such as the estimated 48% decrease in confirmed COVID-19 39 40 cases visiting a clinic following a COVID-19 legal reclassification in Japan.

46 **1. Introduction**

47 Wastewater-based epidemiology (WBE), also known as wastewater surveillance, is an economical, representative, and early means of determining the incidence of infection in a target area without 48 requiring personal information (Hart and Halden, 2020; Kitajima et al., 2020; Murakami et al., 49 2020; Shah et al., 2022). The WBE has been applied since the 1990s as a method to comprehend the 50 infection incidence of polio (Grabow et al., 1999). Since the beginning of the coronavirus disease 51 52 2019 (COVID-19) pandemic, numerous studies have been conducted on correlations between 53 concentrations of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) RNA in untreated wastewater and the infection incidence of catchments (Ahmed et al., 2020; La Rosa et al., 54 2020; Randazzo et al., 2020). The WBE has been applied to other respiratory infections, such as 55 influenza (Schoen et al., 2023; Toribio-Avedillo et al., 2023). Monitoring the infection incidence 56 using WBE provides information that can contribute to public health, such as identifying the origin 57 of infection, promoting infection control measures, including testing and vaccination campaigns in 58 targeted areas, and preparing resource allocation in healthcare institutions (Betancourt et al., 2021; 59 60 Karthikeyan et al., 2022; Kitajima et al., 2022; Klapsa et al., 2022; Li et al., 2023a).

61	In Japan, where comprehensive notifiable disease surveillance of the number of COVID-19-infected
62	individuals has been conducted, a high correlation (Pearson's $r = 0.94$) was reported between the
63	number of newly confirmed COVID-19 cases and SARS-CoV-2 RNA concentrations in wastewater
64	through a two-year sampling campaign with twice-weekly sample collection using an analytical
65	method that is highly reproducible and capable of quantifying low concentrations of viral RNA
66	(Ando et al., 2023). In contrast, several factors influence the correlation between the virus
67	concentration in wastewater and the number of infected individuals in the catchment area. These
68	factors are categorized as clinical, environmental, and wastewater survey methods (Li et al., 2023b).
69	The clinical factors include COVID-19 prevalence and testing coverage. Environmental factors
70	include changes in air temperature and the catchment size of the wastewater treatment plants.
71	Factors related to wastewater survey methods include the sampling frequency (i.e., the number of
72	samples per week). Additionally, the survey duration and virus detection methods, such as analytical
73	reproducibility and quantification at low virus concentrations (analytical sensitivity) in wastewater,
74	are also relevant (Li et al., 2021; Medema et al., 2020). Li et al. (2023b) conducted a systematic
75	review of the correlations between SARS-CoV-2 RNA concentrations in wastewater and infection
76	incidence and reported that COVID-19 prevalence, testing coverage, air temperature variation,
77	catchment size, and sampling frequency were more likely to be associated with the strength of the
78	correlations, whereas the sampling method (i.e., grab or composite sampling) had a smaller effect.
79	Kuroita et al. (2024) reported that at least two samples per week are required to reduce variations in
80	viral concentrations in wastewater to obtain a strong correlation with confirmed COVID-19 cases,

81 irrespective of differences in the type of sewer system (i.e., combined or separated sewer system),

82 sampling method, and areas (i.e., urban or suburban areas).

The World Health Organization declared the end of the Public Health Emergency of International 83 84 Concern on May 5, 2023. The number of infected individuals has shifted towards partial monitoring worldwide. Japan reclassified COVID-19 legal status into the fifth category of communicable 85 86 diseases under the Communicable Diseases Law on May 8, 2023, and also shifted from comprehensive notifiable disease surveillance to sentinel surveillance, in which only the designated 87 88 health facilities report the number of COVID-19 cases seen there. As its clinical ability to ascertain 89 the incidence of infection has declined, the utility of WBE has increased. Therefore, it is important 90 to identify effective survey methods for the WBE that can adequately account for the number of 91 infected individuals in the target areas. Among the aforementioned clinical factors, environmental 92 factors, and wastewater survey methods, wastewater survey methods can be handled by the 93 implementers of the WBE in a target area. However, no studies have comprehensively examined the 94 appropriate wastewater survey methods in terms of sampling frequency, survey duration, analytical 95 sensitivity, and reproducibility.

This study aimed to clarify the survey methods necessary for understanding the incidence of WBE infection based on the correlation with confirmed COVID-19 cases. First, the handling of nondetect data and the calculation of representative values were investigated. Second, the sampling frequency, survey duration, analytical sensitivity, and analytical reproducibility necessary to determine the infection incidence through WBE were analyzed. For the sampling frequency, the

101	correlation between surveys conducted at two or three different catchment areas on the same day of
102	the week and those conducted at the same catchment area on two or three different days of the week
103	was also examined. Additionally, changes in the relationship between virus concentrations and
104	confirmed COVID-19 cases were analyzed, considering the behavior of individuals visiting health
105	facilities before and after the legal reclassification of COVID-19 in Japan.
106	
107	2. Methods
108	2.1. Data
109	In this study, WBE measurements over two and a half years with high analytical accuracy and
110	sampling frequency were used as "gold data," and the strength of the correlation coefficient with the
111	confirmed COVID-19 cases was analyzed under the condition that the quality of wastewater survey
112	methods would decline. WBE data obtained through a survey commissioned by the City of Sapporo
113	and Hokkaido University were used in the analysis. Specifically, this study used data on SARS-
114	CoV-2 RNA concentrations in untreated wastewater (24-hour composite samples) collected three
115	times a week (Monday, Wednesday, and Friday in principle) at each of the five catchment areas
116	covered by three adjacent wastewater treatment plants in the City of Sapporo from April 12, 2021,
117	to September 29, 2023. Pepper mild mottle virus (PMMoV) RNA was also measured from
118	September 27, 2021, to September 29, 2023. The population and area of the City of Sapporo were
119	1.96 million and 1,121 km ² in 2023, respectively. The population covered in each catchment area,
120	estimated from the overall facility's treated population and wastewater flow volume, ranged from

121 165,000 to 246,000, and the five catchment areas together covered 52% of Sapporo' s population.
122 If fewer than 15 samples were collected per week, data from the corresponding week were excluded
123 from the analysis.
124 The limit of detection (LOD) for SARS-CoV-2 RNA by the Efficient and Practical virus

Identification System with ENhanced Sensitivity for Solids (EPISENS-S), the viral RNA detection method used in this study, was 93.1 copies/L, corresponding to approximately one-hundredth that of the common polyethylene glycol precipitation method (Ando et al., 2022). The reproducibility of the SARS-CoV-2 analysis ranged from 0.03 to 0.4 standard deviation at log₁₀ values (Ando et al., 2022). A total of 15 weekly samples were analyzed over 122 weeks, with a total of 1,830 samples

130 and 201 samples below the LOD (i.e., non-detect samples).

131 Two types of clinical data were used for the confirmed COVID-19 cases: comprehensive, notifiable disease surveillance and sentinel surveillance. For the former, published data up to May 7, 2023, 132 133 were used (City of Sapporo, 2024; Data-smart City Sapporo, 2023), and a moving average of the 134 number of newly confirmed COVID-19 cases for a week was calculated using the three days before 135 and after a representative date of wastewater sampling (arithmetic mean of sampling dates). The comprehensive, notifiable disease surveillance data contained 1,515 wastewater samples collected 136 137 over 101 weeks. Regarding the sentinel surveillance data, the confirmed COVID-19 cases per sentinel health facility contained two types of data sources: estimation from the comprehensive 138 139 notifiable disease surveillance data from October 3, 2022, to May 7, 2023 (the confirmed COVID-140 19 cases in the comprehensive notifiable disease surveillance during the epidemiological week

141	multiplied by 0.091891 and divided by 56 sentinel health facilities (Ministry of Health Labour and
142	Welfare, 2023)) and published data thereafter (City of Sapporo, 2024). The sentinel surveillance
143	data comprised 735 wastewater samples collected over a period of 49 weeks. Figure 1 shows the
144	temporal trends of SARS-CoV-2 RNA concentrations in wastewater and confirmed COVID-19
145	cases. The confirmed COVID-19 cases comprised five infection waves in two years for the
146	comprehensive notifiable disease surveillance data period and two infection waves in one year for
147	the sentinel surveillance data period.
148	
149	2.2. Treatment of non-detect data and calculation method of representative values (Preliminary
150	analysis 1)
151	In this study, Pearson's correlation coefficient r was calculated between the log_{10} values of
152	representative SARS-CoV-2 RNA concentrations in wastewater for one week and the log_{10} values
153	of the confirmed COVID-19 cases for one week (hereafter, a correlation represents that between
154	SARS-CoV-2 RNA concentration in wastewater and the confirmed COVID-19 cases unless
155	otherwise noted). To examine the treatment of non-detect data and the method for calculating
156	representative values, the correlation coefficients were analyzed as follows: First, the non-detect
157	data were replaced with four types of values: (1) LOD, (2) LOD/2, (3) LOD/ $\sqrt{2}$, and (4) the value
158	corresponding to half of the non-detect rate using the estimated distribution (hereinafter, distribution
159	estimates). The replacement values for (1)-(3) are often used, as previously reported (Croghan and
160	Egeghy, 2003). The replacement value for (4) was calculated using the maximum likelihood method,

161	assuming a lognormal distribution for all 1,830 left-censored data points. The R package "NADA"
162	was used to estimate the distribution (Lee, 2022; R Development Core Team, 2021). The arithmetic
163	mean, geometric mean, and median values were calculated for one week using the dataset with non-
164	detect data replaced in this manner. Conditions with high correlation coefficients were extracted
165	using a comprehensive notifiable disease surveillance data set ($n = 1,515$) with a range of -7 to $+14$
166	days (time lag) from the representative date of wastewater sampling to the published date of the
167	confirmed COVID-19 cases. For this analysis, three types of corrections were calculated: (a) LOD
168	= 93.1 copies/L without correction by PMMoV; (b) $LOD = 93.1$ copies/L with correction by
169	PMMoV (using the ratio of SARS-CoV-2 RNA concentration to PMMoV RNA concentration
170	instead of SARS-CoV-2 RNA concentration); and (c) LOD = 9,310 copies/L and without correction
171	by PMMoV.
172	Based on this analysis, the following conditions were used to calculate correlation coefficients in
173	subsequent analyses: replacement by distribution estimates, calculation of the geometric mean, no
174	time lag (+0 days), and no correction using PMMoV (detailed in Section 3.1).
175	

176 2.3. Correction of sentinel surveillance data (Preliminary analysis 2)

In the analysis using the sentinel surveillance dataset, the relationship between virus concentration and confirmed COVID-19 cases changed before and after the legal reclassification of COVID-19 in Japan, which might have resulted in behavioral changes in individuals visiting health facilities. Therefore, a multiple regression analysis was conducted with confirmed COVID-19 cases (log₁₀) as

181	the objective variable and SARS-CoV-2 RNA concentration (log_{10}) and a dummy variable for
182	reclassification as explanatory variables. The dummy variable was set to 0 for the period before
183	reclassification and 1 for the period after reclassification. IBM SPSS version 28 was used for all the
184	analyses. Based on these results, in subsequent analyses, the confirmed COVID-19 cases per
185	sentinel medical (\log_{10}) after the reclassification was treated as a corrected value by doing +0.32
186	(detailed in Section 3.2).
187	
188	2.4. Assessment of survey methods based on correlations with the confirmed COVID-19 cases
189	Main analyses 1–4 were conducted to determine the sampling frequency, survey duration, analytical
190	sensitivity, and analytical reproducibility required to adequately explain the number of infected
191	individuals.
192	
193	Main analysis 1: analytical sensitivity and sampling frequency
194	Conditions with LODs of 93.1, 186.2, 465.5, 931, 1,862, 4,655, 9,310, 18,620, and 46,550 copies/L
195	(corresponding to 1, 2, 5, 10, 20, 50, 100, 200, and 500 times the actual values in the dataset,
196	respectively) were established. Hypothetically, by resetting these LODs, the data were treated as
197	non-detect (for example, data detected as 100 copies/L were considered non-detect under the
198	condition of an LOD of 186.2 copies/L). For each condition, as described in Section 2.2,
199	
	replacement values based on distribution estimation for left-censored data were used as non-detect

201	Furthermore, under these LOD conditions, 1–15 samples were assumed to be collected weekly. This
202	corresponds to a hypothetical reduction in the total sampling frequency to 15 samples per week. The
203	catchment areas and days of the week to be sampled were randomly determined according to the
204	sampling frequencies and fixed for the duration of the WBE survey (same as in Main analysis 2 to
205	4).
206	
207	Main analysis 2: Multiple catchment areas on the same day of the week and same catchment areas
208	on multiple days of the week
209	Given that two or three samples were collected per week, the analysis compared collection in two or
210	three catchment areas on the same day of the week with collection in identical catchment areas two
211	or three times per week. The catchment areas and days of the week were randomly determined
212	according to the sampling frequencies from the five catchment areas or three days of the week.
213	
214	Main analysis 3: Survey duration and sampling frequency
215	Different survey durations of 101, 12, 25, 50, and 75 weeks were established from a comprehensive,
216	notifiable disease surveillance dataset. The first week of the survey was randomly selected, and
217	consecutive weeks were selected. The sampling frequency was analyzed from 1 to 15, as in the
218	Main analysis. Only comprehensive, notifiable disease surveillance data were used in this analysis.
219	

11

Main analysis 4: Analytical reproducibility and sampling frequency

221	The analysis assumed conditions under which the analytical reproducibility of SARS-CoV-2 RNA
222	concentrations varied. In accordance with a previous report (Ando et al., 2022), the standard
223	deviation of this dataset was conservatively regarded as 0.4 at log ₁₀ values. Since the number of
224	analyses in this dataset was one for each sample, the "true value" was estimated from the normal
225	distribution when the "measured value" at log_{10} values was taken as the arithmetic mean and the
226	standard deviation as 0.4. The hypothetically measured values were then estimated with standard
227	deviations of 0.4, 0.6, 0.8, and 1, respectively. The sampling frequency was analyzed from 1 to 15,
228	as in the Main analysis 1.
229	
230	Under all conditions, the correlation coefficient between the SARS-CoV-2 RNA concentration in
231	wastewater and the confirmed COVID-19 cases for one week was calculated using Monte Carlo
232	simulations with 10,000 iterations for each. Oracle Crystal Ball version 11.1.2.4.900 was used for
233	analysis. The arithmetic means and 95% uncertainty intervals calculated from the 2.5th and 97.5th
234	percentile values among the 10,000 iterations were used. The conditions were extracted such that
235	the 2.5th percentile value was greater than 0.7.
236	

237 **3. Results**

3.1. Treatment of non-detect data and determination of a method for calculating representative
values

240 Figure 2 presents the results of the Preliminary analysis 1. With regard to the treatment of non-

241	detect data, high correlation coefficients were obtained when the data were replaced with
242	distribution estimates, or LOD/2. The correlation coefficients were high when the geometric mean,
243	or median, was used to calculate representative values. Generally, the correlation coefficient was
244	greatest when the time lag was approximately zero. PMMoV correction did not significantly affect
245	the correlation coefficients.
246	Figure 3(a) shows a scatter plot of SARS-CoV-2 RNA concentrations and confirmed COVID-19
247	cases in the comprehensive notifiable disease surveillance under the conditions of replacement by
248	distribution estimates, calculation of geometric mean, no gap (+0 days), and no correction of SARS-
249	CoV-2 RNA concentrations by PMMoV. The correlation coefficient was as high as 0.87, and the
250	slope of the regression equation using the logarithm of both SARS-CoV-2 RNA concentrations and
251	confirmed COVID-19 cases was 0.96, which is close to 1, confirming a linear relationship between
252	them.
253	
254	3.2. Determination of correction values for sentinel surveillance data
255	Multiple regression analysis (Preliminary analysis 2) showed that the unstandardized partial
256	regression coefficients (95% confidence interval) for SARS-CoV-2 RNA concentration and
257	reclassification were 0.80 (0.63–0.97) and -0.32 (-0.50–-0.14), both significant. A scatter plot of

- 258 SARS-CoV-2 RNA concentrations and corrected confirmed COVID-19 cases is shown in Figure
- 259 3(b). The correlation coefficient and slope of the regression equation were 0.86 and 0.80,
- 260 respectively, confirming a strong linear relationship between SARS-CoV-2 RNA concentrations in

3.3. Effects of sampling frequency, survey duration, analytical sensitivity, and analytical

261 wastewater and confirmed COVID-19 cases, even in the sentinel surveillance data.

reproducibility on the correlation with the confirmed COVID-19 cases

262

263

264

The results of Main analysis 1 showed that the correlation coefficients decreased as the sampling 265 frequencies decreased for both comprehensive notifiable disease surveillance and sentinel 266 surveillance data (Figure 4). Large differences in correlation coefficients were found between one 267 and two samples per week, and three samples per week showed high correlation coefficients similar 268 to those of more frequent sampling under the measurement condition of LOD = 93.1 copies/L (2.5th 269 percentile values: 0.80 for comprehensive notifiable disease surveillance and 0.76 for sentinel 270 surveillance). The correlation coefficients decreased as the LOD value increased (i.e., as the non-271 272 detect rate increased): in the comprehensive notifiable disease surveillance data, there was no large 273 difference in the correlation coefficients for the measurement conditions with LOD between 93.1 and 931 copies/L (non-detect rate: 13-31%), but the correlation coefficients decreased as the LOD 274 increased from 1,862 copies/L (non-detect rate: 42%). Fifteen samples per week, with an LOD of 275 276 1,862 copies/L, did not show a higher correlation than two samples per week, with an LOD of 93.1 277 copies/L. In the sentinel surveillance data, no large differences in the correlation coefficients were 278 found between 93.1 and 9,310 copies/L for the LOD (non-detect rate: 0.4–34%), but the correlation coefficients decreased when the LOD was greater than 18,620 copies/L (non-detect rate: 54%). For 279 both comprehensive notifiable disease surveillance and sentinel surveillance data, the 2.5th 280

281 percentile values of the correlation coefficients exceeded 0.7 for the three samples per week when

the non-detect rate was less than 40%.

300

283 Regarding Main analysis 2, no large differences in the correlation coefficients were found between 284 multiple catchment areas on the same day of the week and identical catchment areas on multiple days of the week (Figure 5), although slightly less variation in the correlation coefficients existed 285 286 for two or three samples per week in the same catchment area than for sampling once per week in two or three catchment areas. The 2.5th percentile values of the correlation coefficients exceeded 287 0.7 for both sampling once at three catchment areas per week and sampling three times at one 288 289 catchment area per week. In Main analysis 3, the 12-week surveys had lower correlation coefficients and wider uncertainty 290

intervals (Figure 6). Compared to the 50-week or longer surveys, the 25-week surveys had similar arithmetic mean correlation coefficients but lower 2.5th percentile values. The 2.5th percentile values in the 50-week or longer surveys with three or more samples per week exceeded 0.7.

In Main analysis 4, as the standard deviation increased, the correlation coefficients decreased (Figure 7). In particular, the uncertainty interval widened with an increase in standard deviation when the number of samples per week was small. In the comprehensive notifiable disease surveillance data, the 2.5th percentile values of the correlation coefficients exceeded 0.7 when the standard deviation was 0.4, with three or more samples per week. In the sentinel surveillance data, the arithmetic mean value of the correlation coefficient was below 0.7 for three samples per week.

The 2.5th percentile value of the correlation coefficient was 0.66 and 0.71 for the five- and seven-

301 weekly surveys, respectively.

302

303 4. Discussion

Using high analytical accuracy and intensive surveys as the gold standard for WBE, this study identified the treatment of non-detect data and the appropriate method for calculating representative values, and analyzed the impact of sampling frequency, survey duration, analytical sensitivity and analytical reproducibility on the correlation between SARS-CoV-2 RNA concentration in wastewater and confirmed COVID-19 cases.

309 First, a preliminary analysis identified the appropriate treatment for non-detect data and the 310 appropriate method for calculating representative values. The validity of treating non-detect data 311 using distribution estimates has been discussed in a previous report (Croghan and Egeghy, 2003). 312 In this study, correlation coefficients were calculated by log-transforming virus concentrations in 313 wastewater and confirmed COVID-19 cases. Therefore, it is reasonable to use geometric means or 314 medians rather than arithmetic means to calculate representative values. The PMMoV correction did not improve the correlation with confirmed COVID-19 cases, which is consistent with the findings 315 316 of our previous study (Ando et al., 2023). The present study performed the main analyses with a 317 time lag of 0 days, which did not negate the early detectability of WBE. In this study, the data were 318 merged into one-week data to calculate representative values, which indicated that it was not 319 necessary to consider the time lag. The early detection of COVID-19 by the WBE in the same catchment area in this study has been demonstrated in detail in our previous report (Ando et al., 320

321	2023). When non-detect data were treated in this manner and representative values were calculated,
322	strong correlations between SARS-CoV-2 RNA concentrations in wastewater and confirmed
323	COVID-19 cases were observed (comprehensive notifiable disease surveillance: $r = 0.87$, sentinel
324	surveillance: $r = 0.86$). The slope with log-transformed data was almost 1, confirming that the WBE
325	was sufficient to determine the COVID-19 infection incidence in the catchment area. Interestingly,
326	sentinel surveillance data showed a 0.32 decrease in confirmed COVID-19 cases at log_{10} values
327	after reclassification. No major change in the prevalence of SARS-CoV-2 variants was observed
328	during this period (Our World in Data, 2024). This suggests that the reclassification of COVID-19
329	led to a change in individuals' healthcare-seeking behaviors, such as hesitation in receiving medical
330	examinations, and that the number of confirmed COVID-19 cases captured by clinics decreased by
331	half (i.e., $10^{-0.32} = 48\%$). This study highlights that the WBE can provide a good picture of the
332	incidence of infection in catchment areas, even when changes in people's consultation behavior
333	occur.

Regarding the analytical sensitivity, a decrease in the correlation coefficients was observed with increasing LOD values (Main analysis 1). In particular, both comprehensive notifiable disease surveillance and sentinel surveillance data showed large decreases in correlation coefficients when the non-detect rate exceeded 40%. Therefore, it is desirable to conduct the analysis with a sensitivity that the non-detect rate does not exceed 40%. The non-detect rate depends not only on the LOD but also on the incidence of infection. This result indicates that it is desirable to use a dataset with a non-detect rate of < 40% (which is more achievable with high-sensitivity methods) to

341	discuss correlations with COVID-19 cases. Ando et al. (2023) reported that a 50% probability of
342	detection corresponded to 0.69 out of 100,000 confirmed COVID-19 cases per day when the
343	EPISENS for membrane (EPISENS-M) method with the LOD of 43.9 copies/L was used for SARS-
344	CoV-2 RNA detection from wastewater.
345	Regarding the sampling frequency, large differences in the correlation coefficients existed between
346	one and two or more samples per week (main analyses 1, 3, and 4). This is consistent with the
347	findings of a previous study (Kuroita et al., 2024). In particular, for both comprehensive notifiable
348	and sentinel surveillance data, a sampling frequency of three or more times per week achieved a
349	2.5th percentile value of correlation coefficients greater than 0.7 when the non-detect rate was $<$
350	40% (Main analysis 1). With three samples per week, no large difference in the correlation
351	coefficients existed between three-day sampling in the same catchment area and one-day sampling
352	in three different catchment areas (Main analysis 2). When the standard deviation of the analysis
353	was 0.4 (Main analysis 4), it was considered possible to survey at least five samples per week given
354	that the correlation coefficient was low for the three-weekly surveys in the sentinel surveillance data.
355	Regarding survey duration, the correlation coefficient was notably low at 12 weeks (Main Analysis
356	3). At three samples per week, the 2.5th percentile values of the correlation coefficients exceeded
357	0.7 at 50 weeks or more. To determine the incidence of COVID-19 infection in the catchment area
358	by the WBE, a survey period that included 50 weeks or more would be necessary. This number of
359	"50 weeks" as survey duration may depend on the number of infection waves as well as the number
360	of data plots to discuss the correlation between virus concentration in wastewater and infection

361	incidence. During the comprehensive, notifiable disease surveillance period, approximately two
362	infection waves were observed over 50 weeks. High correlation coefficients were also observed in
363	other analyses using sentinel surveillance data (49 weeks with two infection waves: Preliminary
364	analysis 1 and Main analysis 1).
365	Regarding analytical reproducibility (Main analysis 4), when the standard deviations of the analysis
366	were large, the uncertainty intervals were wide, particularly for a small number of samples. The
367	2.5th percentile values of the correlation coefficients were below 0.7 when the standard deviation
368	was 0.6 or more for the three samples per week. A standard deviation of 0.4 or less was considered
369	desirable in terms of analytical reproducibility.
370	Overall, it is considered desirable to use an analytical method that can quantify SARS-CoV-2 RNA
371	in wastewater samples with high detectability and reproducibility (non-detect rate: < 40%; standard
372	deviation: ≤ 0.4) and to survey at least three samples per week, preferably five or more samples, for
373	50 weeks or more.
374	This study has some limitations: First, although this study focused on wastewater survey methods, it
375	did not examine clinical factors (e.g., COVID-19 prevalence or testing coverage) or environmental
376	factors (e.g., air temperature or catchment population). Second, among the wastewater survey
377	methods, this study did not examine factors that affect virus recovery rates during the analytical
378	process, such as polymerase chain reaction inhibition. Third, the findings of this study were based
379	on the City of Sapporo, and there is room for further research on the applicability of these findings
380	to other catchment areas. The analyses examined in this study are expected to expand to various

catchment areas, and the accumulation and integration of results will increase the generality of thefindings.

385	The use of the WBE is sufficient to determine the incidence of COVID-19 in catchment areas.
386	Furthermore, the WBE can present additional informational value with respect to understanding the
387	infection incidence of a catchment, as estimated by the 48% reduction in confirmed COVID-19
388	cases visiting health facilities after the reclassification of COVID-19 in Japan.
389	By examining the correlation between SARS-CoV-2 RNA concentrations in wastewater and
390	confirmed COVID-19 cases under hypothetical conditions in which the quality of wastewater
391	survey methods has declined, this study identified WBE survey methods that are necessary for
392	understanding the infection situation in a catchment. The findings of the appropriate WBE survey
393	methods obtained in this study are as follows:
394	• Non-detect data should be replaced by distribution estimates (or LOD/2).
395	• The geometric mean (or median) should be used to calculate representative values.
396	• A quantifiable and highly reproducible method (non-detect rate: < 40%; standard deviation: \leq
397	0.4) is necessary for the analysis of SARS-CoV-2 RNA in samples.
398	• The sampling frequency required is at least three samples per week, preferably five samples per
399	week.
400	• Surveys need to be conducted for a period of time that includes at least 50 weeks or longer.

Figure 1. Temporal changes of SARS-CoV-2 concentrations in wastewater and confirmed COVID19 cases. (a) Comprehensive, notifiable disease surveillance data; (b) sentinel surveillance data. The

510 SARS-CoV-2 RNA concentration in wastewater was calculated based on the geometric mean values

511 for one week (15 samples). The non-detect data were replaced using the distribution estimates.

512

Figure 2. Comparison of Pearson's correlation coefficients (*r*) based on treatment of non-detect data and different methods of calculating representative values. (a) Without PMMoV correction, limit of detection (LOD) = 93.1 copies/L; (b) with PMMoV correction, LOD = 93.1 copies/L; and (c) without PMMoV correction, LOD = 9,310 copies/L. Time lag represents the "published date of the number of infected individuals" minus the "representative date of wastewater sampling." LOD/2, LOD/ $\sqrt{2}$, and LOD estimated represent the replacement of LOD values by LOD/2, LOD/ $\sqrt{2}$, and distribution estimates, respectively.

524 Figure 3. Scatterplots of SARS-CoV-2 RNA concentration vs. confirmed COVID-19 cases. (a)

525 Comprehensive, notifiable disease surveillance data; (b) sentinel surveillance data. r: Pearson

526 correlation coefficients.
