26 Abstract

27 Maintaining normal thyroid function is crucial in pregnancy, yet thyroid dysfunction 28 and the presence of thyroid peroxidase antibodies (TPOAb) affect 0.5% to 18% of 29 pregnant women. Here, we conducted a genome-wide association study (GWAS) of 30 eight thyroid traits, including two thyroid-related hormones, four thyroid dysfunctions, 31 and two thyroid autoimmunity measurements among 85,421 Chinese pregnant women 32 to investigate the genetic basis of thyroid function during pregnancy. Our study 33 identified 176 genetic loci, including 125 previously unknown genome-wide 34 associations. Joint epidemiological and Mendelian randomization analyses revealed 35 significant associations between the gestational thyroid phenotypes and gestational 36 complications, birth outcomes, and later-age health outcomes. Specifically, 37 genetically elevated thyroid-stimulating hormone (TSH) levels during pregnancy 38 correlated with lower glycemic levels, reduced blood pressure, and longer gestational 39 duration. Additionally, TPOAb and thyroid functions during pregnancy share genetic 40 correlations with later-age thyroid and cardiac disorders. These findings provide novel 41 insights into the genetic determinants of thyroid traits during pregnancy, which may 42 lead to new therapeutics, early pre-diagnosis and preventive strategies starting from 43 early adulthood. 44

45

46 Introduction

47 Pregnancy represents a crucial phase in human reproduction, impacting both maternal 48 and offspring health. Particularly, normal maternal thyroid function and lack of 49 autoimmunity during pregnancy, commonly assessed by measuring circulating thyroid-stimulating hormone (TSH), free thyroxine (FT4) levels, and presence and 50 51 quantification of thyroid peroxidase antibodies (TPOAb), holds significant relevance for pregnancy outcomes and long-term health^[1,2]. Thyroid dysfunctions during 52 pregnancy are determined by these measurements and demonstrate varying 53 54 prevalence, ranging from 0.5% for overt hypothyroidism (defined as elevated TSH levels and low free T4 concentrations) to 3.47% for subclinical hypothyroidism 55 (defined as elevated TSH levels with normal FT4 concentrations)^[3], and 18% for 56 thyroid autoimmunity^[2]. Observationally epidemiologic studies have consistently 57 linked abnormal thyroid function tests during pregnancy to adverse maternal and 58 infant outcomes, including preterm birth^[4], low birth weight^[5], miscarriage, and 59 preeclampsia^[6]. However, the underlying biological mechanisms controlling the 60 population variability of TSH, FT4, TPOAb, and thyroid dysfunctions during 61 62 pregnancy, and their potential causal relationships with pregnancy and long-term 63 health outcomes remain unclear. 64 65 Previous research indicates that a significant portion of the inter-individual variability in thyroid hormone levels among general populations can be attributed to genetics. 66 67 Twin and family studies estimate heritable contributions to approximately 64%-70.8% for serum TSH, 39%-80% for FT4^[7-9], and 48.8% for anti-thyroid peroxidase 68 antibody (TPOAb)^[9]. Large-scale meta-genome-wide association studies of thyroid 69 hormones among general European populations have identified lead SNPs explaining 70 22.8% of TSH variation and 4% of FT4 variation, respectively^[10,11]. These studies 71 72 suggest that genetics may also influence thyroid function measurements during 73 gestation, an aspect that has been under-studied. Notably, unlike thyroid functions 74 outside the pregnancy period, changes in the hormonal environment during pregnancy 75 lead to more complex alterations in a woman's thyroid function. Maternal demand for thyroid rises during pregnancy due to fetal use of thyroid hormones and an increase in 76 thyroxine-binding globulin (TBG), among other reasons^[12]. In particular, human 77 78 chorionic gonadotrophin (hCG), which is structurally similar to TSH, significantly 79 increases in early pregnancy, leading to higher thyroid hormone production, 80 eventually resulting in decreased TSH levels under negative feedback regulation eventually^[13]. Therefore, GWAS studies based on pregnant women may not be 81 82 extrapolated from studies on general adults, and would greatly enhance our 83 understanding of the genetic basis of thyroid-related traits throughout life. However, 84 very few GWAS on thyroid-related traits have included pregnant women. To date, 85 only one candidate gene study that involved 974 healthy pregnant women, reported an 86 association between the number of TSH-raising alleles and subclinical

87 hypothyroidism in pregnancy^[14]. In addition, the association between subclinical

88 dysfunction and pregnancy outcomes, as well as the efficacy of treating mild

89 abnormalities, remains uncertain and controversial owing to the lack of robust causal

- 90 evidence^[15,16].
- 91

92 To elucidate the genetic factors influencing thyroid function and disorders during

93 pregnancy, and their potential causal impact on pregnancy complications, birth

94 outcomes, and later-age physical conditions, we conducted a genome-wide

association and Mendelian randomization study among 85,421 Chinese pregnant

96 participants with non-invasive prenatal test (NIPT) sequencing data, comprehensive

97 pregnancy screening and medical records from two hospitals in China. We focused on

98 the most commonly used thyroid biomarkers in pregnancy assessments, including

- 99 thyroid-stimulating hormone (TSH) and free thyroxine (FT4), and thyroid
- 100 autoimmunity measurements such as anti-thyroid peroxidase antibody (TPOAb)
- 101 levels and positivity. Additionally, we examined four clinical or subclinical thyroid
- 102 statuses, including subclinical hypothyroidism (SHO), isolated hypothyroxinemia
- 103 (ISH), overt hyperthyroidism (OHP), subclinical hyperthyroidism (SHP).
- 104

105 **Results**

106 Study design and demographic characteristics

107 Our study design and analysis scheme are depicted in Figure 1. Briefly, we enrolled

108 pregnant women during routine pregnancy screening at two maternal and child

109 healthcare hospitals – abbreviated as Longgang and Baoan hospitals, located in

- 110 Shenzhen, a metropolitan city in southern China. We imputed genotypes and
- 111 examined population structure from non-invasive prenatal test sequencing data

112 following a standardized protocol developed by our laboratory^[17,18]. We conducted

- 113 GWAS analyses for 2 thyroid-related hormones (TSH and FT4) within reference
- 114 ranges, 4 thyroid dysfunctions (subclinical hypothyroidism, isolated
- 115 hypothyroxinemia, subclinical hyperthyroidism, and overt hyperthyroidism), and 2
- 116 thyroid autoimmunity traits (TPOAb levels and TPOAb positivity) for each of the two
- 117 hospitals, followed by a fixed-effect meta-analysis across 12.7 million SNPs

118 (Methods). Subsequently, phenotypic association and Mendelian randomization

analyses were used to investigate the relationships between these eight traits,

- 120 gestational complications such as gestational diabetes mellitus (GDM), birth
- 121 outcomes, and later-life physical conditions using summary statistics from GWAS.
- 122 Since TSH and FT4 have been investigated in prior GWAS studies in the general
- 123 population, we further conducted conditional analyses to identify potential novel
- association signals within the established loci for these two traits. We evaluated the
- 125 GWAS results by examining the consistency of effect size estimates between the two

126 independent hospitals, the direction of effect sizes with an external GWAS with a

127 smaller sample size (NIPT PLUS cohort, n = 4,688), and by comparing effect size

128 estimates with publicly available GWAS data for the same phenotypes among general

129 populations, if available.

130

131 Following the screening process, our analysis included a total of over 85,000 subjects, 132 amalgamating data from the two hospitals (Methods for inclusion and exclusion 133 criteria). Among them, 67,323 participants had available TSH level data within the 134 reference range, and 67,047 participants had available FT4 level data within the 135 reference range. The sample sizes and demographic characteristics of the research 136 subjects included in the GWAS analysis for each trait, such as TSH levels, FT4 levels, 137 TPOAb levels, age, BMI, and gestational weeks at the time of thyroid function 138 measurement, are detailed in **Table S1**. The majority of subjects were in the age range 139 of 29 to 30 years. As expected, maternal serum TSH concentrations decreased from 8 140 to 12 weeks and then increased in both cohorts, while the opposite changing pattern 141 was observed for FT4 (Figure S1), corresponding to the increase of hCG during pregnancy^[19]. 142 143 144 Genetic associations with normal thyroid function during pregnancy 145 We identified 38 genome-wide significant loci associated with serum TSH levels and

22 loci associated with serum FT4 levels (*P*-values $\Box \le \Box \le \Box \le \Box \le 10^{-8}$) (Figure 2 and 146 147 Table S2). The genomic inflation factor for the 12,699,587 SNPs was 1.068 for TSH 148 and 1.069 for FT4, suggesting negligible inflation of test statistics in the genome-wide 149 association analysis (Figure S2). Among the 60 loci, 4 TSH loci and 13 FT4 loci 150 were identified as novel, with the lead variant situated more than 500kb away and 151 demonstrated LD \mathbb{R}^2 less than 0.1 from any previously established loci (Table S3;

- 152 Figure S3).
- 153

154 Among all loci, 59/60(98.3%) loci demonstrated consistent directionality and had a 155 nominally significant *P*-value below 0.05 between the two hospitals, suggesting little 156 heterogeneity and high fidelity of our genetic discoveries (Table S2, Figure S4A, 157 Figure S4C). The remaining SERPINA7 locus was a known locus associated with 158 FT4 in a previous study and the difference in effect size estimates may be attributed to 159 variations in fetal sex distribution between the two hospitals. In comparison with the 160 GWAS statistics with the NIPT PLUS cohort, 86.7% (52/60) of lead SNPs showed 161 consistent effect directions (Figure S5, Table S2). 162

163 Given that available genetic studies on thyroid function among East Asians are

limited to small sample sizes in the general population (e.g., 3,618 Koreans^[20], 4,581 164

Chinese ^[21], and 437 Chinese ^[22]), with only a few suggestive significant sites 165

166 identified for TSH, and the lack of publicly available GWAS summary statistics, we

167 compared our effect size estimates with the two largest-scale GWAS studies of TSH 10^{-23}

168 and FT4 in European populations ($N_{TSH}=249,715$; $N_{FT4}=49,269$)^[10,23]. Among the

loci, 49/60 (81.6%) loci exhibited *P*-values below 0.05 with consistent directional

170 effects compared with the European dataset (**Figure S4B, Figure S4D, Table S2**).

171 While the consistent effect size estimates suggest shared genetic determinants

between the two populations (European and East Asian) and between pregnancy and

173 non-pregnancy status, differences in the comparison could be attributed to different

174 LD structures between Europeans and East Asians, as indicated by differing allele

175 frequencies for the lead SNP (**Figure S6**) or potential effect modifications driven by

176 pregnancy status. Further investigation is required to clarify these hypotheses.

177

178 Novel loci and association signals for TSH and FT4

179 The 4 newly identified loci associated with TSH levels comprise HNRNPA3, FGF10,

180 IGF1, and MAGED2 (Figure 2A, Table S2, Figure S3). The 13 novel loci associated

181 with FT4 levels include SNX7, RRP15, TRH, PDCL2, CAST, CGA, FIG4, UNCX,

182 TRHR, ZNF462, GRK5, METTL15, and SGF29 (Figure 2B, Table S2, Figure S3).

183 Potential eGenes which expression in 49 issues in GTEx demonstrates colocalization

184 signals with the 17 loci are presented in **Table S4**. Among the 17 loci, *HMGA2*, *IGF1*,

185 *CGA* and *TRHR* contain SNPs that were previously reported to have genome-wide

associations with several thyroid-related traits in prior GWAS analyses (Table S3B).

187 And some loci include genes directly involved in thyroid functions, such as *TRH* and

188 *TRHR*, as well as genes involved in the regulation of protein signal transduction and

189 cell proliferation (**Table S5**).

190

191 Furthermore, through stepwise conditional analyses, we identified that 13 out of the

192 60 loci contained more than two independent signals, contributing to a total of 33

193 independent signals (**Table S6, Figure S7**). Particularly, we identified 10 novel

194 significant signals within 10 loci known for their involvement in thyroid function

traits [10 TSH-associated loci: CAPZB, IGFBP5, PDE8B, VEGFA, GLIS3, XPA,

196 *MBIP*, *CEP128*, *DET1*, and *MAF*; 3 FT4-associated loci: *GLIS3*, *FOXE1*, and *DET1*]

- 197 (Table S7, Methods).
- 198

Among the 33 independent signals, the genetic effects of all 33 (100%) SNPs were

200 consistent across the two hospitals (**Table S6**), and 26 out of 33 (78.8%) signals

201 demonstrated consistent direction and significance at P=0.05 compared to the two

202 European datasets mentioned earlier^[10,23] (**Table S6**).

203

204 Collectively, we identified a total of 53 independent association signals across 38 loci

205 for TSH levels and 27 signals across 22 loci for the FT4 levels, collectively

206 explaining 6.6% and 2.8% of the phenotypic variance, respectively.

207

208 Genetic associations with normal thyroid function within 8-12 gestational weeks

209 Considering the strong stimulation of thyroid function by hCG, leading to a

- significant reduction in TSH and an increase in FT4 during early pregnancy (weeks 8
- 211 to 12, Figure S1), we conducted a more focused GWAS analysis within this specific
- timeframe (weeks 8 to 12) to investigate potential association loci related to hCG
- stimulation. Within the 8 to 12 weeks period, we identified 20 genome-wide
- significant loci associated with TSH levels and 11 loci associated with FT4 levels
- 215 (Figure S8). However, after applying the Bonferroni correction, we did not find any
- 216 loci associated with TSH/FT4 within 8 to 12 weeks that were related to previously
- 217 published hCG GWAS after Bonferroni correction (**Table S8**)^[24]. These findings
- suggest that the gestational TSH and FT4 level do not share a significant genetic
- correlation with hCG.

220

221 Interestingly, when comparing the genetic effects of the 31 loci within the 8 to12 222 weeks period with the effects estimated from the entire pregnancy period, we 223 observed that the effect size for 4 out of the 20 TSH loci and 6 out of the 11 FT4 loci 224 did not have overlapping 95% confidence intervals between the two periods (Figure 225 **S9 and Table S9).** Notably, the TSH receptor locus (*TSHR*, marked by the nearest 226 gene CEP128) showed stronger associations with TSH and FT4 specifically during 227 the 8 to 12 weeks timeframe of pregnancy. According to GTEx, we found that the 228 lead SNP mutation rs17111346-G, associated with TSH levels during the 8-12 229 gestational weeks, was associated with a higher TSHR expression level in several 230 tissues and organs (Figure S10). In our study, this variant was associated with 231 increased TSH levels and reduced FT4 levels (Table S9). These observations may 232 provide a genetic explanation for the occurrence of hypothyroxinemia during this 233 stage, despite hCG stimulation. Individuals carrying specific genetic variants, 234 unrelated to hCG stimulation but associated with lower FT4 and higher TSH during 235 early pregnancy, such as the rs17111346-G variant, may have a higher risk of 236 developing hypothyroxinemia, despite hCG stimulation. 237 238 239 Identification of genetic associations with thyroid dysfunction 240 During early pregnancy, the fetus heavily relies on maternal thyroid hormones. 241 Evidence underscores the correlation between untreated clinical thyroid dysfunction and adverse birth outcomes^[25,26]. Subclinical hypothyroidism, characterized by low 242

- 242 and adverse birth outcomes . Subcimical hypothyloidism, characterized by low
- TSH levels but normal FT4 level, and isolated hypothyroxinaemia, characterized by
- 244 low free T4 levels and normal TSH levels—represent common mild thyroid
- 245 dysfunctions during pregnancy associated with adverse pediatric outcomes, including
- 246 preterm birth^[4]. Nevertheless, the optimal management of subclinical thyroid
- 247 dysfunction remains contentious, as some treatments for subclinical hypothyroidism
- 248 or hypothyroxinemia have not significantly improved cognitive or birth

outcomes^[26,27]. Moreover, untreated overt hyperthyroidism during pregnancy is linked
to various maternal and fetal complications, such as pre-eclampsia and pregnancy loss,
while subclinical hyperthyroidism is not thought to be associated with adverse birth
outcomes^[28].

253

254 To elucidate the genetic underpinnings of these thyroid dysfunctions, we conducted a 255 GWAS analysis on four categorical traits: subclinical hypothyroidism, isolated 256 hypothyroxinemia, overt hyperthyroidism, and subclinical hyperthyroidism (cases). 257 We utilized pregnant women with euthyroid function, defined as those maintaining 258 TSH and FT4 levels within the pregnancy-specific reference range throughout 259 pregnancy, as the control group. Notably, we also examined clinical hypothyroidism; 260 however, the statistical power was limited due to the small number of cases 261 (N_{Longgang}=464, N_{Baoan}=148) and robust genetic associations were not identified. 262 Specifically, we excluded individuals who tested positive for TPOAb from both the 263 case and control populations in the analysis for isolated hypothyroxinemia. After 264 exclusions, the sample sizes of the included research subjects were as follows: (1) 265 subclinical hypothyroidism [N=73,050 (Longgang: 3,666 cases versus 43,525 controls; 266 Longang: 1,244 cases versus 24,615 controls)]; (2) isolated hypothyroxinemia: 267 [N=50,407 (Longgang: 2,981 cases versus 37,152 controls; Longang: 613 cases 268 versus 9,961 controls)]; (3) subclinical hyperthyroidism [N=72,631(Longgang: 2,598 269 cases versus 43,525 controls; Longang: 1,893 cases versus 24,615 controls)]; (4) 270 overt hyperthyroidism [N=69,788 (Longgang: 1,229 cases versus 43,525 controls; 271 Longang: 419 cases versus 24,615 controls)]. 272 273 Our analysis led to the identification of 18, 8, 12, and 7 genome-wide association loci 274 associated with maternal subclinical hypothyroidism, isolated hypothyroxinemia, 275 subclinical hyperthyroidism, and overt hyperthyroidism, respectively (Figure 3, 276 **Table S10, Figure S11**). eGenes with colocalization signals with these 45 loci are 277 presented in Table S4. All lead SNPs in these 45 loci exhibited consistent 278 directionality within two hospitals, with 42 out of 45 (93.3%) compared at a *P-value* 279 below 0.05 with consistent directionality (Figure S12A). When we replicated these 280 45 lead SNPs with the NIPT PLUS cohort, 77.8% (35/45) SNPs showed consistent 281 directions of genetic effects (Figure S12B). 282 283 As no previous GWAS studies have been conducted on the four thyroid dysfunctions 284 investigated in this study, we were unable to directly compare the outcome with 285 external datasets. However, we noted that most of these loci have been reported to be 286 associated with thyroid-related traits such as hypothyroidism, TSH, and FT4 (Table 287 **S3B**). After excluding loci previously associated with thyroid traits, we identified 2 288 novel low-frequency genome-wide thyroid-traits loci including isolated 289 hypothyroxinemia-related SPRY1 (rs190595112-G, MAF=0.012, OR[95%]:4.22[2.52-

290 7.07], P= 4.77E-08) and overt hyperthyroidism-related *GAPVD1* (rs78254323-T,

291 MAF=0.04, OR[95%]: 1.72[1.42-2.09], P= 3.94E-08). These two variants

292 demonstrated consistent directionality and significance between the two hospital

293 cohorts (Table S10). The GAPVD1 locus demonstrated certain levels of evidence of

associations with GAPVD1 expression in the thyroid, while we did not find eGene for

295 *SRY1* locus in all tissues (**Table S4**).

296

297 Genetic associations with thyroid autoimmunity

298 Thyroid autoimmunity, characterized by the presence of antibodies targeting

299 thyroperoxidase, thyroglobulin, and thyroid-stimulating hormone receptor antibodies

300 (TRAbs), is prevalent among pregnant women and is often diagnosed through the

301 detection of thyroperoxidase antibodies (TPOAb) in clinical settings. This condition

302 is associated with thyroid dysfunction and adverse obstetric outcomes^[29]. In this study,

303 we conducted genome-wide association studies (GWAS) focusing on TPOAb

304 quantitative levels and positivity during pregnancy (Methods). The sample sizes of

305 the included research subjects were as follows (1) quantitative TPOAb levels [N=

306 60,225 (Longgang: 46,023; Longang: 14,202)]; (2) TPOAb-positivity [N=

307 69,061(Longgang: 7,324 cases versus 45,542 controls; Longang: 2,894 cases versus

308 13,301 controls)].

309

310 We identified 38 and 33 loci associated with TPOAb levels and TPOAb positivity,

311 respectively (Figure 4, Figure S13 and Table S11), revealing 35 and 30 newly

312 identified association loci, respectively compared to previously reported signals in the

313 GWAS catalog. Most of the loci for both traits were shared. The four most significant

314 novel loci including VANGL2, CTLA4, GPX6, and GPR174, were identified as

315 associated with Graves' disease (GD)/Hashimoto's thyroiditis (HT) in the Japanese

316 population^[30] (**Table S3B**). We identified 4 missense variants in novel loci:

317 rs7522061-C in FCRL3, rs3775291-T in TLR3, rs12793348-G in PANX1 and

318 rs229527-C in C1QTNF6. GWAS-eQTL co-localization analyses identified several

319 TPOAb levels and positivity-related loci that regulate the expression of *RPS26*,

320 RNASET2, C1QTNF6, FCRL1, FCRL3 genes in multiple tissues (Table S4). Previous

321 study has reported that *RNASET2* is expressed in CD4 + T-helper and CD8 + T

322 cells^[31], while *FCRL3* is expressed at high levels during the maturation of B-cells and

323 is thought to regulate B-cell signaling in both positive and negative ways^[32]. *FCRL1*

also plays a role in the assembly of the BCR signalosome, influences B cell signaling,
 and enhances humoral responses^[33].

325 326

327 For consistency, 67 out of 71 (94.4%) loci demonstrated consistent direction and

328 significance at *P*=0.05 between the two hospitals (**Figure S14A, Table S11**). When

329 replicating GWAS for TPOAb levels and positivity in the NIPT PLUS cohort, 62 out

of 71 (87.3%) loci showed consistent directions of genetic effects (Figure S14B,

Table S11). Comparing the results with external datasets, we initially compared our

332 results with the largest previous GWAS study on TPOAb levels and positivity,

333 conducted by Marco Medici et al. in the European population in 2014 (N_{TPOAb}-

- $_{\text{levels}}=16,528$ and $N_{\text{TPOAb-positivity}}=18,297)^{[34]}$. Since the study involved 2.14 million
- variants, only 58 of our lead variants (for their proxy SNPs) were available for
- analysis in this study. Among these SNPs, 50 loci (86.2%) exhibited a consistent
- 337 direction of effect between Chinese pregnant women and the European population
- 338 (Figure S15, Table S12).
- 339
- 340 Given the unavailability of previous GWAS summary data for TPOAb in the East
- 341 Asian population and the high correlation between TPOAb positivity and autoimmune
- thyroid diseases such as Graves' disease and Hashimoto's thyroiditis^[35], we also
- examined our associations for TPOAb positivity using the GWAS results for Graves'
- disease and Hashimoto's thyroiditis from the Biobank Japan (BBJ)^[30]. Of these 33 loci,
- 345 H2BC8 (rs1051365311) and its proxy SNP were not available in the BBJ dataset.
- 346 According to the result, 15 loci (FCRL3, VANGL2, CTLA4, LPP, CLNK, TCF7, IRF4,
- 347 GPX6, HBS1L, RNASET2, FAM76B, IFT81, MAF, C1QTNF6, and GPR174) in
- 348 Grave's disease (Table S13, Figure S16A) and 2 loci (GPX6, VANGL2) in
- 349 Hashimoto's thyroiditis showed significant associations (Table S13, Figure S16B).
- 350 The high degree of concordance (32 out of 33) in the direction of locus effects
- 351 suggests a shared genetic basis between TPOAb positivity during pregnancy and352 autoimmune thyroid diseases.
- 353

354 **Pairwise genetic correlation among thyroid traits**

- 355 To explore the pairwise genetic correlation among the thyroid traits investigated, we
- 356 employed LD score regression^[36]. The analysis revealed a significant genetic
- 357 correlation between TSH and all other thyroid traits, including TPOAb levels and
- 358 positivity. Conversely, FT4 exhibited correlation with thyroid dysfunctions but not
- 359 with TPOAb levels and positivity (Figure S17, Table S14). Additionally, we
- 360 observed a correlation between TPOAb level/positivity and subclinical
- 361 hypothyroidism. Nonetheless, this genetic correlation lost significance when the
- 362 analysis was restricted to euthyroid individuals, suggesting that the observed
- 363 correlation stemmed from shared genetics between TPOAb and TSH.
- 364
- 365 Consistent with the established inverse correlation in TSH and FT4 regulation through
- the Hypothalamus-Pituitary-Thyroid Axis (HPT)^[37], we observed a significant
- 367 inverse genetic correlation between TSH and FT4 levels (the genetic correlation
- 368 calculated by LDSC: rg_{TSH-FT4}=-0.16, se=0.04, *P*=8.6E-5)(**Figure S17, Table S14**),
- along with shared associations at 11 loci (TSH: CAPZB, TNS1, GLIS3, XPA, MBIP,
- 370 DET1, MAF, and FT4: FIG4, GLIS3, FOXE1, DET1) (Bonferroni-corrected threshold
- 371 $p \square < \square 0.05/60$) (Figure S18, Table S15). At these 11 loci, alleles associated with
- 372 higher TSH levels were consistently associated with lower FT4 except for three loci -
- 373 FIG4, XPA, and FOXE1 where genetic effects were observed in the same direction
- 374 for both thyroid-related hormones.

375

The influence of thyroid-related traits on gestational complications and fetal

377 obstetric outcomes

378 Previous large meta-analyses of observational studies have demonstrated an

- association between subclinical thyroid dysfunction and maternal complications and
 adverse birth outcomes, including gestational diabetes mellitus (GDM)^[38],
- 381 hypertensive disorders^[39], miscarriage ^[40], preterm birth, and low birth weight^[4,5].
- 382 However, RCTs investigating treatments for mild thyroid function abnormalities have
- 383 yielded inconclusive results ^[27], resulting in uncertainty and controversy regarding the
- 384 relationship between subclinical dysfunction and pregnancy outcomes, as well as the
- therapeutic value of addressing mild abnormalities^[41,42]. High-quality Mendelian
- 386 randomization studies in clinical thyroidology are deemed crucial for gaining valuable
- insights into the relationship between thyroid functions and birth outcomes^[43].
- However, to date, only one MR study has explored the causal effect of TSH and FT4
- 389 levels within the normal range on birth weight and did not identify statistically
- 390 significant causal associations ^[44].
- 391

392 Here, we applied joint phenotypic association and Mendelian randomization to

- investigate the impact of thyroid function during pregnancy on gestational
- 394 complications such as hypertension, and gestational diabetes, as well as birth
- 395 outcomes including birth weight, birth length, and gestational duration (**Table S18**).
- 396 Adhering to the three preconditions for a robust MR analysis, we utilize strong
- instrumental variables (F > 10), accounted for heterogeneity and horizontal
- 398 pleiotropy by applying an inverse weighted approach of random effect (IVWRE) as
- 399 primary results, and conducted several sensitivity analyses, including six additional
- 400 two-sample MR approaches and three scenarios including overlapping (Meta-Meta)
- 401 and non-overlapping samples (Longgang-Bao and Baoan-Longgang)^[45]. In addition,
- 402 for MR analysis of the relationship between thyroid traits and pregnancy
- 403 complications, we accounted for the bi-directionality of the causal estimates
- 404 (Method). Notably, due to the extreme imbalance in the number of cases and controls
- 405 of gestational hypertension and preeclampsia, we employed quantitative systolic and
- 406 diastolic blood pressure as indicators for hypertension. Considering the substantial
- 407 genetic correlation among the gestational thyroid traits (Figure S17), we employed a
- 408 Bonferroni testing criteria based on the total number of investigated gestational
- 409 complication and fetal obstetric outcomes (N=14). The statistical results of all
- 410 methods are presented in **Table S18 and S20**, while the instrumental variables used
- 411 are listed in **Table S19**.
- 412
- 413 Phenotypic association tests revealed numerous strong associations between TSH and
- 414 FT4 within the normal range, thyroid dysfunction, and glucose and blood pressure
- 415 traits, including significant associations between ISH and GDM (P < 0.004) (Figure
- 416 **5A, Table S17**). Mendelian randomization suggested consistent potential causal

- 417 associations for a few of these correlations after Bonferroni correction, including a
- 418 significant negative effect of TSH on fasting plasma glucose (FPG), oral glucose
- 419 tolerance at 1 hour (OGTT1H), and systolic blood pressure (SBP), as well as a
- 420 significant effect of FT4, SHO, SHP on SBP (**Figure 5B-C, Table S18**, P < 0.004).
- 421 Additionally, we found a nominally significant protective effect of genetically
- 422 increased thyroid hormone (FT4) on GDM, consistent between MR and observational
- 423 studies (observational study: OR_{longgang} [95%CI]: 0.861[0.833~0.89], P_{longgang} =8.49E-
- 424 19; MR: OR[95%CI]:0.844[0.732~0.972], P=1.88E-02). Reverse Mendelian
- 425 randomization did not identify significant potential causal associations between the
- 426 pregnancy phenotypes and thyroid-related phenotypes after Bonferroni correction
- 427 (**Figure 5B, Table S20**).
- 428
- 429 As for birth outcomes, observational analysis in the Longgang and Baoan study
- 430 consistently showed that maternal FT4 levels within the reference range were
- 431 significantly associated with lower birth weight, shorter birth length and a higher risk
- 432 of low birth weight. Correspondingly, we also observed a consistently significant
- 433 positive correlation between isolated hypothyroxinemia during pregnancy and greater
- 434 birth weight, as well as a significant association between TPOAb levels and
- 435 decreasing birth weight (Figure 6A, Table S17). However, in MR analysis, we only
- 436 discovered a significant potential causal effect of elevated TSH levels during
- 437 pregnancy on greater gestational duration (days) after Bonferroni correction (β_{MR-}
- 438 _{IVWRE} 95%CI =0.07[0.04-0.11], P_{MR-IVWRE}=7.80E-5) (Figure 6B, Table S18). Similar
- 439 results were observed across other methods of Mendelian randomization, except for
- simple mode (SM), which showed attenuation toward the null. We did not identify
- 441 MR associations between thyroid dysfunction and birth outcomes (Figure 6B, Table
- 442 **S18**).
- 443

444 Bidirectional Mendelian randomization study between gestational thyroid traits 445 and 220 phenotypes in BioBank Japan

- 446 We further investigated the potential relationship between thyroid-related traits during
- 447 pregnancy and 220 health phenotypes and outcomes in Biobank Japan (BBJ), with an
- 448 average age of 62, by conducting a bidirectional Mendelian randomization analysis
- 449 (Methods). Consistent significant associations in both directions suggest genetic
- 450 sharing rather than causal relation. The Bonferroni testing criteria are based on the
- 451 total number of investigated BBJ phenotypes (N=220), considering the substantial
- 452 genetic correlation among the gestational thyroid traits (Figure S17). Results
- 453 surpassing the Bonferroni and MR Egger pleiotropy testing criteria, which mainly
- 454 pertain to BBJ thyroid and cardiac disorders, are discussed herein. The instrumental
- 455 variables used in the forward MR analysis are presented in **Table S22**.
- 456
- 457 Regarding thyroid autoimmunity, forward MR analysis suggested that genetically
- 458 determined elevated susceptibility to TPOAb positivity is associated with an increased

459 risk for all 7 thyroid disorders, with 6 of these associations remaining significant after 460 Bonferroni correction: Graves' disease (OR [95%CI]:1.55[1.41~1.704], P=9.68E-20), 461 thyroid preparations usage (1.364[1.259~1.478], P=2.66E-14), hypothyroidism 462 (1.441[1.297~1.6], P=9.10E-12), hyperthyroidism(1.478[1.318~1.658], P=2.37E-11), 463 Hashimoto thyroiditis(1.454[1.27~1.666], P=6.61E-08), and goiter 464 (1.163[1.077~1.256], P=1.12E-04) (Figure 7, Figure S19A~F, Table S21). Similar 465 observations apply to TPOAb levels and for euthyroid TPOAb positivity with normal 466 TSH and FT4 levels (Figure S19G~N). However, in the reverse MR, statistics are 467 unavailable for thyroid cancer, hypothyroidism, Hashimoto thyroiditis and goiter due 468 to unavailability of instrumental variables. Significant bidirectionality was observed 469 for Graves' disease and thyroid preparations, and same effect direction was observed 470 for hyperthyroidism (Figure 7). Therefore, we infer that TPOAb positivity and levels 471 during pregnancy are genetically correlated with the BBJ thyroid disorders. In 472 addition to thyroid-related diseases, forward MR also revealed that genetic TPOAb 473 positivity is associated with a reduced risk of depression (OR [95%CI]: 474 OR[95%CI]:0.848[0.793~0.907], P=1.60E-06) and an increased risk of Cardiac 475 valvular disease (OR [95%CI]: OR[95%CI]:1.109[1.052~1.169], P=1.24E-04) 476 (Figure S19O~P). Reverse MR is unavailable for both disorders due to a lack of IVs 477 (Figure 7, Table S23). 478 479 In the forward MR analysis of both normal TSH, FT4 and thyroid dysfunction, we 480 observed that genetically elevated TSH levels, and a high risk of subclinical 481 hypothyroidism were linked to an increased usage of thyroid preparations, while overt 482 hyperthyroidism was linked to a decreased usage of thyroid preparations (P < 1.72E-483 04) (Figure 7, Figure S20A~C and Table S21). Except for overt hyperthyroidism, 484 TSH and subclinical hypothyroidism suggest bi-directionality of the MR effect. In 485 addition, genetically elevated TSH (OR [95%CI]:0.66[0.55-0.79], P=1.12E-05) and 486 subclinical hypothyroidism (OR[95%CI]:0.81[0.74-0.89], P=8.54E-06) were 487 associated with a lower risk of goiter (Figure S20D-E). However, reverse MR is 488 unavailable for both disorders due to a lack of IVs (Figure 7, Table S23). Moreover, 489 we found genetically elevated TSH levels but not thyroid dysfunction are associated 490 with a reduced risk of atrial fibrillation (OR [95%CI]: 0.868[0.81~0.931], P=7.91E-05) 491 (Figure S20F), which did not demonstrate evidence of causality in the reverse MR, 492 suggesting potential causal relation. 493

494 **Discussion**

495 Utilizing hospital electronic medical records and NIPT data from 85,421 Chinese
496 pregnancies, we conducted the first and most comprehensive GWAS studies to date of
497 thyroid traits during pregnancy, encompassing thyroid-related hormones, dysfunction,

498 and autoimmunity. Simultaneously, our GWAS facilitates the exploration of thyroid

499 function's impact on gestational complications as well as on birth outcomes, utilizing

- 500 the methods of Mendelian randomization.
- 501

502 In summary, we identified 176 genome-wide loci, among which 125 genome-wide 503 associations had not been previously reported for the 8 thyroid-related traits. This 504 significantly enhances our understanding of the genetic basis of thyroid traits during 505 pregnancy. The high consistency of genetic effects observed across two independent 506 hospitals, and in comparison with external datasets demonstrates the robustness of our 507 GWAS results. Particularly, while the TRH and TRHR genes are well-established in the thyroid axis^[37], our study is the first to identify them as genome-wide association 508 loci for thyroid function (FT4), signifying a significant power gain in our analysis. 509 510 Moreover, we identified 33 independent association signals in 13 loci (TSH: CAPZB, 511 IGFBP5, PDE8B, VEGFA, GLIS3, XPA, MBIP, CEP128, DET1, and MAF; FT4: 512 GLIS3, FOXE1, and DET1) by the stepwise conditional analysis, suggesting allelic 513 heterogeneity at the thyroid-associated loci. Additionally, comparing the genetic 514 associations with normal TSH and FT4 within 8-12 gestations suggests that 515 individuals carrying specific genetic variants have a higher risk of hypothyroxinemia, 516 despite hCG stimulation. 517 518 In the first GWAS of gestational thyroid dysfunction, we identified 18, 8, 12 and 7 519 genome-wide loci associated with subclinical hypothyroidism, isolated 520 hypothyroxinemia, and subclinical hyperthyroidism, and overt hyperthyroidism 521 during pregnancy, respectively. Additionally, our study has doubled the number of 522 genome-wide loci associated with TPOAb levels and positivity. These loci also 523 exhibited connections with other thyroid-related traits and conditions, including 524 hypothyroidism, TSH levels, and the use of thyroid preparations. Further functional 525 and mechanistic studies may be warranted to explore potential new therapeutic targets. 526 527 We completed the first joint epidemiological and Mendelian randomization analysis 528 of gestational thyroid phenotypes and complications. Statistics suggest that 529 genetically predicted lower TSH and higher FT4 correlate with elevated blood 530 glucose levels. However, we did not identify a significant MR association between 531 thyroid dysfunction and GDM, implying a continuum of TSH and FT4 action on 532 blood glucose and blood pressure regulation. Previous studies have yielded 533 conflicting conclusions regarding the association between subclinical hypothyroidism 534 and GDM^[46-48], and our results suggest that the impact of abnormal thyroid function 535 on GDM varies depending on the criteria used for TSH and blood glucose assessment. 536 Moreover, our results suggest the involvement of TSH and FT4 in blood pressure 537 regulation. While a previous MR analysis suggested that genetically predicted TSH elevation leads to reduced systolic blood pressure, this finding lacked significance 538 after Bonferroni correction^[49]. Our study provides more robust evidence to support 539 540 this conclusion.

541

542	In the investigation of relationship of gestational thyroid phenotypes and birth
543	outcomes, retrospective observational analyses revealed that isolated
544	hypothyroxinemia was associated with higher birth weight, while FT4 levels within
545	the reference range were inversely associated with birth weight, aligning with findings
546	from a previous large meta-analysis ^[5] . However, we did not find sufficient evidence
547	to suggest that abnormal TSH levels during pregnancy (overt and subclinical
548	hyperthyroidism, subclinical hypothyroidism) and TPOAb positivity increase the risk
549	of adverse outcomes such as preterm delivery, macrosomia, and low birth weights.
550	Nonetheless, we cannot exclude the possibility that thyroid dysfunction and
551	autoimmunity may contribute to other adverse outcomes. Consistent with a previous
552	MR study ^[44] , we also did not identify an MR association between maternal TSH
553	levels within the reference range and birth weight. Notably, our MR analyses provide
554	evidence suggesting that maternal TSH levels during pregnancy may potentially
555	influence gestational duration, although the effect may be nonlinear. Notably,
556	genetically predicted higher maternal TSH are nominally associated with a heightened
557	risk of preterm birth, and previous research has demonstrated a U-shaped association
558	between FT4 levels and preterm birth ^[50] . Further validation through intervention
559	studies is warranted to ascertain the genuine effects.
560	-
561	TPOAb is commonly acknowledged as a pathogenic antibody associated with
562	Hashimoto's thyroiditis (HT), yet its role in Graves' disease (GD) remains uncertain,
563	despite the fact that 50–70% of individuals with GD also exhibit TPOAb
564	positivity ^[51,52] . TPOAb has been proposed as a marker of impaired thyroid function
565	rather than a direct cause of thyroid damage ^[2] . Our bidirectional MR analyses with
566	BBJ phenotypes suggest a genetic correlation between TPOAb positivity and several
567	thyroid disorders in older, general individuals, regardless of their thyroid function
568	status. Additionally, we observed that genetically predicted maternal TPOAb
569	positivity was associated with an increased risk of cardiac valvular disease, consistent
570	with previous observations of an association between thyroid autoimmunity and
571	rheumatic heart valve disease ^[53] . In addition, in line with the findings of previous MR
572	studies conducted in population of European ancestry ^[23,54] , identified protective
573	effects of lower thyroid function during pregnancy against atrial fibrillation and goiter
574	in East Asians. The consistently observed genetic correlation or MR associations of
575	gestational thyroid phenotypes and later-age thyroid and cardiac diseases suggest the
576	potential for early screening of thyroid disorders in early adulthood and may warrant
577	further clinical studies.

578

579 Despite the positive findings, there are limitations in our study. Firstly, while we

580 conducted the first and most comprehensive GWAS study of thyroid-related traits in

581 pregnancy, focusing on a critical period of human reproduction, the study population

582 consisted solely of Chinese women, potentially limiting the generalizability of our

583 findings to other ancestries. However, we would like to note that non-invasive 584 prenatal testing data are widely adopted in clinical settings due to their high sensitivity and specificity^[55]. The methods used in this study^[17,18] will facilitate 585 further investigations into thyroid-related traits in pregnancy across different 586 587 populations, enhancing our understanding of the trans-ancestral genetic basis. In 588 addition, the shared genetic correlation between the gestational thyroid traits in this 589 study and the thyroid phenotypes in European general population suggests that the 590 existance of strong correlation between thyroid traits in different life stages. 591 592 Secondly, in our Mendelian randomization analysis examining the relationship 593 between gestational thyroid traits and complications as well as birth outcomes, we 594 utilized a strategy involving two-sample MR analytical methods within a single 595 cohort setting, which has been empirically proved not to be prone to sampleoverlapping bias if the IVs were sufficiently strong^[45]. Nonetheless, to enhance the 596 597 robustness of our findings, replication in a two-sample MR without sample overlap 598 would be ideal. We attempted to address this by conducting analyses in multiple 599 scenarios, including using exposures from one hospital and outcomes from the other 600 hospitals, to support our MR results. These strategies consistently suggested that 601 genetically determined elevated TSH levels during pregnancy were associated with 602 lower glycemic levels, reduced blood pressure, and longer gestational duration. 603 Furthermore, in our MR study of gestational thyroid traits and birth outcomes, we did 604 not differentiate between fetal genetic and intrauterine effects of exposure on birth 605 outcomes. This aspect could benefit from expansion of sample size in family genomes 606 from birth cohorts in Chinese ancestry^[56]. Additionally, when analyzing the impact of 607 thyroid traits on other outcomes, we focused solely on additive linear effects, without 608 considering nonlinear effects. Finally, in the bidirectional MR study between 609 gestational thyroid traits and phenotypes in BBJ, we were unable to distinguish 610 genetic correlation from potential causal effect of the exposures of thyroid related 611 traits during pregnancy on a later-age health result. This purpose can be addressed 612 when GWAS studies of the same thyroid traits investigated in this study among 613 general East Asian population become available, enabling a multi-variable Mendelian 614 randomization analysis integrating GWAS statistics of thyroid traits in pregnancy and among the general populations^[57]. 615 616

Despite the genetic findings, our study suggests two clinical implications. First, serum 617 levels of TSH and FT4 exhibit substantial interindividual variation among healthy 618 individuals, with much smaller intraindividual variation^[58]. This indicates that each 619 person has a unique setpoint for TSH and FT4^[59]. Hence, when initiating RCTs or 620 621 treatments for thyroid disorders in pregnant women, it may be beneficial to consider 622 the genomic profile of the patients, as revealed in our study. This approach can help 623 prevent overtreatment, may explain the varying responses of the pregnant women to 624 medications such as levothyroxine, commonly prescribed for gestational thyroid

- 625 disorders^[27]. Secondly, as pregnancy screening represents the most comprehensive
- 626 physical examination during early adulthood for most women, it is valuable to explore
- 627 early diagnosis and preventive strategies for thyroid disorders later in life, starting
- 628 from this critical early period.

629

630 Methods

631 Longgang and Baoan Study

632 The Longgang Study enrolled 70,608 pregnant women who received NIPT results

633 during the first or second trimester at Longgang District Maternal and Child Health

Hospital, located in the eastern region of Shenzhen, China, between 2017 and 2022.

- Of these, 58,351 participants had available measurements for TSH, FT4, and TPOAb
- 636 levels.
- 637

638 The Baoan Study included 50,948 pregnant women who visited the Baoan District

- 639 Maternal and Child Health Hospital in the western region of Shenzhen, China, and
- 640 completed an NIPT test during the first or second trimester between 2017 and 2022.
- 641 Of these, 33,781 participants had available TSH measurements, 33,516 had FT4
- 642 measurements, and 16,393 had TPOAb measurements.
- 643

This study was reviewed and approved by the Ethics Committee of School of Public

645 Health (Shenzhen), Sun Yat-Sen University (2021. No.8), as well as the Institutional

646 Board of Shenzhen Baoan Women's and Children's Hospital (LLSC2021-04-01-10-

647 KS) and Longgang District Maternity and Child Healthcare Hospital of Shenzhen

648 City (LGFYYXLLL-2022-024). The study strictly adhered to regulations governing

649 ethical considerations and personal data protection. Data collection was approved by

650 the Human Genetic Resources Administration of China (HGRAC). Written informed

- 651 consent of all participants were obtained.
- 652

653 Biochemical measurements and definition of thyroid-related traits

654 Because TSH and FT4 concentrations during pregnancy are related to gestational

655 week, pregnancy-specific reference ranges are recommended^[1]. In this project, the

diagnosis of thyroid dysfunction was based on a method-specific and pregnancy-

657 specific reference interval, as recommended by the Chinese Medical Association

Guideline on the diagnosis and management of thyroid diseases during pregnancy and

659 postpartum (2nd edition)^[60]. We also used the cutoff value provided by the kit

660 company to determine whether the subject was in a TPOAb positivity state.

661

662 In the Longgang study, thyroid function tests measured concentrations of thyroid

stimulating hormone (TSH), free thyroxine (FT4), and anti-thyroid peroxidase

antibody (TPOAb). These measurements were taken during a physical examination

using the UniCel DxI 800 Immunoassay System (Beckman Coulter Inc., Brea, CA,

666 USA) along with its respective system accessory kit. The reference ranges for TSH

are 0.05-3.55 mIU/L for the first trimester, 0.21-3.31 mIU/L for the second trimester,

- and 0.43-3.71 mIU/L for the third trimester. The reference ranges for FT4 are 9.01-
- 669 15.89 pmol/L for the first trimester, 6.62-13.51 pmol/L for the second trimester, and

6.42-10.75 pmol/L for the third trimester^[60]. TPOAb positivity was defined according 670 671 to the cutoff (TPOAb > 9 IU/mL). 672 673 In Baoan study, serum levels of TSH, FT4, and TPOAb were measured by Abott 674 I2000 Immunoassay System. The reference ranges of TSH are (0.07-3.38 mIU/L), 675 (0.34-3.51 mIU/L) and (0.34-4.32 mIU/L) for the first trimester, second trimester and 676 third trimester, respectively. And the reference ranges of FT4 are (11.30-17.80 677 pmol/L), (9.30-15.20 pmol/L) and (7.90-14.10 pmol/L) for the first trimester, second trimester, and third trimester, respectively^[60]. The cut-off value we used for TPOAb 678 679 positivity is 5.6 IU/ml. 680 681 In each study, a pregnant woman with both TSH and FT4 levels within the 682 pregnancy-specific reference range was considered a subject with normal thyroid 683 function (ie, euthyroidism). The serum TSH and FT4 levels were analyzed as 684 continuous variables after inverse normal transformation, based on the euthyroid 685 subjects. Additionally, for the GWAS of continuous TPOAb levels, pregnant women 686 exhibiting TPOAb levels below the minimum detection limits of the assay (0.25 687 IU/ml for the Longgang Study and 0.159 IU/ml for the Baoan Study) were excluded. 688 TPOAb levels were natural log-transformed before performing the GWAS analysis. 689 690 The thyroid dysfunction was defined following the 2017 medical guidelines of the 691 American Thyroid Association for the Diagnosis and Management of Thyroid Disease During Pregnancy and the Postpartum^[1]. Specifically, overt hyperthyroidism was 692 693 defined as a TSH concentration below the lower limit of the reference range, 694 accompanied by an FT4 concentration exceeding the upper limit of the reference 695 range. Subclinical hyperthyroidism was defined as a TSH concentration below the 696 lower limit of the reference range while maintaining a normal FT4 concentration. 697 Subclinical hypothyroidism was defined by as a TSH concentration upper the limit of 698 the reference range with normal FT4 concentration. Isolated hypothyroxinemia is 699 typically defined as having an FT4 concentration below the lower limit of the 700 reference range while maintaining a normal maternal TSH concentration. 701 702 To comprehend the genetic underpinnings of these thyroid dysfunctions, we 703 conducted a GWAS analysis on four categorical traits: subclinical hypothyroidism, 704 isolated hypothyroxinemia, overt hyperthyroidism, and subclinical hyperthyroidism 705 (case group). We used pregnant women with euthyroid function, defined as those 706 maintaining TSH and FT4 levels within the pregnancy-specific reference range 707 throughout pregnancy, as the control group. Specifically, we excluded individuals 708 who tested positive for TPOAb from both the case and control populations in the 709 analysis for isolated hypothyroxinemia (**Table S1**). It is worth noting that we also 710 examined overt hypothyroidism; however, the statistical power was limited due to the

small number of cases ($N_{Longgang}$ =464, N_{Baoan} =148) and we did not identify robust

712 genetic associations.

713

714 Statistical analysis

For all participants, baseline characteristics were described using mean \pm standard

- deviation, and results of thyroid function tests (TSH, FT4, and TPOAb) for different
- 717 pregnancies were presented in median [interquartile range]. In the phenotype
- association analysis of thyroid-related traits with gestational complications and fetal
- obstetric outcomes, quantitative traits were analyzed using multiple linear regression,
- and categorical traits were analyzed using logistic regression. All statistical analyses
- 721 were conducted using R version 4.3.2.
- 722

723 Genotyping, Imputation, and Variant annotation

- Non-invasive prenatal testing (NIPT), which employs low-pass massively parallel
- sequencing of cell-free DNA fragments from peripheral blood of a pregnant woman,
- has gained prominence as an unparalleled screening test for fetal aneuploidy due to its
- high sensitivity and specificity^[61]. Our prior research and recent study have illustrated
- that when NIPT data (0.06x 0.3x) are integrated with a reference panel, it can
- achieve high accuracy in genotype imputation, matching or even exceeding the
- 730 performance of an array^[17,18].</sup>
- 731
- 732 In summary, we first collected data from NIPT for 121,578 pregnant women in Baoan
- and Longgang Hospitals in Shenzhen city, Guangdong Province. Each of these
- participants was whole-genome sequenced to 9.9-21.9 million cleaned reads,
- representing a sequencing depth of around 0.11x-0.25x. Next, we applied BWA^[62] to
- align the cleaned reads to the Genome Reference Consortium Human Reference 38
- (GRCh38) and used the rmdup option in samtools^[63] to remove potential PCR
- 738 duplicates. The GATK realignment and base quality recalibration method was utilized
- to align the reads and adjust base quality $cores^{[64]}$. After that, the alignment files were stored as bam files.
- 741
- 742 Subsequently, we employed the Glimpse software (version 1.1.1)^[65], which
- implements an algorithm for genotype imputation, in conjunction with a deep whole-
- genome sequencing reference panel of 10K Chinese^[66], to perform individual
- 745 genotype imputation for the NIPT data. Finally, variant annotation was carried out
- via using Ensembl Variant Effect Predictor^[67] (version 101), utilizing indexed GRCh38
- cache files (version 109). All the data used for annotation were obtained in advance
- from the Ensembl FTP server (https://ftp.ensembl.org/pub/). Considering that a
- variant can span across multiple transcripts, we employed the "--pick" option to
- assign a single consequence block to each variant based on a predefined set of default
- 751 criteria in VEP. In addition, the "--nearest" option was applied to identify the nearest

gene with a protein-coding transcription start site (TSS) for variants located in the

753 intergenic region.

754

755 Genome-wide association analysis in individual Studies

- 756 The association of the SNPs was analyzed by GWAS in PLINK 2.0, using linear
- regression for three continuous traits (levels of TSH, FT4, and TPOAb) and logistic
- regression for five binary phenotypes (subclinical hypothyroidism, isolated
- hypothyroxinemia, subclinical hyperthyroidism, overt hyperthyroidism, and TPOAb
- positivity), separately in two cohorts (Baoan and Longgang). The genotype-phenotype
- association was conducted using an additive genetic model on SNP dosages.
- 762 Moreover, analyses were adjusted for the gestational week of the thyroid test,
- 763 maternal age, and the top ten principal components to account for population
- 764 stratification.
- 765

766 Meta-analysis

- 767 We conducted fixed-effect GWAS meta-analyses based on an inverse-variance
- 768 weighting of Baoan and Longgang using METAL software^[68]. To visualize the meta-
- analysis results, we generated a Manhattan plot and a quantile–quantile (QQ) plot
- with an R script.
- 771
- In terms of interpreting the results of the meta-analysis, we defined the lead SNP as
- the SNP with the most significant P-value in the single-SNP association test within a
- 1-Mbp window. A locus was considered to have reached the significance threshold if
- the lead SNP within that locus had a P-value $\leq 5 \times 10^{-8}$. A locus is considered novel
- locus for the trait if its leading SNP is in linkage equilibrium (LD $R^2 < 0.2$) with any
- known variants (listed in the GWAS Catalog as of December 31, 2023) on the same
- chromosome. Specifically, using the GWAScatalog database, we obtained all the
- trait-related known variants located on the same chromosome as our novel lead
- variants (Triat ID in the Experimental Factor Ontology: TSH: EFO_0004748, FT4:
- 781 EFO_0005130, thyroid peroxidase antibody measurement: EFO_0005666, and
- hyperthyroidism: EFO_0009189)^[69]. And then, for all of our novel SNPs, we use East
- Asians (EAS) and Europeans (EUR) populations in the 1000G genome to calculate
- the linkage disequilibrium R-square between variants we identified and all known
- 785 SNPs on the same chromosome using LDpair (<u>https://ldlink.nih.gov/?tab=ldpair</u>). And
- the results of linkage disequilibrium R-square between novel variants and known
- variants are shown in **Table S4A**.
- 788

789 Conditional analysis

- 790 Stepwise conditional analyses were performed for the GWAS-meta results to identify
- 791 independent signals that affect TSH and FT4 levels, conditioning on the most
- significant variants (known and novel) identified in our GWAS. After conditioning on
- the lead genome-wide significant variant, variants identified within a 1 MB region of

- the variant with a p-value $< 5.0 \times 10^{-8}$ were considered independent significant
- signals. These conditional analyses were repeated, adding in the conditional lead
- variants until no variant had a conditional p-value less than the genome-wide
- significance (P < 5.0×10^{-8}). To determine whether the identified independent
- significant signals at known loci were independent novel signals, we analyzed East
- Asian (EAS) and European (EUR) populations from the 1000 Genomes Project. We
- 800 used LDpair (<u>https://ldlink.nih.gov/?tab=ldpair</u>) to calculate the linkage
- 801 disequilibrium R-square (R²) between the variants we identified and those previously
- 802 associated with trait-linked traits. Subsequently, we defined an SNP as an independent
- significant signal at a locus if the R² was less than 0.2 in both EAS and EUR
- 804 populations.
- 805

806 **Consistency and replication**

- 807 To enhance the reproducibility of the findings, we checked internal and external
- 808 consistency across different datasets. Consistency between the two hospitals involved
- 809 examining the consistency of the effect direction of the lead SNPs and assessing the
- 810 significance of the GWAS P-values in the Baoan and Longgang Studies. On the other
- 811 hand, consistency of our meta-GWAS results and external datasets involved
- 812 examining the consistency in an independent dataset from three separate cohorts
- 813 (ThyroidOmics Consortium, the GWAS meta-analysis of Alexander T Williams et al.,
- the GWAS meta-analysis of M. Medici et al) $^{[10,11,34]}$.
- 815
- 816 Beyond the participants previously referenced, our research included 4,688
- 817 individuals who attended Baoan District Maternal and Child Health Hospital for
- 818 maternity check-ups during their 40-week gestation. Throughout 2020 and 2021, these
- 819 participants underwent non-invasive prenatal testing (NIPT) in the first or second
- 820 trimester. These samples notably underwent more in-depth sequencing than standard
- 821 NIPT, achieving an average depth of 0.3x. The serum levels of TSH, FT4, and
- 822 TPOAb in NIPT PLUS cohort in were measured by Abott I2000 Immunoassay
- 823 System with its respective system accessory kit. Using a process similar to Baoan
- 824 Study, we completed GWAS for thyroid-related traits in the NIPT PLUS cohort.
- 825

826 eQTL Colocalization analysis

- 827 Colocalization analyses were performed for novel lead variants using *coloc* R
- 828 package^[70]. Gene expression data from 49 tissues in European ancestry samples
- included in the GTEx Project version 8 release were used (<u>https://gtexportal.org/</u>)^[71].
- GWAS data from a region spanning ± 1 Mb around each novel SNPs were compiled,
- 831 integrated with the corresponding GTEx eQTL data for each specific tissue, and
- 832 subsequently used as the input for related analyses. Regions that show evidence of
- 833 colocalization between eQTL and GWAS signals were identified using pre-defined
- thresholds: $PP4 \ge 0.75$ and $PP4/PP3 \ge 3^{[70]}$. Here, PP4 denotes the posterior
- probability of Hypothesis 4, which assesses the likelihood that both the assumed

- 836 model is correct and that the GWAS and expression data are simultaneously
- 837 associated with a single causal variant. PP3 denotes the posterior probability that two
- 838 distinct causal variants exist for GWAS and expression data, respectively. Given the
- 839 genetic structural differences between our East Asian cohort and European
- 840 populations, our findings should be considered an exploratory endeavor.
- 841

842 Genetic correlation estimate

- 843 The meta GWAS summary statistics were used to estimate SNP-based heritability and
- genetic correlation (r_g) for all phenotypes using LD Score Regression^[36,72]. GCTA
- was used to calculate LD score files using a deep whole-genome sequencing reference
 panel of 10k Chinese^[36,66,73].
- 847

848 Mendelian randomization

- 849 Mendelian randomization (MR) is a method for inferring causal associations between 850 exposures and outcomes through the use of genetic variants as instrumental variables 851 $^{[74]}$. To avoid bias caused by linkage disequilibrium, we selected the IV (instrumental 852 variable) SNPs that reached genome-wide significance in GWAS meta-analysis (P < 5 853 $\times 10^{-8}$) and achieved independence in linkage disequilibrium (LD) $r^2 = 0.2$ by GCTA-854 COJO analysis^[75]. The SNPs with a minor allele frequency (MAF) of <0.01 were
- 855 excluded^[76].
- 856

857 Since GWAS summary data for maternal and fetal pregnancy outcomes in East Asian

- ancestry is currently unavailable, we conducted Mendelian randomization analyses
- between thyroid-related traits and maternal and fetal pregnancy outcomes using the
- 860 two-sample method within a single cohort^[45,77], utilizing the TwoSampleMR package
- after completing our GWAS-meta analysis of the Baoan Study and Longgang

862 Study^[78]. We implemented MR analyses under 3 scenarios:

- 863 (1) Meta-Meta: the two-sample MR method is conducted in one-sample setting;
- 864 (2) Baon-Longgang: Baoan Study served as the source of exposed GWAS data, while
 865 the Longgang Study provided the outcome population.
- 866 (3) Longgang-Baoan: Longgang Study served as the source of exposed GWAS data,
 867 while the Baoan Study provided the outcome population.
- 868

869 In order to achieve sufficient power as much as possible, we regard meta-meta as the 870 main MR result, and the MR results of the remaining two situations serve as support 871 for the meta-meta result.

872

873 The variance of continuous traits explained by variants (R²) was estimated using the

- 874 formula $R^2 = (effect \ size)^2 \times 2 \times MAF \times (1 MAF) / [(effect \ size)^2 \times 2 \times MAF \times (1 MAF))]$
- 875 MAF) + (SE)² × 2 × N × MAF × (1 MAF)], where the effect size is measured in
- 876 units of the continuous traits after inverse normal transformation. We calculated the
- 877 F-statistic to evaluate the instrument strength, with values greater than 10 indicating

878 sufficient strength. We applied inverse variance-weighted (IVW), inverse variance-879 weighted using multiplicative random effects (IVWRE), MR-Egger, weighted median (WM) methods, weighted mode, and outlier methods using MR PRESSO^[79]. If MR 880 881 PRESSO successfully excludes outlier IVs, we re-execute the MR analysis using the 882 new set of IV SNPs. To avoid the effects of the presence of heterogeneity in IVs, the 883 IVWRE method is regarded as the most accurate estimation. 884 885 Maternal and fetal pregnancy outcomes 886 We made full use of relevant data on gestational diabetes and gestational hypertension 887 in our cohort. Because the prevalence of gestational hypertension and preeclampsia 888 was less than 2% in our cohort (gestational hypertension: 0.95% for Longgang and 889 0.47% for Baoan; preeclampsia: 0.42% for Longgang and 1.39% for Baoan), we did 890 not include these two pregnancy complications in our analysis. 891 892 Finally, we included five blood glucose traits (FPG: Fasting Plasma Glucose; HBA1c: 893 Glycated Hemoglobin; OGTT0H: Oral Glucose Tolerance Test at 0 hours; OGTT1H: 894 Oral Glucose Tolerance Test at 1 hour; OGTT2H: Oral Glucose Tolerance Test at 2 895 hours) and two blood pressure traits (SBP: Systolic Blood Pressure; DBP: Diastolic 896 Blood Pressure) in our analysis. We completed the meta-GWAS analyses for these 897 seven quantitative traits and Gestational Diabetes Mellitus (GDM). 898 899 Furthermore, we conducted GWAS and meta-GWAS analyses for six birth outcomes, 900 including gestational duration (birth gestational days), preterm birth (deliveries 901 occurring at less than 37 weeks gestational age), birth weight, birth length, low birth weight (defined as birth weight less than 2500g), and macrosomia (defined as birth 902

weight more than 4000g)^[5,80]. For the birth outcomes of birth gestational days and
 preterm birth, we limited the study subjects to mothers who delivered live-born

905 offspring through vaginal delivery.

906

907 Given that some studies have shown that TPOAb positivity with euthyroid is also a risk factor for various pregnancy complications^[1], we included euthyroid TPOAb 908 909 positivity as an exposure to our analysis. Therefore, after deciding on the list of IV 910 SNPs, we conducted MR analyses of associations between 9 thyroid-related traits 911 (TSH levels within reference range during pregnancy, FT4 levels within reference 912 range during pregnancy, subclinical hypothyroidism during pregnancy, isolated 913 hypothyroxinemia during pregnancy, overt hyperthyroidism during pregnancy, 914 subclinical hyperthyroidism during pregnancy, TPOAb levels during pregnancy, 915 TPOAb positivity with euthyroid during pregnancy, and TPOAb positivity during 916 pregnancy) and 14 maternal and neonatal outcomes (GDM, FPG, HBA1c, OGTT0H, 917 OGTT1H, OGTT2H, SBP, DBP, birth gestational days, preterm birth, birth weight,

918 birth length, low birth weight, macrosomia).

010

919	
920	We also used phenotypic associations to explore associations between 9 thyroid traits
921	and 14 maternal and neonatal outcomes. We collected birth outcome data for 92,132
922	pregnant women with thyroid function test results from two hospitals (Table S16).
923	Before performing phenotypic association analyses, we excluded pregnant women
924	with multiple pregnancies, vitro fertilization, and aborted stillbirth outcomes. In the
925	regression analysis of birth length, birth weight, low birth weight, and Macrosomia,
926	we adjusted for fetal sex, BMI, age, and birth gestational days. For the analysis of
927	gestational duration and preterm birth, we adjusted only for fetal sex, maternal BMI,
928	and maternal age.
929	
930	Because the 9 thyroid trait exposures are highly correlated (Figure S17, Table S14),
931	we computed the Bonferroni correction mainly based on the number of outcomes. A
932	Bonferroni correction for the 14 traits (P-value $\square < \square 0.05/14 \square = 0.0036$) was applied on
933	the IVWRE P-value I to define significant results of phenotypic associations and MR.
934	
935	Biobank Japan Study (BBJ)
936	To investigate the potential causal association between thyroid traits during pregnancy
937	and the physical conditions/diseases in older age, we conducted a bidirectional two-
938	sample Mendelian randomization study using our GWAS results and datasets from
939	the BioBank Japan Study. The BioBank Japan Study conducted genome-wide
940	association studies for 220 deep phenotypes (including diseases, biomarkers, and
941	medication usage) in a cohort of 179,000 Japanese individuals ^[30] . Approximately 47%
942	of these subjects were women, and the average age of all subjects was over 62
943	years ^[81] .
944	
945	A Bonferroni correction for the 220 traits (P-value $\square < \square 0.05/220 \square = 0.00023$) was
946	applied on the IVWRE P-value to define significant MR results.
947	
948	Data Availability
949	GWAS summary statistics for the eight thyroid traits investigated can be accessed
950	through the GWAS catalog (Study Accession: GCST90296455- GCST90296462) and
951	GWAS Atlas upon publication, with approval from the Human Genetic Resources
952	Administration of China (HGRAC) (ID: XXX). Researchers can register and gain

- 953 access to use data. Raw sequencing data have been deposited to the Genome
- 954 Sequence Archive (GSA) for Human (https://ngdc.cncb.ac.cn/gsa-human/) at the BIG
- 955 Data Center, Beijing Institute of Genomics, Chinese Academy of Sciences, under the
- 956 BioProject accession number (GSA-Human: HRA006833), with approval from
- 957 HGRAC (ID: XXX). In compliance with the regulations of the Ministry of Science
- 958 and Technology of the People's Republic of China, the raw sequencing data contain
- 959 information unique to an individual and thus require controlled access. Researchers

960 who are interested in collaboration are welcome to contact Siyang Liu

961 (liusy99@mail.sysu.edu.cn).

1019 Figure 5. The association between thyroid-related traits and maternal blood

1020 glucose and blood pressure traits during pregnancy: (A)Observational analysis. (B)

1021 Bidirectional mendelian randomization. (C)The forest plot of MR results under 3

- 1022 scenarios between TSH and 5 blood glucose and blood pressure traits.
- 1023 In Figure A, the upper left triangle of each grid indicates the phenotypic association
- 1024 results in the Longgang cohort, while the lower right triangle indicates the phenotypic

association results in the Baoan cohort. To facilitate the comparison of effect

- 1026 estimates corresponding to different traits, we converted the absolute values of the
- 1027 estimates of phenotypic associations into Q-quantiles for plotting. Shaded areas
- 1028 indicate that the results of the associations between FPG and each of SHO, OHP, and
- 1029 EUTb(+) are unavailable due to an insufficient number of subjects in Baoan hospital.
- 1030 In Figure B, the upper left triangle of each grid indicates the results of forward MR
- 1031 (thyroid traits as exposure variables), while the lower right triangle indicates reverse
- 1032 MR (thyroid traits as outcome variables).
- 1033 In Figure C, the MR results for three scenarios are shown: (1) Meta-Meta: the two-

sample MR method is conducted in one-sample setting; (2) Baon-Longgang: Baoan

- 1035 Study served as the source of exposed GWAS data, while the Longgang Study
- 1036 provided the outcome population. (3) Longgang-Baoan: Longgang Study served as

1037 the source of exposed GWAS data, while the Baoan Study provided the outcome1038 population.

- 1039 TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within
- 1040 reference range during pregnancy; SHO: subclinical hypothyroidism during
- 1041 pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt
- 1042 hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during
- 1043 pregnancy, TPOAb: TPOAb levels, Tb(+): TPOAb positivity during pregnancy and
- 1044 EUTb(+): TPOAb positivity with normal functioning thyroids(ie, euthyroid). SBP:
- 1045 systolic blood pressure; DBP: diastolic blood pressure, HBA1c, Glycated hemoglobin;
- 1046 FPG, Fasting plasma glucose, OGTT0H, Oral glucose tolerance test 0 hour; OGTT1H,
- 1047 Oral glucose tolerance test 1 hour; OGTT2H, Oral glucose tolerance test 2 hour,
- 1048 GDM, Gestational diabetes mellitus.
- 1049
- 1050

1051 Figure 6. The association between thyroid-related traits during pregnancy and

- 1052 **birth outcomes:** (A)Prospective observational analysis. (B) Mendelian randomization.
- 1053 (C)Mendelian randomization analysis for casual associations between TSH and 1054 thyroid cancer and between TSH and gestational duration.
- In Figure A, the upper left triangle of each grid indicates the phenotypic associationresults in the Longgang cohort, while the lower right triangle indicates the phenotypic
- 1057 association results in the Baoan cohort.
- 1058 In Figure C, TSH and gestational duration are based on summary statistics from the
- 1059 meta-analysis of the Baoan and Longgang Study. ($N_{TSH}=\Box$ 67,471, and $N_{gestational duration}$
- $1060 = \Box 51,592$). The results of the IVW, IVWRE, MR Egger, Simple mode, and Weighted
- 1061 mode methods are based on the analysis of the IVs excluded by MR PRESSO. The
- 1062 crosshairs on the plots represent the 95% confidence intervals for each SNP-TSH or
- 1063 SNP-outcome association. IVW, Inverse Variance Weighted; IVWRE, Inverse
- 1064 Variance Weighted with Multiplicative Random Effects.
- 1065 TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within
- 1066 reference range during pregnancy; SHO: subclinical hypothyroidism during
- 1067 pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt
- 1068 hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during
- 1069 pregnancy, TPOAb: TPOAb levels; Tb(+): TPOAb positivity during pregnancy and
- 1070 EUTb(+):TPOAb positivity with normal functioning thyroids(ie, euthyroid).
- 1071
- 1072

Figure 7. The results of bidirectional mendelian randomization analysis between thyroid-related traits during pregnancy and thyroid-related diseases in middle-

- 1075 aged and elderly people.
- 1076 The upper left triangle of each grid indicates the results of forward MR (thyroid traits
- 1077 as exposure variables), while the lower right triangle indicates the results of reverse
- 1078 MR (thyroid traits as outcome variables). Shaded areas indicate that reverse MR
- 1079 results with goiter, Hashimoto's thyroiditis, hypothyroidism and thyroid cancer as the
- 1080 exposure variable are not available due to insufficient number of IVs.

- 1081 TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within
- 1082 reference range during pregnancy; SHO: subclinical hypothyroidism during
- 1083 pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt
- 1084 hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during
- 1085 pregnancy, TPOAb: TPOAb levels, Tb(+): TPOAb positivity during pregnancy and
- 1086 EUTb(+): TPOAb positivity with normal functioning thyroids (ie, euthyroid).

Comprehensive thyroid traits during pregnancy

Figure 1. Schematic design of the study. TSH: thyroid stimulating hormone; **FT4**: free thyroxine; **TPOAb** thyroid peroxidase antibody. **BBJ:** Biobank Japan study.

Figure 2. The Manhattan for GWAS meta-analyses of TSH(A), and FT4(B). The x-coordinate of the SNPs in the plot represents their position on each chromosome when the y-coordinate implies their P-value (-log10 scale) of the association test. The black dotted horizontal line indicates the significant threshold for the genome-wide association test(i.e., 5×10^{-8}). Genomic loci containing phenotype-associated variants previously reported in the GWAS catalog are colored in black, while novel loci are colored in red.

Figure 3. The manhattan plots for GWAS meta-analyses of thyroid dysfunction: subclinical hypothyroidism(**A**), isolated hypothyroxinemia (**B**), overt hyperthyroidism(**C**), and subclinical hyperthyroidism(**D**). Figure 2. The Manhattan for GWAS meta-analyses of TSH(A), and FT4(B).

The x-coordinate of the SNPs in the plot represents their position on each chromosome when the y-coordinate implies their P-value (-log10 scale) of the

association test. The black dotted horizontal line indicates the significant threshold for the genome-wide association test(i.e., 5×10 -8). Genomic loci containing phenotype-associated variants previously reported in the GWAS catalog are colored in black, while novel loci are colored in red.

Figure 4. The manhattan plot for GWAS meta-analyses of thyroid autoimmunity: TPOAb levels (A), TPOAb positivity (B). The x-coordinate of the SNPs in the plot represents their position on each chromosome when the y-coordinate implies their P-value (-log10 scale) of the association test. The black dotted horizontal line indicates the significant threshold for the genome-wide association test(i.e., 5×10 -8). Genomic loci containing phenotype-associated variants previously reported in the GWAS catalog are colored in black. Before performing the GWAS analysis, TPOAb levels were natural log-transformed.

(C)Forward MR results of TSH for 3 scenarios

Figure 5. The association between thyroid-related traits and maternal blood glucose and blood pressure traits during pregnancy: (A)Observational analysis. (B) Bidirectional mendelian randomization. (C)The forest plot of MR results under 3 scenarios between TSH and 5 blood glucose and blood pressure traits. In Figure A, the upper left triangle of each grid indicates the phenotypic association results in the Longgang cohort, while the lower right triangle indicates the phenotypic association results in the Baoan cohort. To facilitate the comparison of effect estimates corresponding to different traits, we converted the absolute values of the estimates of phenotypic associations into Q-quantiles for plotting.

In Figure B, the upper left triangle of each grid indicates the results of forward MR (thyroid traits as exposure variables), while the lower right triangle indicates reverse MR (thyroid traits as outcome variables).

In Figure C, the MR results for three scenarios are shown: (1) Meta-Meta: the twosample MR method is conducted in one-sample setting; (2) Baon-Longgang: Baoan Study served as the source of exposed GWAS data, while the Longgang Study provided the outcome population. (3) Longgang-Baoan: Longgang Study served as

the source of exposed GWAS data, while the Baoan Study provided the outcome population.

TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within reference range during pregnancy; SHO: subclinical hypothyroidism during pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during pregnancy and EUTb(+): TPOAb levels, Tb(+): TPOAb positivity during pregnancy and EUTb(+): TPOAb positivity with normal functioning thyroids(ie, euthyroid). SBP: systolic blood pressure; DBP: diastolic blood pressure, HBA1c, Glycated hemoglobin; FPG, Fasting plasma glucose, OGTT0H, Oral glucose tolerance test 0 hour; OGTT1H, Oral glucose tolerance test 1 hour; OGTT2H, Oral glucose tolerance test 2 hour, GDM, Gestational diabetes mellitus.

Figure 6. The association between thyroid-related traits during pregnancy and birth outcomes. (A)Prospective observational analysis. (B) Mendelian randomization. (C)Mendelian randomization analysis for casual associations between TSH and thyroid cancer and between TSH and gestational duration.

In Figure A, the upper left triangle of each grid indicates the phenotypic association results in the Longgang cohort, while the lower right triangle indicates the phenotypic association results in the Baoan cohort.

In Figure C, TSH and gestational duration are based on summary statistics from the meta-analysis of the Baoan and Longgang Study. ($N_{TSH}=\Box 67,471$, and $N_{gestational duration} = \Box 51,592$). The results of the IVW, IVWRE, MR Egger, Simple mode, and Weighted mode methods are based on the analysis of the IVs excluded by MR PRESSO. The

crosshairs on the plots represent the 95% confidence intervals for each SNP-TSH or SNP-outcome association. IVW, Inverse Variance Weighted; IVWRE, Inverse Variance Weighted with Multiplicative Random Effects. TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within reference range during pregnancy; SHO: subclinical hypothyroidism during pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during pregnancy, TPOAb: TPOAb levels; Tb(+): TPOAb positivity during pregnancy and

EUTb(+):TPOAb positivity with normal functioning thyroids(ie, euthyroid).

Figure 7. The results of bidirectional mendelian randomization analysis between thyroid traits during pregnancy and thyroid-related diseases in middle-aged and elderly people.

The upper left triangle of each grid indicates the results of forward MR (thyroid traits as exposure variables), while the lower right triangle indicates the results of reverse MR (thyroid traits as outcome variables).

TSH: TSH levels within reference range during pregnancy; FT4: FT4 levels within reference range during pregnancy; SHO: subclinical hypothyroidism during pregnancy; ISH: isolated hypothyroxinemia during pregnancy, OHP: overt hyperthyroidism during pregnancy; SHP: subclinical hyperthyroidism during pregnancy, TPOAb: TPOAb levels, Tb(+): TPOAb positivity during pregnancy and EUTb(+): TPOAb positivity with normal functioning thyroids (ie, euthyroid).
