ABSTRACT

1 **Allostatic self-efficacy (ASE) represents a computational theory of fatigue and depression. In brief, it postulates that (i) fa-**
2 **tigue is a feeling state triggered by a metacognitive diagnosis of loss of control over bodily states (persistently elevated in-**
3 **teroceptive surprise); and that (ii) generalisation of low self-efficacy beliefs beyond bodily control induces depression.**
4 **Here, we convert ASE theory into a structural causal model (SCM). This allows for identification of empirically testable hy-**
5 **potheses regarding casual relationships between variables of interest. We use conditional independence tests on ques-**
6 **tionnaire data from healthy volunteers (N=60) to identify contradictions to the proposed SCM. Moreover, we estimate two**
7 **causal effects proposed by ASE theory using three different methods.**
8 **Our analyses suggest that, in healthy volunteers, the data are not fully compatible with the proposed SCM. We therefore**
9 **refine the SCM and present an updated version for future research. Second, we confirm the predicted negative average**
10 **causal effect from metacognition of allostatic control to fatigue across all three different methods of estimation.**
11 **Our study represents an initial attempt to refine and formalise ASE theory using methods from causal inference. Our results**
12 **confirm key predictions from the ASE theory but also suggest revisions which require empirical verification in future stud-**
13 **ies.**

14 INTRODUCTION

15 Fatigue is a prominent symptom of major clinical significance in numerous disorders across medical disciplines^{7,44}. It is funda-
16 mentally disabling for patients and profoundly affects their quality of life¹⁰. Fatigue is a common feature across a wide range of im-
17 munological and endocrine disorders, cancer, and neuropsychiatric diseases. In particular, it constitutes one of the core diagnostic
18 criteria of major depression in standard psychiatric classification schemes (ICD-10 and DSM-5;^{2,22}).

19 The clinical concept of fatigue is a heterogeneous construct, and fatiguability of cognitive and motor processes needs to be distin-
20 guished from the subjective perception of fatigue¹⁸. This study focuses on the latter. The pathophysiological mechanisms leading
21 to fatigue are likely diverse¹⁸. Previous theories have focused on a variety of neurophysiological, immunological and inflammatory
22 processes. Unfortunately, there are no mechanistically interpretable clinical tests available for fatigue that could be used to guide
23 individual treatment¹⁸.

24 More recently, a novel perspective on fatigue has been proposed – the allostatic self-efficacy theory (ASE;^{18,27,40}). The ASE theory is
25 based on computational concepts of brainbody interactions^{27,40} which, in turn, are conceptually related to and inspired by Bayesian
26 theories of perception (predictive coding;¹²) and action (active inference;¹³). The ASE theory emphasises the role of two cognitive
27 factors for fatigue: interoception and metacognition.

28 Interoception corresponds to the perception of bodily states and is of major importance for understanding determinants of men-
29 tal health^{15,20}. Many contemporary concepts of interoception are grounded in Bayesian theories of perception and conceptualise
30 interoception as an inference process based on the brain's generative model of sensory inputs from the body^{1,15,27,28,36,37}. More
31 specifically, interoception can be conceptualised as "inferences about bodily (physiological and biochemical) states that are coupled
32 to regulatory processes which serve to control these states"⁴¹. Metacognition can be summarised as cognition about cognition¹¹,
33 comprising a variety of evaluation processes by which the brain monitors its own performance. Building on a generic mathematical
34 model of brainbody interactions, the ASE theory describes how the brain attempts to control bodily states via monitoring interocep-
35 tive surprise (as an index of the degree of dyshomeostasis;⁴⁰).

NOTE: This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

36 In brief, the ASE theory proposes that the subjective experience of fatigue arises when, in a situation of persistent dyshomeostasis
37 (and thus enduringly elevated interoceptive surprise), the brain arrives at the metacognitive diagnosis that its control over bodily
38 states is failing; a condition also referred to as low allostatic self-efficacy. (Put differently, fatigue is a feeling state signalling the im-
39 perative need to rest because regulatory actions fail to resolve dyshomeostasis.) Once a generalisation of low self-efficacy beliefs be-
40 yond the body has taken place, leading to a general sense of helplessness and perceived lack of control, this is postulated to trigger
41 the onset of depression^{33,40}.

42 At present, the ASE theory is arguably the only concept of fatigue that explains its ubiquitous occurrence across chronic disorders.
43 It offers testable predictions based on either (i) computational quantities (prediction error or surprise) which can be estimated from
44 behavioural and/or neurophysiological data or on (ii) self-report data about perceived control over bodily states (metacognition of
45 allostatic control). In this study, we focus on the latter option.

46 Empirically, there is initial evidence that metacognition of allostatic control – as measured by a self-report questionnaire – is inversely
47 associated with fatigue, as predicted by ASE theory³³. However, a comprehensive investigation of the predictions made by the ASE
48 theory is still lacking to date. Furthermore, as almost all disease concepts in psychiatry, ASE theory has been formulated verbally,
49 but not as a precise causal model.

50 Here, we present an initial attempt to tackle the latter issue. To this end, we identify variables of central interest in the ASE theory,
51 namely metacognition of allostatic control (M ; specifically, the feeling of being in control over one's own bodily states), fatigue (F),
52 general self-efficacy (S), and depression (D). We then formalize the causal structure implied by the ASE theory in the language of
53 causal inference, more precisely, in the form of a structural causal model (SCM; ^{5,24,25}). In contrast to classical probabilistic models,
54 an SCM induces not only an observational distribution but also a set of so-called interventional distributions. In other words, an SCM
55 predicts how a system reacts under interventions⁴³. We make use of a publicly available empirical dataset to test key aspects of the
56 structure of the proposed SCM. Moreover, we use established methods for the estimation of average causal effects focusing on cen-
57 tral aspects of the ASE theory.

58 MATERIALS AND METHODS

59 Empirical Dataset

60 In this work, we used data from a previous study conducted at the Translational Neuromodeling Unit (TNU) Zurich, the perception
61 of breathing in the human brain (PBIHB) study; a detailed description of the dataset can be found elsewhere¹⁴. It comprises be-
62 havioural, questionnaire and neuroimaging data from 60 healthy individuals. The questionnaire data used for our analysis are freely
63 available for download from the Zenodo open data repository at <https://doi.org/10.5281/zenodo.10992529>. Participants completed
64 a battery of psychological questionnaires assessing subjective affective measures, both general and breathing-specific subjective
65 interoceptive beliefs as well as measures of general positive and negative affect, resilience, self-efficacy and fatigue.

66 For our analysis, we focused on the following measures as representations of the central quantities of the ASE theory:

- 67 · **fatigue (F)**: Fatigue Severity Scale (FSS)
- 68 · **general self-efficacy (S)**: General Self-Efficacy Scale (GSES)
- 69 · **depression (D)**: Centre for Epidemiologic Studies Depression Scale (CES-D)
- 70 · **metacognition of allostatic control (M)**: Sum of the subscales 3 (not worrying) and 8 (trusting) of the Multidimensional As-
71 sessment of Interoceptive Awareness (MAIA_{3,8}).

72 One important caveat is that, to our knowledge, there does not yet exist a measure that was specifically developed for the construct
73 of M (metacognition of allostatic control, i.e. the feeling of being in control over one's own bodily states). In this study, as a proxy
74 measure, we use the sum of the subscales 3 and 8 of the MAIA questionnaire. These subscales reflect an individual's tendency not
75 to experience distress in response to bodily inputs signalling dyshomeostasis and to perceive the body as a safe place, respectively.
76 The sum of these subscales was used in a previous study testing predictions from ASE theory³³ and may currently represent the
77 best approximation to M that is easily applied in practice.

78 SCM of the ASE theory

79 An SCM^{5,25} over variables $\mathbf{X} = [X_1, \dots, X_n]$ comprises a set of structural equations and distributions of the noise variables (a formal
80 definition of an SCM is provided in Appendix A1). The structural equations together with the noise distributions induce the obser-
81 vational distribution $\mathbb{P}_{\mathbf{X}}$ as simultaneous solution to the structural equations⁴³. In addition to the observational distribution, an SCM
82 induces interventional distributions. Each intervention denotes a scenario in which we fix a certain subset of the variables to a cer-
83 tain value, e.g. $\mathbb{P}_{do(X_1:=x_1)}$.

84 Under assumptions of linearity and normality, the SCM of the ASE theory takes the following form:

$$A = N_a \tag{1}$$

$$G = N_g \tag{2}$$

$$M = \theta_1 A + \theta_2 G + N_m \tag{3}$$

$$F = \theta_3 M + \theta_4 A + \theta_5 G + N_f \tag{4}$$

$$S = \theta_6 A + \theta_7 G + N_s \tag{5}$$

$$D = \theta_8 F + \theta_9 S + \theta_{10} FS + \theta_{11} A + \theta_{12} G + N_d \tag{6}$$

85 where A stands for age, G for gender, M for metacognition of allostatic control, F for fatigue, S general self-efficacy, D for depres-
86 sion, and N_i are jointly independent noise variables. $\forall i \neq g, N_i$ follows a normal distribution and N_g is a Bernoulli random variable.

DAG J_0

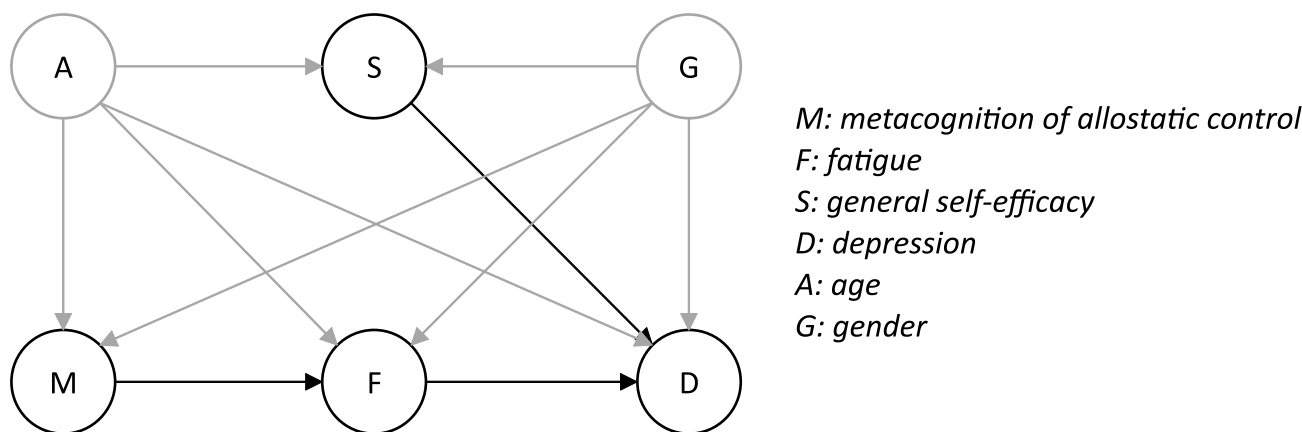

Figure 1: Directed acyclic graph (DAG) J_0 summarizing the key proposal of the allostatic self-efficacy theory (ASE;⁴⁰). The DAG J_0 is representative for the induced observational distribution \mathbb{P} and the interventional distributions induced by interventions on metacognition of allostatic control ($M; \mathbb{P}_{do(M:=m)}$), fatigue ($F; \mathbb{P}_{do(F:=f)}$) or general self-efficacy ($S; \mathbb{P}_{do(S:=s)}$). The other variables in the graph are depression (D), age (A) and gender (G). Black edges represent causal directions as proposed by the ASE theory, grey edges represent effects that are not explicitly part of the ASE theory but are likely to exist.

87 Figure 1 displays a graphical summary of the causal structure implied by the ASE theory in the form of a directed acyclic graph (DAG)
88 J_0 . The directed edge from metacognition of allostatic control (M) to fatigue (F) represents the prediction that fatigue arises as a
89 consequence of a metacognitive diagnosis by the brain – i.e. the brain concludes that it has low control over its bodily states. When
90 this low allostatic self-efficacy (for which fatigue is the accompanying feeling state) is combined with beliefs of lack of control in
91 other domains than the body (low general self-efficacy), this is predicted to lead to the onset of depression. These effects are rep-
92 resented by the directed edges from fatigue (F) to depression (D) and from general self-efficacy (S) to depression (D). The variables
93 age (A) and gender (G) are not explicitly part of the ASE theory, but are known to be associated with the central quantities of the
94 theory. Hence, the DAG J_0 in Figure 1 is representative for the induced observational distribution \mathbb{P} and the interventional distribu-
95 tions induced by interventions on metacognition of allostatic control ($M; \mathbb{P}_{do(M:=m)}$), fatigue ($F; \mathbb{P}_{do(F:=f)}$) or general self-efficacy ($S;$
96 $\mathbb{P}_{do(S:=s)}$).

97 When taking a closer look at the causal graph in Figure 1, there are a number of points worth highlighting. (i) There is no direct link
98 between metacognition of allostatic control (M) and general self-efficacy (S). (ii) There is no direct link from metacognition of al-
99 lostatic control (M) to depression (D). All of its influence is mediated by fatigue (F). (iii) There is no direct link between fatigue (F)
100 and general self-efficacy (S). While these three links are, in principle, plausible causal influences, they were not included in the orig-
101 inal formulation of the ASE theory⁴⁰. Whether these links should be included in a revision of the ASE theory can, in principle, be
102 tested using methods of causal inference, given appropriate readouts of the involved quantities and relying on the assumption of
103 the Markov condition.

104 **Statistical Analysis**

105 Our hypotheses as well as the entire analysis were pre-registered in a time-stamped analysis plan that is publicly available on the
106 Zenodo open data repository at <https://doi.org/10.5281/zenodo.10559656>. Below, we explicitly highlight any deviations from the
107 pre-specified analysis plan. The analysis code is available at <https://github.com/alexjhess/pbihb-ase-causality>. The analysis pipeline
108 underwent an internal code review by a researcher not involved in the initial data analysis to identify errors and ensure the repro-
109 ducibility of our results.

110 **Causal structure of ASE theory in the PBIHB dataset**

111 Learning causal structure from observational data is inherently difficult. One reason is the existence of models that are observation-
112 ally but not interventionally equivalent^{6,25,26,43}. This has several implications (e.g. see⁴³), one of them being that without assump-
113 tions, it is impossible to learn causal structure from observational data.

114 In graphical models, the Markov condition (see e.g.¹⁶) is a formalisation of the following principle (sometimes referred to as Reichen-
115 bach's common cause principle): If two random variables X and Y are dependent, then there must be some cause-effect structure
116 that explains the observed dependence. That is, either X causes Y , or Y causes X , or another unobserved variable H causes both
117 X and Y , or some combination of the aforementioned²⁹. A formal definition of the Markov condition is presented in Appendix A2.
118 The Markov condition establishes a connection from graphical separation properties (d -separation; see Appendix A3 for a formal
119 definition) to conditional independencies in the distribution. Any distribution induced by an acyclic SCM satisfies the Markov con-
120 dition with respect to the corresponding graph^{17,25}. Hence, the Markov condition is typically considered to be a mild assumption.
121 Assuming that the observational distribution \mathbb{P} induced by the SCM of the ASE theory (equations 1-6) is Markov with respect to the
122 DAG J_0 , we tested whether we find any contradictions to the structure of the DAG J_0 in the PBIHB dataset. More precisely, we ex-
123 amined the three predictions described in the last paragraph of and formalised as part of our pre-registered **Hypothesis 1**: Data
124 from the PBIHB study satisfy the following conditional independence statements:

125 (i) $M \perp\!\!\!\perp S \mid A, G$

126 (ii) $M \perp\!\!\!\perp D \mid F, A, G$ and $M \perp\!\!\!\perp D \mid F, A, G, S$

127 (iii) $F \perp\!\!\!\perp S \mid A, G$ and $F \perp\!\!\!\perp S \mid A, G, M$

128 As a statistical test for conditional independence, we used the asymptotic χ^2 test on the mutual information for conditional Gaus-
129 sians (MI_{cg}) for mixed discrete and normal variables as implemented in the R package **bnlearn**³⁵, using a significance level $\alpha = 0.01$
130 (Bonferroni corrected).

131 Since conditional independence testing is a difficult statistical problem³⁸, we validated our results using two alternative methods:
132 a kernel conditional independence test (KCI;⁴⁵) as implemented in the R package **CondIndTests**, and a test based on the gener-
133 alised covariance measure (GCM;³⁸) as implemented in the R package **GeneralisedCovarianceMeasure**. These additional tests of
134 conditional independence were not part of our pre-specified analysis. We decided to conduct these additional tests to evaluate the
135 robustness of our results across different methods of conditional independence testing (i.e. a sensitivity analysis). We used the same
136 significance level $\alpha = 0.01$ for the KCI as well as the GCM based tests to ensure compatibility with the pre-specified tests.

137 **Estimating the average causal effect from M to F**

138 ASE theory predicts that fatigue is a feeling state that is triggered by a metacognitive diagnosis of loss of control over bodily states.
 139 We aimed to test this prediction as part of our **Hypothesis 2**: There is a negative average causal effect from metacognition of allo-
 140 static control (M) to fatigue (F)

$$\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3. \quad (7)$$

141 Adjusting for covariates is one of various methods for estimating causal effects from observational data. Suppose we are interested
 142 in finding the effect of M on F and assume the factors deemed relevant to the problem are structured as in Figure 1. In other words,
 143 we are interested in calculating the intervention distribution $\mathbb{P}_{do(M:=m)}(f)$. Given a valid adjustment set (VAS) \mathbf{Z} , here e.g. $\mathbf{Z} = (A, G)$,
 144 the intervention distribution can be calculated (see^{23,30,39}) as $\mathbb{P}_{do(M:=m)}(f) = \sum_{\mathbf{z}} \mathbb{P}(f | m, \mathbf{z}) \mathbb{P}(\mathbf{z})$, since

$$\mathbb{P}_{do(M:=m)}(f) = \sum_{\mathbf{z}} \mathbb{P}_{do(M:=m)}(f, m, \mathbf{z}) \quad (8)$$

$$= \sum_{\mathbf{z}} \mathbb{P}_{do(M:=m)}(f | m, \mathbf{z}) \mathbb{P}_{do(M:=m)}(m, \mathbf{z}) \quad (9)$$

$$= \sum_{\mathbf{z}} \mathbb{P}_{do(M:=m)}(f | m, \mathbf{z}) \mathbb{P}_{do(M:=m)}(\mathbf{z}) \quad (10)$$

$$= \sum_{\mathbf{z}} \mathbb{P}(f | m, \mathbf{z}) \mathbb{P}(\mathbf{z}) \quad (11)$$

145 where in the last step one can use the fact that causal relationships are autonomous under interventions (this property is some-
 146 times referred to as "autonomy")²⁶.

147 In linear Gaussian systems, a causal effect from M to F can be approximated by $\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F]$ (see e.g.²⁶). Assuming that \mathbf{Z} is a
 148 VAS for $\{M, F\}$ and $\{M, F\}, \mathbf{Z}$ follow a Gaussian distribution, then the conditional $F | M = m, \mathbf{Z} = \mathbf{z}$ follows a Gaussian distribution as
 149 well. Hence, the mean of the distribution is given by

$$\mathbb{E}[F | M = m, \mathbf{Z} = \mathbf{z}] = \theta_3 m + \mathbf{b}^t \mathbf{z} \quad (12)$$

150 for some θ_3 and \mathbf{b} . It follows from equation 11 that

$$\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3 \quad (13)$$

151 One can estimate the conditional mean (eq. 12) by regressing F on M and \mathbf{Z} and subsequently reading off the regression coeffi-
 152 cients for M . Alternatively, more sophisticated techniques for estimation of the average causal effect can be used, such as the propen-
 153 sity score method³² and double/debiased machine learning (DML;⁸). In Appendix B, the two methods are described in more detail.
 154 As pre-specified in our analysis plan, we conducted linear regression in combination with a one-sided t-test on the regression coeffi-
 155 cient of M to evaluate Hypothesis 2. We compared our estimate of the causal effect from M to F obtained via linear regression with
 156 the results obtained from using more sophisticated estimation techniques, i.e. the propensity score method³² and DML⁸, following
 157 our pre-registered analysis plan.

158 **Estimating the average causal effect from F^*S on D**

159 Another prediction of ASE theory is that fatigue, in combination with a generalisation of low self-efficacy beliefs beyond bodily con-
 160 trol, induces depression. We formalised this prediction as part of our **Hypothesis 3**: There is a negative average causal effect of the
 161 interaction term between fatigue and general self-efficacy (F^*S) on depression (D)

$$\frac{\partial}{\partial f \partial s} \mathbb{E}_{do(F:=f, S:=s)} [D] = \theta_{10}. \quad (14)$$

162 Evaluation of Hypothesis 3 followed the same line of reasoning as for Hypothesis 2. We used linear regression in combination with
 163 a one-sided t-test on the regression coefficient of F^*S . Subsequently, we compared the resulting estimate to the results obtained

164 using the propensity score method and DML.

165 **RESULTS**

166 **Raw Data**

167 Figure 2 shows a scatter plot matrix of the raw data. Displayed are the measures for all variables A, G, M, F, S, D used in the analysis.

Figure 2: Scatter plot matrix of raw data used in the analysis. Displayed are all the pairwise scatter plots of the variables used for the analysis in a matrix format. For example, the scatter plot located on the intersection of row 3 and column 2 is a plot of variables age versus fatigue (as measured by the FSS). The variables displayed are gender, age, fatigue (assessed by the FSS), metacognition of allostatic control (assessed by the MAIA_{3,8}), self-efficacy (assessed by the GSES) and depression (assessed by the CES-D).

168 **Results from the Statistical Analysis**

169 **Causal structure of ASE theory in the PBIHB dataset**

170 Table 1 displays the results from conditional independence testing to evaluate the three predictions formulated as part of Hypothe-
 171 sis 1. The results can be summarised as follows:

Table 1: Results from different conditional independence test methods (MI_{cg} , GCM, KCI) for the three predictions formulated as part of Hypothesis 1. Results are presented for three different test methods. An asterisk indicates statistically significant evidence against the null hypothesis (H_0 : variables are conditionally independent) using the pre-specified level $\alpha = 0.01$, which corresponds to a threshold of $p < 0.05$ Bonferroni corrected for the multiple comparisons of the five tests, p -values are shown in parentheses.

Hypothesis 1	d -separation statement	MI_{cg} (p -value)	GCM (p -value)	KCI (p -value)
(i)	$M \perp_{J_0} S \mid A, G$	22.044* (1.634e-05)	4.254* (2.104e-05)	26.451* (5.194e-06)
(ii)	$M \perp_{J_0} D \mid F, A, G$	24.167* (5.652e-06)	-3.131* (0.001743)	8.513* (0.001346)
	$M \perp_{J_0} D \mid F, A, G, S$	16.883* (0.000216)	-2.574 (0.010064)	2.992 (0.022626)
(iii)	$F \perp_{J_0} S \mid A, G$	13.010* (0.001496)	-3.390* (0.000700)	13.613* (0.001279)
	$F \perp_{J_0} S \mid A, G, M$	4.057 (0.131500)	-2.088 (0.036799)	2.013 (0.118908)

172 (i) $M \perp\!\!\!\perp S \mid A, G$. We find significant evidence that metacognition of allostatic control (M) and general self-efficacy (S) are not in-
 173 dependent conditional on age (A) and gender (G) across all three different conditional independence test methods. In other words,
 174 we find a contradiction regarding the conditional independence of M and S given A, G , within the DAG J_0 .

175 (ii) $M \perp\!\!\!\perp D \mid F, A, G$ and $M \perp\!\!\!\perp D \mid F, A, G, S$. We find significant evidence that M and depression (D) are not independent conditional
 176 on fatigue (F), A, G across all three methods for conditional independence testing. This result is consistent with our findings for (i)
 177 in the sense that if we add a directed edge from M to S in the DAG J_0 (Figure 1), the only set of variables that d -separates M and D
 178 is the set F, A, G, S (and not F, A, G). However, the results for conditional independence tests of M and D conditional on F, A, G, S
 179 are mixed with 2 out of 3 tests (GCM and KCI) not reaching the pre-specified significance level $\alpha = 0.01$. Hence further evidence is
 180 needed to draw conclusions regarding the statement $M \perp\!\!\!\perp D \mid F, A, G, S$.

181 (iii) $F \perp\!\!\!\perp S \mid A, G$ and $F \perp\!\!\!\perp S \mid A, G, M$. When looking at the conditional independence between F and S , the results depend on
 182 the set of variables that we condition on. We find significant evidence that F and S are not independent conditional on A, G across
 183 all three different test methods. However, we fail to reject the null hypothesis that F and S are independent conditional on the set
 184 M, A, G consistently across all three different test methods. This result is also in line with our findings for (i) in the sense that if we
 185 add a directed edge from M to S in the DAG J_0 (Figure 1), the only set of variables that d -separates F and S is the set M, A, G .

186 Estimating the average causal effect from M to F

187 As predicted by the ASE theory, we find significant evidence for a negative average causal effect from metacognition of allostatic
 188 control (M) to fatigue (F) $\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3$ across all three different estimation methods. The resulting estimates $\hat{\theta}_3$ for the VAS
 189 $\mathbf{Z} = (A, G)$ are displayed in Table 2 alongside lower and upper bounds of a 95% confidence interval for $\hat{\theta}_3$, the corresponding value
 190 of the t -statistic as well as the p -value for the one-sided t -test.

Table 2: Average causal effect from M to F using $\mathbf{Z} = (A, G)$. Displayed are estimates of the average causal effect from M to F $\hat{\theta}_3$ across three different methods to adjust for the covariates $\mathbf{Z} = (A, G)$. We report a point estimate $\hat{\theta}_3$, the lower and upper bounds of a 95% confidence interval for $\hat{\theta}_3$, the value of the t -statistic as well as the p -value for the one-sided t -test. An asterisk indicates a statistical significance using the pre-specified level $\alpha = 0.017$ (Bonferroni-corrected).

estimation method	$\hat{\theta}_3$	confidence interval		t value	p -value
linear regression	-0.4845*	-0.712	-0.257	-4.259	3.968e-05
propensity score	-0.4816*	-0.717	-0.246	-4.092	6.689e-05
DML	-0.3872*	-0.6481	-0.1262	-2.9082	0.0018

191 The results from our sensitivity analysis, i.e. estimating θ_3 using a different VAS $\mathbf{Z} = (A, G, S)$, are listed in Table 3. They confirm the
 192 finding of a negative average causal effect from M to F when using $\mathbf{Z} = (A, G)$ as a VAS. The main difference between the results
 193 of the two analyses are that the second analysis using $\mathbf{Z} = (A, G, S)$ yields a slightly lower absolute value for $\hat{\theta}_3$ as well as a non-
 194 significant p -value using the DML method.

Table 3: Average causal effect from M to F using $\mathbf{Z} = (A, G, S)$. Displayed are estimates of the average causal effect from M to F $\hat{\theta}_3$ across three different methods to adjust for the covariates $\mathbf{Z} = (A, G, S)$. We report a point estimate of $\hat{\theta}_3$, the lower and upper bounds of a 95% confidence interval for $\hat{\theta}_3$, the value of the t -statistic as well as the p -value for the one-sided t -test. An asterisk indicates a statistical significance using the pre-specified level $\alpha = 0.017$ (Bonferroni-corrected).

estimation method	$\hat{\theta}_3$	confidence interval		t value	p -value
linear regression	-0.3545*	-0.610	-0.099	-2.785	0.0037
propensity score	-0.3775*	-0.692	-0.063	-2.400	0.0098
DML	-0.2049	-0.563	0.153	-1.122	0.1309

195 Estimating the average causal effect from F^*S to D

196 We do not find evidence for the predicted negative average causal effect of the interaction term between fatigue and general self-
197 efficacy (F^*S) on depression (D) $\frac{\partial}{\partial f \partial s} \mathbb{E}_{do(F:=f, S:=s)} [D] = \theta_{10}$ across all three different estimation methods for both VAS $\mathbf{Z} = (A, G)$
198 and $\mathbf{Z} = (A, G, M)$. Tables containing the resulting estimates for $\hat{\theta}_{10}$ including a 95% confidence interval and the value of the t -
199 statistic as well as the p -value for the one-sided t -test are listed in the Appendix C.

200 DISCUSSION

201 In this paper, we proposed a formulation of the allostatic self-efficacy (ASE) theory of fatigue and depression in the language of causal
202 inference. Specifically, we identified the variables of central interest to the ASE theory and formulated a structural causal model (SCM)
203 under assumptions of linearity and normality. The SCM as well as the induced directed acyclic graph (DAG) describe the direction of
204 causality among these variables. Using data of 60 healthy individuals from a previous study on interoception of breathing and its
205 relation with several psychopathological constructs¹⁴, we tested the proposed causal model empirically. Relying on the assumption
206 of the Markov condition, we used the dataset to search for contradictions to conditional independence statements (Hypothesis 1)
207 that are implied by the graph structure (d -separation). In a second and third step, we estimated the value of two causal effects that
208 are predicted by the ASE theory using methods of covariate adjustment, propensity scores and double/debiased machine learning.
209 As predicted by the ASE theory, we found a statistically significant negative average causal effect from metacognition of allostatic
210 control (M) to fatigue (F) $\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3$ across all three methods of estimation. Our sensitivity analysis using a different valid
211 adjustment set largely confirmed this finding with two out of three estimation methods yielding a significant result.

212 The assumption of the Markov condition establishes a connection from d -separation statements in a causal graph to conditional
213 independence statements in the distribution. In the analysis of Hypothesis 1, we tested concrete predictions implied by the DAG
214 J_0 (Figure 1). (i) Using the the data from the PBIHB study, we were able to reject the null hypothesis of $M \perp\!\!\!\perp S \mid A, G$ at the pre-
215 specified level $\alpha = 0.01$. (ii) We found significant evidence against $M \perp\!\!\!\perp D \mid F, A, G$ in the empirical data set. However, in line with
216 the graph structure J_0 implied by the ASE theory, we did not find clear evidence against $M \perp\!\!\!\perp D \mid F, A, G, S$. That is, only one out
217 of three conditional independence tests rejected the null hypothesis of metacognition of allostatic control (M) being independent
218 from depression (D) conditional on the set F, A, G, S . (iii) We also found significant evidence against $F \perp\!\!\!\perp S \mid A, G$ in the empirical
219 data. Yet, we did not find any evidence against (iii) $F \perp\!\!\!\perp S \mid A, G, M$. All three conditional independence test methods consistently
220 failed to reject the null hypothesis of fatigue (F) and general self-efficacy (S) being independent given the set A, G, D, M .

221 There are a number of potential explanations for the results related to Hypothesis 1. The most straightforward explanation is that
222 the proposed causal model is incorrect. This can include the presence of additional edges between nodes as well as variables that
223 were not considered acting as mediators or confounds or a combination of all of the aforementioned. For example, although the
224 ASE theory does not make an explicit statement about a direct link between metacognition of allostatic control (M) and general
225 self-efficacy (S), it is plausible to assume the existence of a directed edge from M (the feeling of control over bodily states) to S (an
226 individuals general expectation of personal mastery and control⁴). The construct of S is closely related to concepts of metacog-
227 nition (see e.g.⁹) and represents a "global" construct of self-beliefs about one's capacity to achieve goals and overcome adversity;
228 this can be understood as including more "local" domain-specific forms of self-efficacy, such as metacognition of allostatic control.
229 From this view, the idea that metacognition of allostatic control (M) may contribute to (and thus influence) beliefs of general self-
230 efficacy (S) is therefore not entirely unreasonable and would be a potential explanation for the results of (i) and (iii). More precisely,
231 a directed edge from M to S would render M and S d -connected, since there would always exist a path between M and S that is
232 not blocked by any set of variables. This cause-effect structure would explain the observed dependence between the two variables
233 in the empirical data set according to Reichenbach's common cause principle²⁹. Another consequence of introducing an edge
234 from M to S would be that the set of variables that d -separates F and S would consist of variables A, G, M and not A, G only, which
235 corresponds to our findings for (iii). The same is true for the set of variables d -separating M and D , which would consist of variables
236 F, A, G, S and not F, A, G in this case, potentially explaining our findings for (ii). However, since the evidence for (ii) $M \perp\!\!\!\perp D \mid F, A, G, S$
237 was mixed, further research needs to bring clarity to the question of (conditional) independence of M and D .

238 The revised DAG J_1 (Figure 3) provides a graphical summary of the above considerations regarding the results related to Hypoth-
239 esis 1. From DAG J_0 to J_1 , we added a directed edge from M to S . However, there are several other potential explanations for the
240 observed results, so this example should by no means be taken as "the correct model". If anything, this should be regarded as an
241 updated hypothesis to be tested in future investigations.

DAG J_1

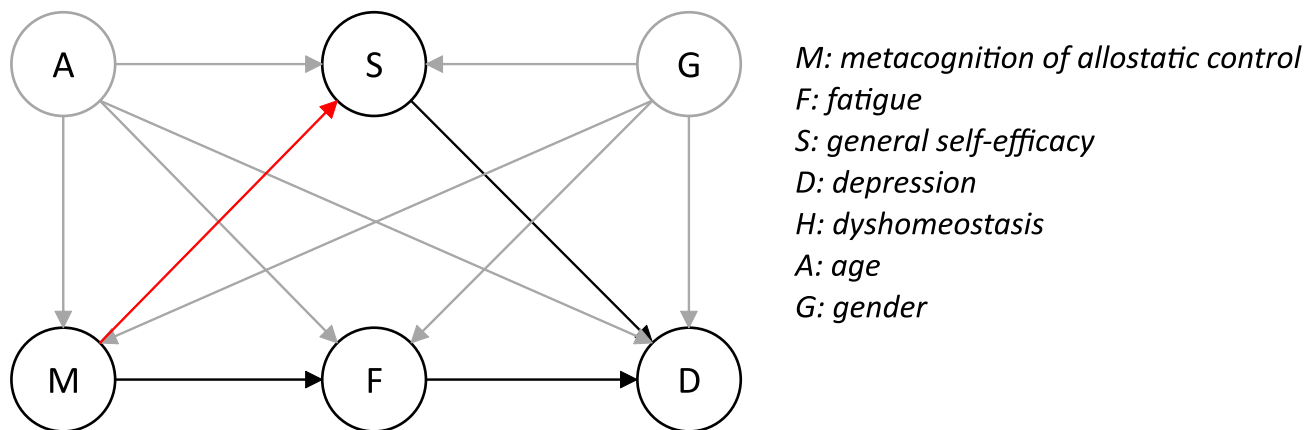

Figure 3: Updated directed acyclic graph (DAG) J_1 of the allostatic self-efficacy theory (ASE;⁴⁰) providing one potential explanation for the observed results from analysis of Hypothesis 1. Modifications from DAG J_0 to J_1 are shown in red.

242 Concerning Hypothesis 2, we found evidence for a negative average causal effect from metacognition of allostatic control (M) to fati-
243 gue (F) $\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3$ across all three estimation methods (covariate adjustment, propensity scores, DML) for two differ-
244 ent VAS. This is in line with the prediction by the ASE theory that the subjective experience of fatigue arises as a consequence of a
245 metacognitive diagnosis that the brain's control over bodily states is failing (low allostatic control). This also confirms findings from
246 previous research, which identified metacognition of allostatic control (M) (operationalised by the sum of the subscales 3 and 8 of
247 the MAIA questionnaire) to be associated with fatigue (F) scores³³. Our new results go beyond this previous finding, in the sense
248 that the current study suggests a direction of the effect as opposed to purely associative statements. It is worth highlighting that
249 the estimation of the causal effect from M to F would not be affected by the proposed additional link between M to S as suggested
250 by the analysis results concerning Hypothesis 1 (i) (see Figure 3) since the set A, G would still be a valid adjustment set (VAS).

251 With regard to Hypothesis 3, we did not find evidence for a negative average causal effect of the interaction term between fatigue
252 and general self-efficacy ($F*S$) on depression (D) $\frac{\partial}{\partial f \partial s} \mathbb{E}_{do(F:=f, S:=s)} [D] = \theta_{10}$. The present work is, to the best of our knowledge,
253 the first attempt to investigate the predicted influence of the interaction between fatigue and general self-efficacy on depression.
254 Across all three different estimation methods and using different VAS, we found, if anything, very small effects. However, one may
255 rightfully question whether the sample in this study was adequate for testing Hypothesis 3, at least in the context of the ASE theory.
256 This is because our participants were drawn from the general population and, not surprisingly, did not show pronounced levels of
257 depression (compare Figure 2). By contrast, predictions of the ASE theory concerning depression assume a clinically relevant state
258 of depression⁴⁰. Therefore, the potential interaction effect $F*S$ on D remains an open question that should be addressed in the fu-
259 ture, using samples with clinically relevant levels of depression.

260 The present study has a number of limitations. First of all, we are limited by certain features of the dataset at hand. In addition to
261 the low levels of depression discussed above, the sample size ($N=60$) is relatively small. Therefore, it will be crucial to see whether
262 our findings can be reproduced in larger population samples. Moreover, the dataset is purely observational, meaning that there are
263 no interventions on any of the variables of interest. This makes the problem of causal inference (even more) challenging. A logical
264 aim for future studies would be to use variables like M as targets for cognitive interventions.

265 Additionally, our analysis relies on the assumption that we have access to valid measurements of the variables in our SCM. While
266 we employed validated and widely used measures for fatigue, depression, and general self-efficacy, there does not yet exist a val-

267 idated measurement tool that was specifically developed for the construct of metacognition of allostatic control (M). Here, as in
268 previous research³³, we used a plausible proxy measure, the sum of the MAIA subscales 3 and 8 (for a detailed motivation, please
269 see the Methods section). An important goal for future research is the development and validation of easily applicable readouts for
270 metacognition of allostatic control (M).

271 Beyond the limitations of the dataset, our proposed SCM of the ASE theory is arguably only a crude approximation to reality. The
272 most obvious concern is the one of unobserved confounds, which we articulated in more detail in the discussion of the results from
273 Hypothesis 1. More specifically, one important limitation of the present study is that our SCM does not include sleep. While sleep
274 is not an explicit component of the ASE theory, previous work has repeatedly demonstrated the importance of sleep quality for fa-
275 tigue (e.g.^{19,33}). In the present study, we did not examine the potential influence of sleep since the available dataset did not include
276 any measures of sleep quality.

277 A second limitation is that we adopt the common assumption that all effects are linear and that all of the random variables follow
278 a normal distribution (except gender). These assumptions of linearity and normality should be kept in mind when interpreting our
279 findings for Hypotheses 2 and 3. Another potential drawback of our SCM is that we did not explicitly consider the role of time. Most
280 of the variables in our SCM are plausibly considered to be dynamic states, i.e. their values are likely to change over time. In this work,
281 we used a dataset representing a snapshot in time and implicitly assumed that the causal effects take place instantaneously. How-
282 ever, it is plausible to assume that, for example, the effects of elevated fatigue levels do not immediately lead to elevated symptoms
283 of depression, but that this effect evolves over timescales of weeks, months or even years.

284 Finally, there are numerous assumptions underlying our statistical tests. Conditional independence testing, which lies at the heart
285 of causal discovery³⁹, is one of its most challenging tasks³⁴. For Hypothesis 1, we additionally rely on the assumption of the Markov
286 condition. Without going into details for any of these assumptions, we highlight that the strongest of all the assumptions made
287 throughout the entire analysis is the assumption of unconfoundedness. In other words, our results are based on the assumption
288 that our proposed SCM contains all variables relevant for the phenomenon under consideration. However, it is likely that further
289 variables exist that influence those in the proposed SCM (e.g. sleep, see above). The omission of these (partially unknown) variables
290 may affect the results for all three hypotheses that we tested.

291 Despite the numerous limitations, this work also has several strengths worth highlighting. Foremost, we provided the first concrete
292 formulation of the ASE theory in the language of causal inference. Our proposal of an SCM brings the content of a verbally formu-
293 lated theory into the realm of concrete mathematical equations. Together with the induced DAG, they provide a formal basis for
294 analysis and allowed us to identify a set of empirically testable hypotheses which may guide future research. Secondly, we used
295 multiple independent methods for both conditional independence testing (Hypothesis 1) as well as the estimation of causal effects
296 (Hypotheses 2 and 3). In this way, we are able to draw conclusions in that they do not depend on assumptions and properties of any
297 single method. Last but not least, all of our hypotheses and statistical analysis procedures were pre-registered and specified in de-
298 tail in an ex ante analysis plan (<https://doi.org/10.5281/zenodo.10559656>). Preregistration is an important and effective protection
299 for the robustness of research, given the many degrees of freedom and the numerous cognitive biases that scientists may inadver-
300 tently be affected by²¹.

301 CONCLUSIONS

302 In summary, our work provides a formal basis for testing predictions by the ASE theory of fatigue and depression in the context of
303 causal inference. We evaluated central aspects of our proposed SCM using a publicly available dataset and provided an updated
304 version of the SCM that accounts for our empirical findings. In addition, we were able to confirm previous findings regarding the as-
305 sociation between metacognition of allostatic control (M) and fatigue (F). Our analysis enabled us to quantify the direction as well
306 as the sign of the causal effect, i.e. we found a negative average causal effect from M to F $\frac{\partial}{\partial m} \mathbb{E}_{do(M:=m)} [F] = \theta_3$, as predicted by
307 the ASE theory. Finally, we identified a number of open questions that remain to be addressed in future research and that may help
308 unravel the mechanisms behind fatigue and depression.

APPENDIX A. DEFINITIONS

A1. Structural Causal Model

We adopt the definition of SCMs according to ⁴³:

Definition 1. An SCM over variables $\mathbf{X} = [X_1, \dots, X_n]$ comprises

- structural equations which relate each variable X_k to its parents $\mathbf{PA}(X_k) \subseteq \{X_1, \dots, X_n\}$ and a noise variable N_k via a function f_k such that $X_k := f_k(\mathbf{PA}(X_k), N_k)$, as well as a
- noise distribution \mathbb{P}_N of the noise variables $\mathbf{N} = [N_1, \dots, N_n]^T$.

In a directed causal graph associated with an SCM, the nodes correspond to the variables X_1, \dots, X_n and there is an edge from X_i to X_j whenever X_i appears on the right hand side of the equation $X_j := f_j(\mathbf{PA}(X_j), N_j)$. In other words, if $X_i \in \mathbf{PA}(X_j)$ the graph contains the edge $X_i \rightarrow X_j$. For this work, we assume that the graph does not contain any cycles. The structural equations together with the noise distributions induce the observational distribution \mathbb{P}_X of X_1, \dots, X_n as simultaneous solution to the equations.

A2. Markov condition

Definition 2. Given a DAG G over nodes \mathbf{X} , we say that the distribution \mathbb{P}_X satisfies

- the **global Markov property** (MP) with respect to G if \forall disjoint $A, B, C \subseteq \mathbf{X}$
 A d -sep $B \mid C \implies A \perp\!\!\!\perp B \mid C$
- the **local Markov property** (MP) if $\forall j$ $X_j \perp\!\!\!\perp ND_j \mid PA_j$
- the **factorisation property** if \mathbb{P}_X is absolutely constant with respect to a product measure and $\forall x \forall j$, $p(x_{PA_j}) > 0 : p(\mathbf{x}) = p(x_1, \dots, x_d) = \prod_j^d p(x_j \mid x_{PA_j})$

In the above definition, we used the following notation: ND_j represent the non-descendants of node X_j and PA_j denotes all nodes that have a directed edge to node X_j .

A3. d -separation

Definition 3. d -separation is a graphical criterion whether two nodes are connected or not. Let $\mathbf{X}, \mathbf{Y}, \mathbf{Z}$ disjoint.

- A path $X = i_1, \dots, i_m = Y$ is blocked by $\mathbf{Z} \iff \exists$ node i_k with $i_{k-1} \rightarrow i_k \rightarrow i_{k+1}$ and $i_k \in \mathbf{Z}$
OR \exists node i_k with $i_{k-1} \leftarrow i_k \leftarrow i_{k+1}$ and $i_k \in \mathbf{Z}$
OR \exists node i_k with $i_{k-1} \leftarrow i_k \rightarrow i_{k+1}$ and $i_k \in \mathbf{Z}$
OR \exists node i_k with $i_{k-1} \rightarrow i_k \leftarrow i_{k+1}$ and $i_k \notin \mathbf{Z}$ and $DE(i_k) \cap \mathbf{Z} = \emptyset$
- \mathbf{X}, \mathbf{Y} are d -connected given $\mathbf{Z} \iff \exists X \in \mathbf{X}, Y \in \mathbf{Y}$ s.t. \exists path between X and Y that is not blocked
- if \mathbf{X}, \mathbf{Y} are not d -connected, then they are d -separated. We sometimes write \mathbf{X} d -sep $\mathbf{Y} \mid \mathbf{Z}$ or $\mathbf{X} \perp\!\!\!\perp_G \mathbf{Y} \mid \mathbf{Z}$

APPENDIX B. ESTIMATING CAUSAL EFFECTS USING COVARIATE ADJUSTMENT

B1. The "propensity score" method

In a point treatment situation one can adjust for a set of confounders $\mathbf{Z} = (A, G)$ when estimating the effect of exposure M by weighting observations i by the inverse probability weights

$$w_i = \frac{1}{P(M_i = m_i \mid \mathbf{Z}_i = \mathbf{z}_i)} \quad (15)$$

To increase statistical efficiency, one can use stabilised weights, e.g.

$$sw_i = \frac{P(M_i = m_i)}{P(M_i = m_i \mid \mathbf{Z}_i = \mathbf{z}_i)} \quad (16)$$

When dealing with a continuous exposure variable M , one can use stabilised weights

$$sw_i = \frac{f(m_i)}{f(m_i \mid \mathbf{z}_i)} \quad (17)$$

where $f(m_i)$ is the marginal density function of M , evaluated at the observed value in unit i , m_i , and $f(m_i \mid \mathbf{z}_i)$ conditional density function of M given \mathbf{Z} , evaluated at the observed values in unit i , $\{m_i, \mathbf{z}_i\}$ ⁴². Weighting observations i by sw_i , one can fit a causal model, for instance a marginal structural model (MSM)

$$\mathbb{E}[F_m] = \beta_0 + \theta_3 m \quad (18)$$

with continuous outcome fatigue F . The response variable F_m is the potential outcome that could have been observed in a unit under study, when that unit would have received a specific treatment level m ³¹. The expectation $\mathbb{E}[F_m]$ is the mean outcome, when all units under study would have received a specific treatment level m . Parameter θ_3 then quantifies the causal effect of M on F ⁴².

B2. Double/Debiased Machine Learning

DML removes the impact of regularisation bias and overfitting on estimation of the parameter of interest θ_3 by using Neyman-orthogonal moments and cross-fitting⁸. One application of DML is in the context of a partial linear regression model,

$$F = M\theta_3 + J_0(\mathbf{Z}) + N_f, \quad \mathbb{E}(N_f | M, \mathbf{Z}) = 0, \quad (19)$$

$$M = m_0(\mathbf{Z}) + V, \quad \mathbb{E}(V | \mathbf{Z}) = 0, \quad (20)$$

with fatigue F , metacognition of allostatic control M , a VAS $\mathbf{Z} = (A, G)$ consisting of confounding covariates and stochastic error terms N_f and V . The confounding covariates \mathbf{Z} affect M and F via the functions m_0 and J_0 , respectively. DML can be used to estimate θ_3 , i.e. the main regression coefficient that we would like to infer, which can be interpreted as the average causal effect from M to F ³.

APPENDIX C. RESULTS FROM ESTIMATING THE AVERAGE CAUSAL EFFECT FROM F^*S TO D

Table 4: Average causal effect of the interaction term F^*S to D using $\mathbf{Z} = (A, G)$. Displayed are estimates of the average causal effect of the interaction term F^*S to D $\hat{\theta}_{10}$ across three different methods to adjust for the covariates $\mathbf{Z} = (A, G)$. We report a point estimate of $\hat{\theta}_{10}$, the lower and upper bounds of a 95% confidence interval for $\hat{\theta}_{10}$, the value of the t -statistic as well as the p -value for the one-sided t -test. An asterisk indicates a statistical significance using the pre-specified level $\alpha = 0.017$ (Bonferroni-corrected).

estimation method	$\hat{\theta}_{10}$	confidence interval	t value	p -value
linear regression	0.0281	-0.191 0.247	0.257	0.6010
propensity score	0.0142	-0.151 0.180	0.172	0.5680
DML	-0.2051	-0.476 0.066	-1.482	0.0691

Table 5: Average causal effect of the interaction term F^*S to D using $\mathbf{Z} = (A, G, M)$. Displayed are estimates of the average causal effect of the interaction term F^*S to D $\hat{\theta}_{10}$ across three different methods to adjust for the covariates $\mathbf{Z} = (A, G, M)$. We report a point estimate of $\hat{\theta}_{10}$, the lower and upper bounds of a 95% confidence interval for $\hat{\theta}_{10}$, the value of the t -statistic as well as the p -value for the one-sided t -test. An asterisk indicates a statistical significance using the pre-specified level $\alpha = 0.017$ (Bonferroni-corrected).

estimation method	$\hat{\theta}_{10}$	confidence interval	t value	p -value
linear regression	0.0671	-0.122 0.257	0.711	0.7599
propensity score	0.0337	-0.159 0.227	0.350	0.6362
DML	0.0153	-0.283 0.314	0.100	0.5399
