## Abstract

Genome-wide association studies (GWAS) traditionally analyze single traits, e.g., disease diagnoses or biomarkers. Nowadays, large-scale cohorts such as the UK Biobank (UKB) collect imaging data with sample sizes large enough to perform genetic association testing. Typical approaches to GWAS on high-dimensional modalities extract predefined features from the data, e.g., volumes of regions of interest. This limits the scope of such studies to predefined traits and can ignore novel patterns present in the data. TransferGWAS employs deep neural networks (DNNs) to extract low-dimensional representations of imaging data for GWAS, eliminating the need for predefined biomarkers. Here, we apply transferGWAS on brain MRI data from the UKB. We encoded 36,311 T1-weighted brain magnetic resonance imaging (MRI) scans using DNN models trained on MRI scans from the Alzheimer’s Disease Neuroimaging Initiative, and on natural images from the ImageNet dataset, and performed a multivariate GWAS on the resulting features. Furthermore, we fitted polygenic scores (PGS) of the deep features and computed genetic correlations between them and a range of selected phenotypes. We identified 289 independent loci, associated mostly with bone density, brain, or cardiovascular traits, and 14 regions having no previously reported associations. We evaluated the PGS in a multi-PGS setting, improving predictions of several traits. By examining clusters of genetic correlations, we found novel links between diffusion MRI traits and type 2 diabetes.

## 1 Author Summary

Genome-wide association studies are a popular framework for identifying regions in the genome influencing a trait of interest. At the same time, the growing sample sizes of medical imaging datasets allow for their incorporation into such studies. However, due to high dimensionalities of imaging modalities, association testing cannot be performed directly on the raw data. Instead, one would extract a set of measurements from the images, typically using predefined algorithms, which has several drawbacks - it requires specialized software, which might not be available for new or less popular modalities, and can ignore features in the data, if they have not yet been defined. An alternative approach is to extract the features using pretrained deep neural network models, which are well suited for complex high-dimensional data and have the potential

39 to uncover patterns not easily discoverable by manual human analysis. Here, we extracted deep  
40 feature representations of brain MRI scans from the UK Biobank, and performed a genome-  
41 wide association study on them. Besides identifying genetic regions with previously reported  
42 associations with brain phenotypes, we found novel regions, as well as ones related to several  
43 other traits such as bone mineral density or cardiovascular traits.

## 44 2 Introduction

45 The growing size of medical imaging datasets within biobanks is increasing the power of genome-  
46 wide association studies (GWAS) performed on such modalities. For example, the number of  
47 associated loci found in a GWAS of phenotypes derived from brain magnetic resonance imaging  
48 (MRI) data in the UK Biobank (UKB) increased over 4-fold between the initial study of Elliott  
49 et al. [14] and the consecutive study of Smith et al. [49]. The initial approaches to imaging GWAS  
50 were based on the extraction of predefined image-derived phenotypes (IDPs) [14, 49, 43]. While  
51 being interpretable, such analyses require the availability of automated tools for IDP extraction  
52 for the modality of interest and are limited to traits defined a priori, potentially preventing novel  
53 genetically-driven phenotypes from being discovered.

54 Instead of using manually defined traits, a recent line of work employed deep learning (DL) to  
55 derive imaging features using pretrained deep neural network (DNN) models to perform GWAS  
56 on. This approach has been demonstrated to be successful in a range of imaging modalities,  
57 including retinal fundus images [24, 53], cardiovascular magnetic resonance (CMR) images [3, 4],  
58 or brain MRI scans [39]. In this work, we perform an imaging GWAS on  $N = 36,311$  T1-weighted  
59 brain MRI scans from the UKB dataset. As opposed to the ENDO approach of Patel et al.  
60 [39], who pretrained a DNN on data from the same dataset where the GWAS was performed, we  
61 employed the transferGWAS pipeline of Kirchler et al. [24] and used two DNN models pretrained  
62 on other datasets, following a transfer learning methodology. We encoded the brain scans using  
63 models pretrained on the ImageNet [48] and Alzheimer’s Disease Neuroimaging Initiative (ADNI)  
64 datasets [35], with the former extracting “general” image features and the latter focusing on brain  
65 MRI and dementia-specific ones. Our GWAS performed on these features identified a number  
66 of loci not detected in the IDP or ENDO brain MRI studies, several of which were not reported  
67 in any previous GWA studies. We further conducted downstream analyses using the discovered  
68 genetic variants, demonstrating their utility in creating more predictive polygenic score (PGS),  
69 and pointing to novel genetic correlations between type 2 diabetes (T2D) and diffusion magnetic  
70 resonance imaging (dMRI) traits (see Fig 1 for an overview of our workflow).

## 71 3 Results

### 72 3.1 Interpretation of the DNN Features

73 In order to interpret the signal carried by the DNN features, we extracted the first 10 princi-  
74 pal components (PCs) of both DNN models, and performed a phenome-wide association study  
75 (PheWAS) against each PC and 7,744 UKB phenotypes (supplementary Table S2). We found  
76 2,408 and 2,622 significantly associated phenotypes for the ImageNet and ADNI PCs respec-  
77 tively, having P-values below the Bonferroni-corrected threshold of  $\approx 6.5 \cdot 10^{-7}$ . Fig 2 shows  
78 the percentage of significantly associated traits per category. The top 35 categories with the  
79 highest ratio of significant hits contained 17 brain-related categories, with the other ones being  
80 bone density, body composition, or blood-related categories. In almost all cases the ADNI PCs  
81 were associated with a higher number of phenotypes than the ImageNet PCs.

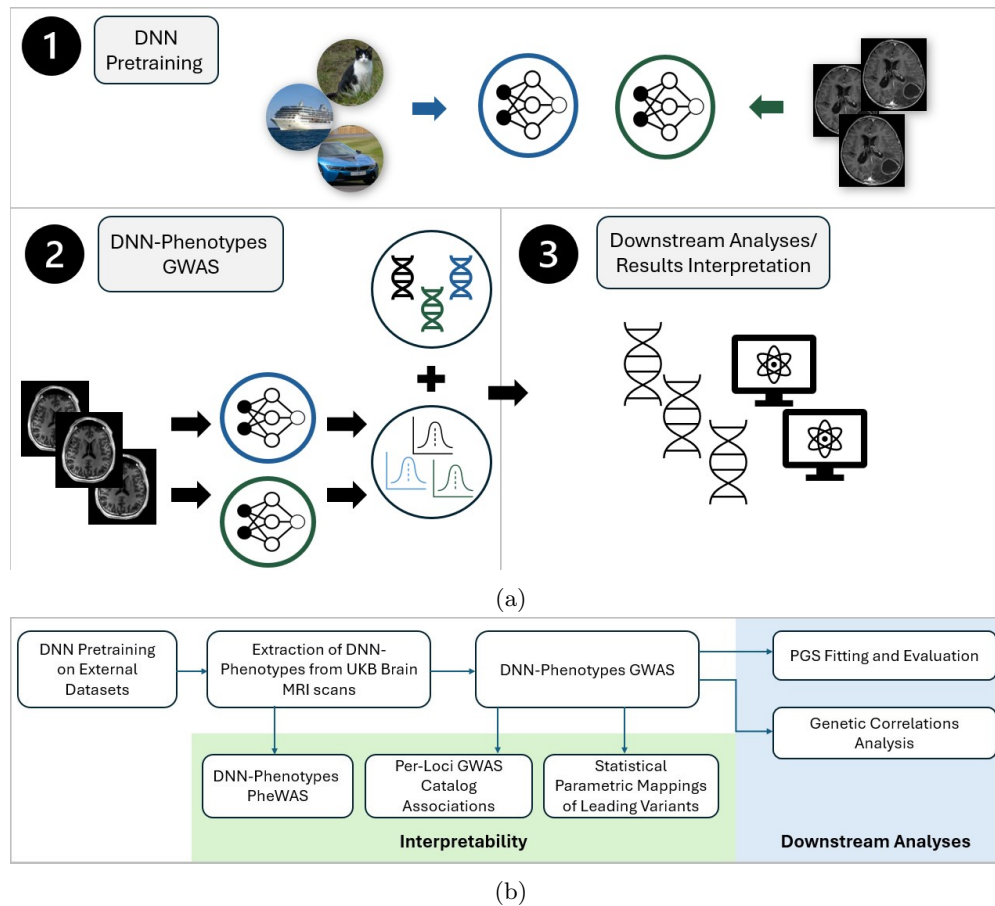

Figure 1: **Overview of our study and workflow.** (a) A general overview of the study: (1) - we pretrained 2 DNN models on external datasets of natural images, and of brain MRI scans (2) - encoded brain MRI data from the target datasets and performed GWAS on the DNN-derived phenotypes (3) performed a series of downstream analyses using the learned DNN features and discovered genetic variants. (b) Description of each step involved in the complete workflow of our study.

Figure 2: Results of the PheWAS performed on the principal components (PCs) of the ImageNet (blue) and ADNI (yellow) pretrained models. For each phenotype category from the UK Biobank (UKB) we plot the number of significant associations per model divided by the total number of traits in that category. Shown are the top 35 phenotype categories with the highest ratio of significant associations.

## 82 3.2 GWAS Results

83 At the Bonferroni-corrected significance threshold of  $2.5 \cdot 10^{-9}$ , we found 4,665 peak associations  
 84 for the ImageNet and 5,291 for the ADNI pretrained models, resulting in 4,382 and 4,360  
 85 distinct variants for ImageNet and ADNI. The clumping procedure then identified 194 and 165  
 86 independent regions for the ImageNet and the ADNI models respectively. This amounted to  
 87 7,458 distinct variants and 289 distinct regions across all 20 features of both DNN models. Fig 3  
 88 shows the Manhattan plots for both models, aggregated over each of the 10 PCs per model.  
 89 We estimated the heritability of each PC using linkage disequilibrium score regression (LDSC)  
 90 (Section 5.5) and found the ADNI-pretrained PCs to be more heritable, with a mean  $h^2 = 0.19$ ,  
 91 and the ImageNet PCs having a mean  $h^2 = 0.13$  (Fig 4). The summary statistics for all PCs are  
 92 made publicly available as a figshare resource under [https://doi.org/10.6084/m9.figshare.](https://doi.org/10.6084/m9.figshare.25933717.v1)  
 93 [25933717.v1](https://doi.org/10.6084/m9.figshare.25933717.v1).

### 94 3.2.1 GWAS Catalog Associations

95 For each independent locus, we queried associations reported in previous GWA studies from the  
 96 NHGRI-EBI GWAS Catalog [7] (Fig 5). The dominating phenotype categories included bone  
 97 mineral density (BMD)-related traits and a range of brain traits, such as cortical thickness,  
 98 diffusion, or volumes of brain regions of interest (ROIs). We note that the ADNI-pretrained  
 99 features tagged more regions corresponding to brain-related traits, whereas the ImageNet model

Figure 3: Manhattan plots for the GWAS ( $n = 36,311$  individuals, 16,472,121 SNPs) performed on features of the ImageNet (plot *a*) and the ADNI (plot *b*) pretrained models. The horizontal lines mark the initial significance threshold of  $5 \cdot 10^{-8}$  (dashed line) and Bonferroni-corrected threshold of  $2.5 \cdot 10^{-9}$  (solid line). For visualization purposes we truncate P-values below  $10^{-40}$  and plot only the minimal P-values across each of the 10 features per model.

100 tagged more regions related to “general” body structure, such as BMD, height, or body mass  
101 index (BMI). Overall, out of the 289 independent loci, 72 did not have brain-related associations  
102 reported in the catalog.

103 Among neuropsychiatric disorders with the highest number of distinct regions, 47 were asso-  
104 ciated with schizophrenia, 37 with neuroticism, 36 with attention deficit hyperactivity disorder,  
105 35 with bipolar disorder, 33 with depression, 32 with Alzheimer’s disease, 30 with autism, 22  
106 with anorexia nervosa and 21 with anxiety.

107 3 out of the 10 first traits were not directly brain-related: heel bone mineral density (HBMD)  
108 (144 regions), total BMD (125 regions), and height (113 regions). The associations between BMD  
109 and the brain have been investigated in the context of neurological disorders [29, 30, 54], as well  
110 as in samples of healthy subjects [2]. Loskutova et al. [29, 30] reported a correlation between  
111 BMD and an early onset of Alzheimer’s disease (AD), as well as with several brain volumes.  
112 HBMD is postulated to be a causal factor for multiple sclerosis (MS) through an increased risk  
113 of fractures [54]. Bae et al. [2] showed that osteoporosis increases the pace of parenchymal  
114 atrophy and ventricular enlargement during aging of healthy individuals.

115 Another prevalent category were blood-related traits, such as cell counts: white (67), red  
116 (32), monocyte (45), neutrophil (41), eosinophil (40), lymphocyte, (25) reticulocyte (23), blood  
117 pressure (95) or hypertension (45), or hemoglobin (68). Blood pressure and hypertension are  
118 known factors influencing brain morphology, as well as cognitive performance or dementia [50,  
119 13, 15, 45], while anemia is a causal factor for cognitive decline and AD [40, 52].

### 120 3.2.2 Novel Loci

121 In total, we found existing associations for 275 regions in studies conducted on the British  
122 population, and 278 regions among all populations. Out of the remaining 11 loci, one was located  
123 within an RNA gene, and 10 within 7 distinct protein-coding genes. Among the associated  
124 phenotypes, 6 genes were associated with mental or neurodevelopmental disorders such as AD,  
125 schizophrenia, or attention-deficit/hyperactivity disorder (ADHD), and 4 genes were associated  
126 with T2D.

127 As a further means of interpreting the novel regions, we computed statistical parametric  
128 mappings (SPMs) for each leading single-nucleotide polymorphism (SNP) (Fig 6) and computed  
129 the fractions of volume of each brain region correlated with each lead variant (Fig 7). All SNPs

Figure 4:  $h^2$  heritability estimates of principal components (PCs) of the ImageNet (blue) and ADNI (yellow) pretrained models, obtained using linkage disequilibrium score regression (LDSC). Black lines indicate the standard error of the estimates.

130 were correlated with the left cerebral cortex and cerebrospinal fluid. Most notable was the variant  
 131 rs111469125 (16:87268090) located inside the C16orf95 gene, being correlated with 19 out of 22  
 132 brain regions, in particular with several ventricle structures: the 3rd and 4th ventricles (3% of  
 133 total voxels), and the left and right lateral ventricles (1% and 1.5% of total voxels). It was also  
 134 correlated with 3% of the voxels of cerebrospinal fluid, and was the only new variant correlated  
 135 with the left cerebellum white matter, the left thalamus, and the right caudate.

### 136 3.2.3 Comparison with Previous Studies

137 We performed another GWAS using discovery and replication cohorts (23,604 and 12,709 sam-  
 138 ples), replicating 1,631 hits over 1,510 unique variants, which amounted to 70 replicated loci. We  
 139 compared our results with two GWA studies on UKB brain MRI data - the first one using 3,144  
 140 brain imaging-derived phenotypes [49] and the second study using 256 DL-based features [39],  
 141 which yielded 692 and 43 replicated loci respectively. Out of our 70 replicated loci, 9 were not  
 142 present in the 692 of Smith et al. [49], and 28 were not present in the 43 loci of Patel et al. [39].

### 143 3.3 TransferGWAS Polygenic Scores

144 Here, we evaluated the potential of variants discovered in our study for downstream prediction  
 145 of phenotypes using 20 PGS fitted for each of the 20 DNN PCs with the summary statistics  
 146 from our GWAS. In order to compute the features of the DNN models, imaging data need to be  
 147 present, which constitutes less than a tenth of all UKB samples. On the other hand, genotyping

Figure 5: Number of independent loci per trait with associations reported in previous studies included in the NHGRI-EBI GWAS Catalog [7]. Shown are the top 35 traits with the highest number of associated regions.

148 data were available for all participants. This allowed us to calculate the PGS for all remaining  
 149  $N = 451,450$  participants not included in the GWAS sample. The corresponding methods are  
 150 described in Section 5.4, while the weights of the fitted scores are made publicly available as a  
 151 figshare resource under <https://doi.org/10.6084/m9.figshare.25933663.v1>.

### 152 3.3.1 PGS PheWAS

153 To gain insights into which traits the PGS might be predictive of, we performed a PheWAS on  
 154 the 20 PGS and the 7,744 UKB phenotypes (supplementary Table S2). Note that while the  
 155 “raw” DNN PCs can encode both genetic and environmental signals, the PGS should capture  
 156 only the former, and thus we expected the associations between the phenotypes to differ from the  
 157 PheWAS performed on the PCs. The total number of significant PC-phenotype associations and  
 158 the effect sizes were higher for the original PCs than for the PGS: 28,767 vs. 25,948 significant  
 159 associations in total, 2,928 vs. 2,860 distinct associated traits, with mean effect sizes of  $\beta = 0.08$   
 160 vs.  $\beta = 0.04$ . We identified 3 potentially interesting groups of associations (Fig 8):

- 161 • traits related to BMD
- 162 • weight/fat mass/BMI
- 163 • cardiovascular traits

164 which we decided to investigate further in a prediction setting.

### 165 3.3.2 Predictive Performance Compared to Trait-Specific PGS

166 We tested the utility of our developed PGS by evaluating whether they can improve predictions  
 167 of phenotypes from UKB over PGS designed specifically for particular traits in a multi-PGS

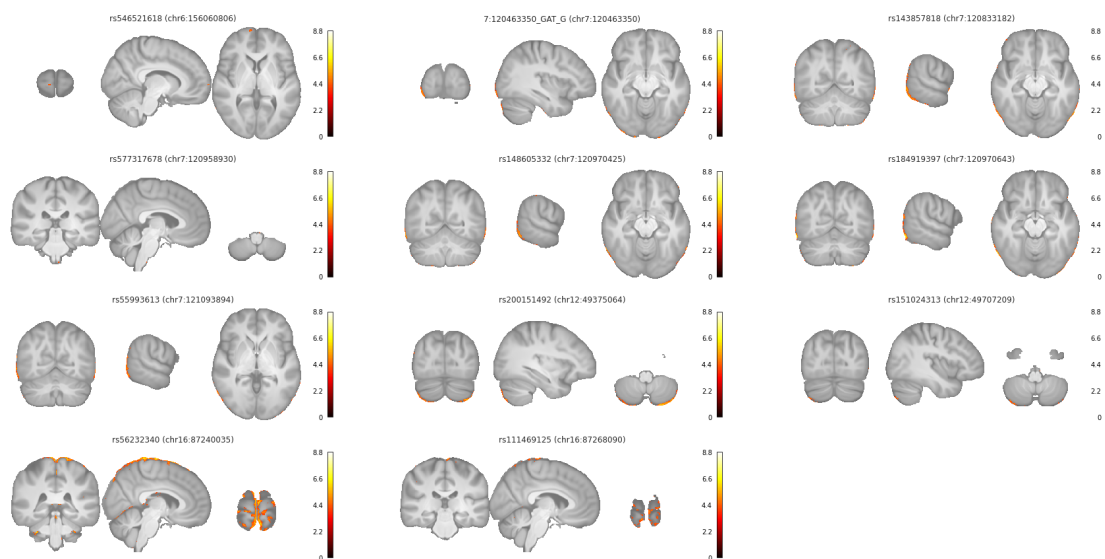

Figure 6: Statistical parametric mappings (SPMs) for genetic regions with no previously reported GWAS associations. Plotted are values of the  $t$ -statistics of the correlation coefficients between lead variants of each region and each single voxel in the MRI scans. We plot values below the Bonferroni-corrected significance threshold accounting for the total number of voxels tested.

168 setting [25]. We chose a set of 9 phenotypes based on the PheWAS results and computed their  
169 corresponding scores using PGS available in the PGS Catalog [26]. For each phenotype, we then  
170 fitted and evaluated two linear models: one fitted using only the trait-specific PGS, and one ad-  
171 ditionally using our transferGWAS PGS. While there were statistically significant improvements  
172 in predictions for 4 out of 9 traits, they yielded arguably small performance increases ( $\sim 1.5\%$   
173 of relative improvement), with the exception of predicting HBMD using a (general) BMD PGS,  
174 where the relative improvement was over 20% (Table 1). We decided to further investigate the  
175 HBMD results. Since the improvement could have been stemming from a lower signal in the  
176 dataset of the external PGS, compared to the UKB, we conducted a further comparison within  
177 the UKB. We performed a GWAS on HBMD using 19,909 samples from our GWAS data which  
178 had HBMD measurements available, and 16,404 randomly drawn from the remaining samples of  
179 the white-british participants, to match the sample size and population of our GWAS, and fitted  
180 a new PGS on the resulting summary statistics. We then evaluated the newly-created HBMD  
181 PGS with and without our transferGWAS PGS on the remaining UKB data and observed the  
182 same relative improvement of 1% in performance ( $p < 0.001$ ). This indicates that transferGWAS  
183 has the potential to identify additional variants for related traits while using the sample size.  
184 We hypothesize that this might be due to certain pleiotropic variants having a larger effect on  
185 the DNN PCs than on HBMD, and thus being able to be detected with our DL GWAS and not  
186 with the HBMD-dedicated GWAS.

### 187 3.4 Genetic Correlations

188 The results of the PheWAS conducted on the learned PCs led us to a set of traits that we  
189 decided to investigate further. In order to analyze the genetic components of the PCs, we  
190 computed genetic correlation coefficients between 102 selected traits and each of the 20 PCs

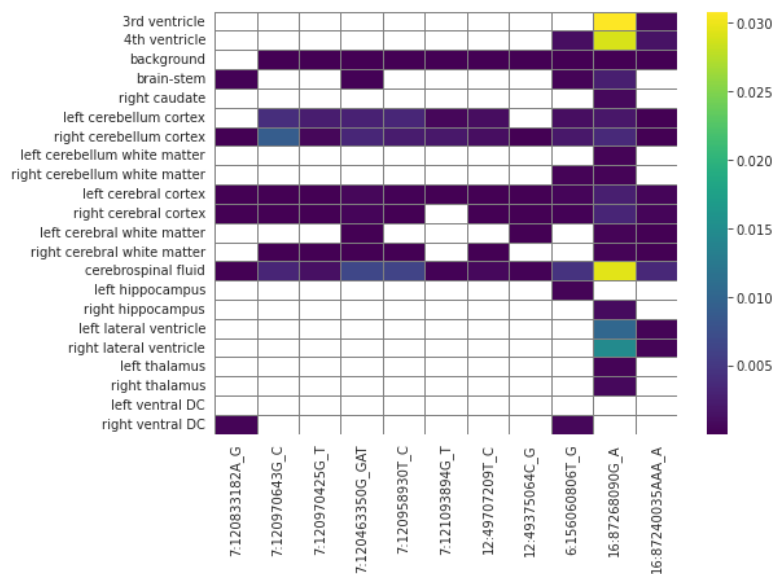

Figure 7: Fractions of volume of brain regions correlated with genetic regions with no previously reported GWAS associations. The values are computed as the total number of voxels in a given brain region significantly correlated with a lead variant, divided by the total number of voxels in that brain region. White cells indicate no voxels being significantly correlated for a given brain region-genetic region pair.

191 (see Section 5.5 for details). 39 traits were significantly correlated, surpassing the Bonferroni-  
 192 corrected threshold of  $\approx 2.5 \cdot 10^{-5}$ . We grouped the traits into 3 groups:

- 193 • (volumes of) brain ROIs (e.g., ventricles, brain stem, cerebrospinal fluid (CSF))  
 194 • dMRI traits (e.g., fractional anisotropy (FA), orientation dispersion index (ODI))  
 195 • “general” traits: Height, T2D, BMI, HBMD

196 Additionally, we tested for correlations with AD, educational attainment, and unipolar depres-  
 197 sion, finding no significant correlations when corrected for multiple testing ( $p > 0.001$ ). The  
 198 significantly associated traits are shown in Fig 9, where we observed several “clusters” of PC-  
 199 trait associations.

200 Several PCs were associated with volumes of multiple brain ROIs. The first two PCs of Ima-  
 201 geNet (IMGNET0, IMGNET1) seemed to capture the overall body size, as they were negatively  
 202 correlated with height and white matter volume, and positively with ventricular ROIs and CSF.

203 PCs ADNI2, ADNI3, and IMGNET4 were genetically associated with volumes of several  
 204 brain ROIs, e.g., cerebral white matter, putamen, or thalamus. ADNI2 and ADNI3 were also  
 205 associated with volumes of CSF and the lateral ventricle. Interestingly, ADNI2 had a positive  
 206 correlation both for CSF and the lateral ventricle, as well as for gray and white matter structures,  
 207 whereas one might expect the ventricular volumes (and thus CSF) to grow with the shrinkage of  
 208 brain structures.

209 PCs associated with HBMD seemed to capture different aspects of brain anatomy. IMGNET2  
 210 had a negative correlation with HBMD, BMI, and cerebral white matter, but also with multiple  
 211 ventricular volumes. On the other hand, ADNI8 and IMGNET4 also had negative genetic  
 212 correlations with HBMD, but positive ones with cerebral white matter.

Figure 8: Results of the PheWAS ( $N = 451,450$ ) between the polygenic scores (PGS) fitted on the features of the DL models (rows) and phenotypes from the UK Biobank (UKB) dataset (columns). Cell colors represent the magnitudes and the signs of the estimated association coefficients between each PGS and phenotype combination.

213 ADNI0 and ADNI4 were associated with a range of Diffusion MRI traits, as well as with  
 214 several ventricular ROIs. Furthermore, ADNI4 was genetically correlated with HBMD and BMI,  
 215 and was the only PC associated with T2D, which we further discuss below.

### 216 3.4.1 ADNI4 and T2D

217 BMI was shown to increase the risk of developing T2D [8, 17], as well as being genetically  
 218 correlated to T2D [8]. The signs of genetic correlations between ADNI4, and BMI and T2D were  
 219 also matching. ADNI4 was also positively genetically associated with HBMD. T2D patients have  
 220 been shown to have a higher bone density [42, 27]. Evidence also exists for shared heritability  
 221 between BMD and T2D, albeit relatively small [47, 55]. As with BMI, the sign of the genetic  
 222 correlation between ADNI4 and HBMD was positive. Regarding the brain ROIs, ADNI4 was  
 223 positively correlated with volumes of the lateral, 3rd, and 4th ventricles, as well as with the  
 224 CSF. Ventricular enlargement and increase in CSF are associated with several neurodegenerative  
 225 diseases, such as AD, MS, or schizophrenia [9, 36]. Several studies showed an association between  
 226 T2D and volumes of white matter structures (whole brain volume, frontal lobe), gray matter  
 227 (overall trend in all structures), as well as CSF and ventricular volumes [33]. Furthermore,  
 228 ADNI4 was genetically correlated with 35 different dMRI traits:

Trait	PGS Catalog	Our PGS + PGS Catalog	$\Delta$
Height	0.759	0.759	0.000
BMI	0.284	0.284	0.000
Heel bone mineral density (1)	0.273	0.275	0.002*
Heel bone mineral density (2)	0.064	0.078	0.014*
Red blood cell count	0.387	0.387	0.000
White blood cell count	0.104	0.106	0.002*
Systolic blood pressure	0.283	0.284	0.000
Diastolic blood pressure	0.175	0.176	0.001*
Ventricular rate	0.027	0.025	-0.001

Table 1: Comparison of predictive performance of Multi-PGS models using only trait-specific polygenic scores (PGS) (2nd column) and including our TransferGWAS PGS (3rd column) for a set of selected phenotypes from UK Biobank (UKB), measured with the  $R^2$  coefficient of determination. Significant differences are marked with (\*). Heel bone mineral density (1) and (2) correspond to results of using PGS for heel bone mineral density, or (general) bone mineral density respectively.

229 **Mean diffusivity (MD) traits** 4 MD traits were positively genetically correlated with ADNI4:  
 230 fornix, superior cerebellar peduncle (both sides), and the superior fronto-occipital fasciculus  
 231 (left). Positive associations between T2D and MD have been found in observational stud-  
 232 ies [19, 46].

233 **Fractional anisotropy (FA) traits** FA traits have been found to be negatively correlated  
 234 with T2D in literature [19, 46, 33]. We found 4 traits to be negatively genetically correlated with  
 235 ADNI4, however the posterior limb of left internal capsule was positively genetically correlated  
 236 with the PC. The direction of this correlation seemed to be in opposition to the associations  
 237 found in observational studies [33]. On the other hand, it is postulated to be causal with the same  
 238 sign for fasting insulin [12], an increase of which is an indicator of T2D. We identified two regions  
 239 containing shared variants located at Chr2:27766284 and Chr14:91881387. The first region con-  
 240 tains missense and intron variants for GCKR gene (ENSG00000133962), a glucokinase regulator,  
 241 with no previously reported associations for brain phenotypes, missense and intron variants for  
 242 C2orf16 (ENSG00000221843) and intron variants for ZNF512 (ENSG00000243943) both protein  
 243 coding genes with association with neurodegenerative diseases, T2D, and blood measurements.  
 244 The second region contains intron variants for the CCDC88C (ENSG00000151133), a protein  
 245 coding gene, with associations with glucose metabolism, brain measurements, and neurodegen-  
 246 erative diseases, and CCDC88C-DT (ENSG00000258798), and RNA gene that is a divergent  
 247 transcript for CCDC88C, with associations with brain measurements and hypertension. The  
 248 above may be another indicator of a non-trivial relation between FA of limb of internal capsule  
 249 and T2D, with potentially different shared heritability and environmental effects.

250 **Orientation dispersion index (ODI) traits** 7 ODI traits were positively correlated with  
 251 ADNI4, while 3 traits were correlated negatively. ODI of white matter tracts was reported to  
 252 be positively correlated with duration of T2D and with levels of HbA1c, a marker for T2D,  
 253 while ODI of internal capsule was reported to have a negative correlation [1], which is consistent  
 254 with 9 out of 10 of our findings. We found a negative genetic correlation for the posterior right  
 255 corona radiata, which had shared variants in regions located at chr8:119486034 and 11:27465591.  
 256 The first region has intron variants for SAMD12 (ENSG00000177570), a protein coding gene

257 with associations with brain measurements, MS, bone density, and blood measurements. The  
 258 second region has intron variants for LGR4 (ENSG00000205213), a protein coding gene with  
 259 associations with brain measurements, bone density, and body mass traits.

260 **Mode of anisotropy (MO) traits** 5 MO traits were genetically positively correlated with  
 261 ADNI4, and 6 negatively. Fasting insulin, a marker for T2D was reported to be negatively  
 262 associated with anterior corona radiata [12]. We found positive genetic correlations between  
 263 both sides of the posterior and superior corona radiata and ADNI4, with shared variants with  
 264 T2D located in the region chr2:27766284 for the superior, and in chr8:119486034 for the posterior.  
 265 The first region contains missense and intron variants for the GCKR and C2orf16 genes, and an  
 266 intron variant for ZNF512 (see the FA regions), and the second region has intron variants for  
 267 SAMD12 (see the ODI regions above). The correlations between the other 7 traits are reported  
 268 in supplementary Table S3.

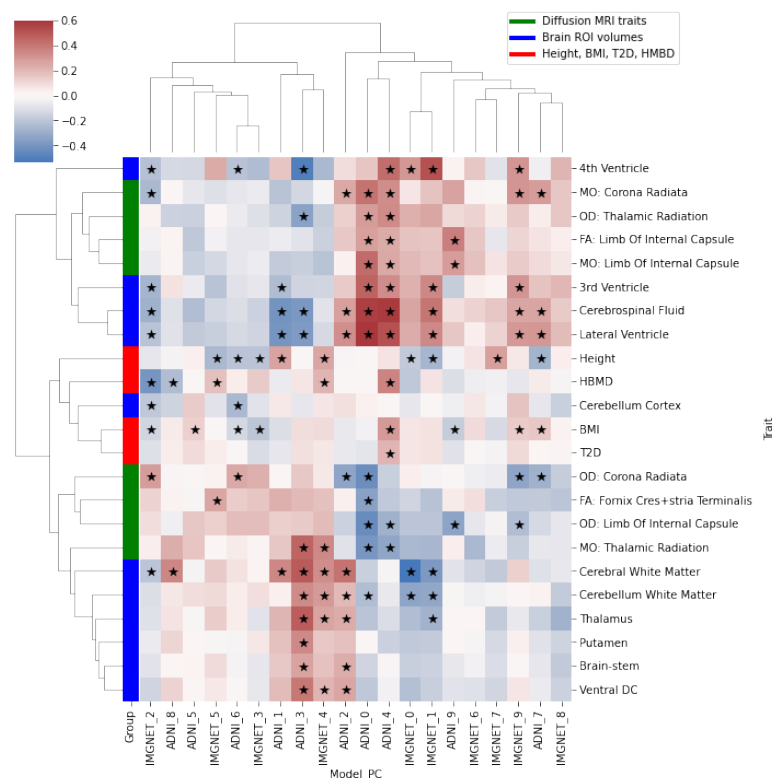

Figure 9: Genetic correlation coefficients between the 20 deep neural network (DNN) principal components (PCs) (rows) and 23 significantly associated phenotypes (columns), out of 27 candidate traits from the UK Biobank (UKB). Cell colors represent the magnitudes and the signs of the estimated genetic correlation coefficients between each PC and phenotype combination.

## 269 4 Discussion

270 Using the transferGWAS approach we performed a GWAS on 20 DNN feature representations  
271 of 36,311 T1-weighted brain MRI scans from the UKB, identifying 289 loci, 11 of them without  
272 any previously reported associations, and 72 without any associations for brain-related traits.  
273 Similar to the findings of the initial transferGWAS study of retinal fundus images of Kirchler  
274 et al. [24], the features of an ImageNet-pretrained model were associated with a higher number  
275 of loci related to “general” body structure traits, such as BMD or BMI, whereas features  
276 from a model pretrained directly on brain MRI data identified more loci corresponding to brain  
277 measurements and neurodegenerative diseases. Overall, features of both DNN models were as-  
278 sociated directly, through PheWAS, or genetically, through GWAS-identified loci, with a large  
279 number of BMD traits. For example, the ImageNet and ADNI-derived features were signifi-  
280 cantly associated with over 50% and 70% of phenotypes under the UKB category 125 “Bone  
281 size, mineral, and density by DXA”, and with over 120 and 40 distinct loci associated “Total  
282 body bone mineral density” in the NHGRI-EBI GWAS Catalog. Detecting these genetic regions  
283 in features derived from brain MRI data seems to confirm the connections between BMD and  
284 brain measurements, as well as with neurodegenerative diseases previously reported in the liter-  
285 ature (as discussed in Section 3.2.1), which we further investigated with an analysis of genetic  
286 correlations (Section 3.4), highlighting particular brain ROIs genetically associated with BMD.  
287 Furthermore, the genetic correlations identified by our study shed more light on the relations  
288 between dMRI measurements and T2D, BMI, as well as cardiovascular traits, also reported in  
289 several studies (Section 3.4.1). Finally, we demonstrated a practical application of our findings  
290 by constructing PGS of our DNN-derived phenotypes, which improved predictions of existing  
291 PGS of BMD, white cell blood count, or diastolic blood pressure. In a further analysis, we fitted  
292 a PGS directly to HBMD measurements on a UKB sample of the same size as our GWAS and  
293 observed the same improvement in performance when augmented with our DNN PGS, indicating  
294 that the transferGWAS approach can identify additional variants for a trait of interest, being  
295 complementary to conducting a trait-dedicated GWAS.

296 We demonstrated how transferGWAS can be applied to discover new variants and in turn,  
297 lead to better phenotype predictions. However, a drawback of using features of pretrained DNN  
298 models as traits of interest is their reduced interpretability compared to predefined phenotypes.  
299 While we analyzed both the DNN-derived traits and the discovered loci with a range of techniques  
300 (PheWAS, querying the GWAS Catalog, SPMs), we highlight the need for further developing  
301 a possibly automated pipeline for interpretability of the DNN features, to foster their utility for  
302 consecutive research and clinical applications.

## 303 5 Materials and Methods

### 304 5.1 Pretraining of the Neural Network Models

305 The first model used for feature extraction was trained on 4,480 T1-weighted scans from the  
306 ADNI dataset [41]. The network architecture was a 3D convolutional variational autoencoder  
307 (VAE) [23], trained in a multi-task manner. The model consisted of 3 sub-networks: an en-  
308 coder, a decoder, and a prediction head. The 256-dimensional outputs of the encoder network  
309 constituted the latent representations of the input data. The first task was the standard VAE  
310 objective, i.e., reconstructing the input scans from the latent representations, while regularizing  
311 the representations to match a standard normal prior distribution with a Kullback-Leibler diver-  
312 gence (KLD) loss term. The second task was to predict the clinical dementia rating (CDR) from  
313 the latent representations. The aim of the VAE objective was to learn general structural features

314 describing an MRI scan, while the prediction task should promote neurodegenerative features  
315 associated with the presence of dementia. Additionally, we input the age and sex of each partici-  
316 pant into the decoder and prediction networks, forcing the model to learn latent representations  
317 invariant to age and sex, and thus potentially increasing the statistical power of the GWAS.  
318 We trained the model for 500 epochs with the Adam optimizer [22], with a mini-batch size of  
319 128. The weights of the reconstruction, KLD, and the predictions loss terms were 1,  $10^{-5}$  and  
320  $10^{-2}$  respectively. For data preprocessing, we skull-stripped each scan using the HD-BET  
321 tool [20], performed a non-linear registration to the MNI152 template with a  $1\text{mm}^3$  resolution  
322 using the FLIRT and FNIRT commands from the FSL software [21], and finally downsampled  
323 the scans to a size of  $96 \times 96 \times 96$  voxels each.

324 Following Kirchler et al. [24], we also employed a 2D ResNet50 [18] model pretrained on  
325 ImageNet, a non-medical dataset of natural images [48]. We used a readily available trained  
326 model from the PyTorch library [38]. We selected the 2048-dimensional output of the penultimate  
327 layer as the latent features used for the GWAS. Since the model was trained on 2D data, we  
328 could not directly extract features from the 3D MRI scans. Instead, for each scan, we computed  
329 the features over each single slice across the axial axis and averaged the results into a single  
330 vector.

## 331 5.2 GWAS

332 We selected a sample of  $N = 36,311$  UKB participants who “self-identified as ‘White British’ and  
333 have very similar genetic ancestry based on a principal components analysis of the genotypes”  
334 (UKB field 22006). We performed the association testing within the linear mixed model (LMM)  
335 framework using the BOLT-LMM software [28]. We adjusted for confounding using age, sex, the  
336 identifiers of the genotyping array and UKB assessment center, and the first 10 genetic principal  
337 components. We filtered the SNPs with the following criteria:  $\text{MAF} \geq 0.1\%$ , Hardy-Weinberg  
338 Equilibrium with a significance level of 0.001, pairwise LD-pruning with  $R^2 = 0.8$ , and maximum  
339 missingness of 10% per SNP and participant, which resulted in 577,570 directly genotyped SNPs.  
340 Including imputed genotype data resulted in 16,472,121 variants in total, on which we performed  
341 the GWAS. We clumped the variants into independent loci using the PLINK software [44], with  
342 a physical distance threshold of 250kb and a significance threshold of  $10^{-9}$  for the index SNPs.  
343 We queried the NHGRI-EBI GWAS Catalog [7] using the LDtrait web application [31], with an  
344  $R^2$  cutoff of  $10^{-1}$  and a 250kb window.

## 345 5.3 PheWAS

346 We performed the PheWAS on the PCs of both pretrained models using the PHEWAS soft-  
347 ware [32], with a P-value threshold of  $\approx 6.5 \cdot 10^{-7}$  from the Bonferroni correction to account for  
348 20 PCs and 7,744 different phenotypes from UKB, adjusting for age and sex.

## 349 5.4 Polygenic Scores

350 We fitted the DNN PGS and the custom HBMD PGS using the PRSCs method [16], with the  
351 prspipe software [37, 34]. For the predictive performance comparison, we queried the PGS  
352 Catalog [26] API for a list of PGS developed for each of the 9 phenotypes, ignoring scores that  
353 used the UKB for development, to avoid data leakage. We then computed scores for the  $N =$   
354 451,450 participants who were not in our GWAS sample using the PGS Catalog Calculator [51].  
355 For each phenotype, we fitted a baseline linear model using all corresponding trait-specific PGS  
356 and covariates (age, sex, UKB assessment center, UKB genotyping batch, all UKB genetic PCs)

357 and another linear model which additionally included our 20 DNN PGS. We used 60% of  
358 the data for model fitting and evaluated it on the remaining 40%. We computed P-values for  
359 differences between achieved  $R^2$  scores of the two linear models using permutation tests with  
360 1,000 permutations, randomly selecting predictions from either model for each test sample in  
361 each permutation.

## 362 5.5 Genetic Correlations

363 To compute the genetic correlation scores between the PCs and selected traits, we used the LDSC  
364 method [6, 5]. We used the provided LD scores precomputed on 1000 Genomes data [10] over  
365 HapMap3 [11] SNPs, and used the default values for other parameters of the LDSC. In order to  
366 find regions potentially contributing to the genetic correlations between ADNI4, T2D, and dMRI  
367 traits (Section 3.4.1), we selected SNPs with a P-value below 0.0001 for which the magnitude  
368 of the product of the z-scores between both ADNI4 and T2D, and ADNI4 and a dMRI trait  
369 exceeded a threshold of 15. For the dMRI traits, we selected pairs where the sign of the product  
370 of the z-scores matched the sign of the genetic correlation with ADNI4. We consider a region a  
371 set of variants within 250,000 base pairs from a “central” variant.

## 372 6 Acknowledgments

373 This research has received funding by the European Commission in the Horizon 2020 project  
374 INTERVENE (Grant agreement ID: 101016775), and was partially funded by the HPI Research  
375 School on Data Science and Engineering.
