26 Abstract (249 words)

27 Rationale. Mechanical ventilation plays an important role in critical illness-associated 28 diaphragm weakness. Weakness contributes to difficult weaning and is associated with 29 increased morbidity and mortality. Diaphragm weakness is caused by a combination of atrophy and dysfunction of myofibers, which are large syncytial cells maintained by a 30 population of myonuclei. Each myonucleus provides gene transcripts to a finite fiber volume, 31 termed the myonuclear domain. Changes in myonuclear number in myofibers undergoing 32 atrophy has not been investigated in mechanically ventilated ICU patients. Myonuclear 33 number is a determinant of transcriptional capacity, and therefore critical for muscle 34 35 regeneration after atrophy. 36 **Objectives.** Our objective was to investigate if and how myonuclear number changes in the diaphragm of mechanically ventilated ICU patients and whether changes are associated with 37 38 myofiber atrophy. Methods. We used a combination of transcriptomics, immunohistochemistry, and confocal 39 40 microscopy to study myonuclear alterations in diaphragm and quadriceps biopsies from mechanically ventilated ICU patients. 41 Results. Myonuclear number and myonuclear domain were reduced in patients with 42 43 diaphragm myofiber atrophy. Intrinsic apoptotic pathway activation was identified as a mechanism underlying myonuclear removal in the diaphragm of mechanically ventilated ICU 44 patients. Total transcriptional activity in myofibers decreased with myonuclear loss. 45 Furthermore, muscle stem cell number was reduced in the patients with diaphragm atrophy. 46 47 **Conclusion.** We identified myonuclear loss due to intrinsic apoptotic pathway activation as a potential mechanism underlying diaphragm atrophy in mechanically ventilated patients. This 48 provides novel insights in diaphragm weakness of ICU patients. Targeted therapies may limit 49 development of diaphragm weakness and improve weaning outcome. 50

51

52 Introduction

Weakness of the diaphragm is a well-known consequence of critical illness and mechanical 53 54 ventilation (MV) in patients admitted to the intensive care unit (ICU). It contributes to difficult 55 weaning, which is associated with increased morbidity, mortality, and healthcare costs (1). Furthermore, it can lead to physical disability and long-term impairment in intensive care 56 survivors (2). Diaphragm weakness is caused by a combination of atrophy and dysfunction of 57 the remaining contractile material, leading to weakness of muscle cells (i.e., myofibers). In 58 59 recent years, several mechanisms underlying contractile dysfunction have been identified (3-5), including changes in myosin conformation (6). The mechanisms underlying atrophy are 60 not well understood. Increased proteolysis, resulting in a reduction of contractile material, 61 may play a role (7, 8), but it is unclear whether other pathways contribute as well. Identifying 62 63 the pathways that are involved in diaphragm myofiber atrophy will have important considerations for the development of therapies and for clinical practice, as diaphragm 64 atrophy is associated with prolonged mechanical ventilation, longer ICU length of stay and 65 increased risk of complications (9, 10). 66

67 Myofibers are large syncytial cells that are maintained by a population of post-mitotic myonuclei. Each myonucleus provides gene transcripts to a finite fiber volume, termed the 68 myonuclear domain (11-14). During changes in muscle mass, myofibers' nuclear number 69 may change (15). In several pathological states resulting in myofiber atrophy, apoptosis 70 71 regulates myonuclear number (16). In the diaphragm of ventilated rodents and brain-dead organ donors, myonuclear loss and upregulated apoptosis were identified to underlie 72 73 diaphragm atrophy, but these pathways have not yet been investigated in ventilated ICU 74 patients (17, 18). Furthermore, the brain-dead organ donors and rodents are very different 75 from typical ICU patients, from perspective of ventilator mode, but also systemic 76 inflammation and exposure to drugs; therefore, these models do not adequately reflect ICU 77 patients (17). It is critical to investigate whether apoptosis and myonuclear loss occur in these patients as, during weaning, the diaphragm needs to regain mass and function for 78

79 which nuclear number and their transcriptional activity are important (19, 20). Furthermore, 80 loss of myonuclei may lead to longer-term functional impairment and weakness after hospital discharge, with have important consequences for patients including the risk for ICU 81 82 readmission and persistent dyspnea (21). Finally, if myonuclear apoptosis plays a role in critical illness-associated diaphragm weakness, inhibiting the underlying mechanism may be 83 84 a promising therapeutic venue (19, 20). 85 Thus, our objective was to study apoptotic pathways and myonuclear regulation in the 86 diaphragm of mechanically ventilated ICU patients. Hence, we performed next-generation 87 RNA-sequencing in diaphragm biopsies of MV ICU patients and immunofluorescence labeling of biopsy cryosections to investigate whether myonuclei undergo apoptosis. 88 Furthermore, we studied myonuclear number and morphology in myofibers isolated from 89 90 diaphragm biopsies. Additionally, we obtained quadriceps biopsies of MV ICU patients to investigate whether our findings were specific to the diaphragm. Some of the results of these 91 studies have been previously reported in conference abstracts and as a preprint (22, 23). 92

93 Methods

94 For further details on the applied methods, see the online supplement.

95 Patients, diaphragm biopsies

Diaphragm muscle biopsies were obtained from ICU patients receiving invasive mechanical 96 ventilation (ICU patients, n = 24) and patients undergoing elective lung surgery for early-97 stage lung malignancy without critical illness (*Control* patients, n = 10). Exclusion criteria 98 99 were chronic obstructive pulmonary disease (\geq GOLD stage III), congestive heart failure. 100 neuromuscular diseases, chronic metabolic disorders, pulmonary hypertension, chronic use of corticosteroids (> 7.5mg/day for at least 3 months), and more than 10% weight loss within 101 the last 6 months. The exclusion criteria were similar for all experimental groups. Patients' 102 103 characteristics are presented in Table 1. The biopsy protocol was approved by the 104 institutional review board at Amsterdam UMC (location VUmc), the Netherlands. Patients were recruited in Amsterdam UMC, the Netherlands Cancer Institute-Antoni van 105

Leeuwenhoek Hospital (both in Amsterdam, the Netherlands), and Medisch Spectrum
 Twente (Enschede, the Netherlands). Written informed consent was obtained from the
 patients or their legal representative.

109 Patients, quadriceps biopsies

110 Quadriceps biopsies of ICU patients (n = 10) were obtained in the context of a separate

111 study that has been filed in the Clinical Trial Register under #NCT03231540 and was

approved by the Medical Ethical Committee of VU Medical Center, Amsterdam, the

113 Netherlands. Informed consent was obtained from the patient or a legal representative.

114 Patients \geq 18 years that had an expected ventilation duration of \geq 72 hours, were expected to

tolerate enteral nutrition ≥72 hours, and had a Sequential Organ Failure Assessment (SOFA)

116 score ≥6, were considered eligible for inclusion. Exclusion criteria were contra-indications to

117 enteral nutrition, short bowel syndrome, type C liver cirrhosis or acute liver failure,

dependency on renal replacement therapy, requiring another specific enteral nutrition

119 formula for medical reasons, BMI >35 kg/m2, extensive treatment limitations, disseminated

120 malignancy, hematological malignancy, primary neuromuscular pathology, chronic use of

121 corticosteroids for >7 days before ICU admission or contra-indications for muscle biopsy

such as the need for continuous systemic anticoagulation, INR >1.3 or thrombocytes <100 ×

123 10³ / mm³.

124 Single myofiber microscopy

125 Single myofibers were manually isolated from the biopsies. Myonuclear number, myofiber

volume, myonuclear morphology, and RNA-polymerase-II Ser5 fluorescence were

127 determined using immunofluorescence labeling in combination with confocal microscopy.

128 RNA-sequencing

129 RNA was extracted using a commercially available kit and sequenced using a NextSeq500130 (Illumina).

131 Immunohistochemistry

- 132 Serial cryosections were cut from the biopsies and stained to study myonuclear number,
- 133 myonuclear domain, markers for apoptosis, and satellite cell content.

134 Statistical analysis

- 135 Normality of the distribution of the studied variables was assessed visually on normal
- 136 probability plots. Log transformation was performed if necessary. To compare the difference
- 137 between ICU patients and control patients, student's t-test or Mann-Whitney-U was applied
- 138 for non-repeat measurements; and linear mixed model with patients as the random factor
- 139 was applied for measurements involving technical replicates in all human samples. For linear
- 140 mixed models, Greenhouse-Geisser correction was applied to adjust for potential lack of
- sphericity. For the comparison of three groups or more, one-way analysis of variance
- 142 (ANOVA) or Kruskal-Wallis tests were performed with Tukey's or Dunn's post-hoc tests,
- depending on the distribution of the data. We used a two-sided significance level of 5% for all
- analyses. Unless otherwise noted, data are expressed as mean (± standard error), median
- 145 [interquartile range], or frequencies (percentage), as appropriate.

- 147

148 **Results**

Diaphragm biopsies were collected from 24 mechanically ventilated ICU patients who 149 150 underwent laparotomy or thoracotomy for a clinical indication. The biopsies were collected 151 from the left anterolateral part of the zone of apposition of the diaphragm. In Table 1 we summarize the clinical parameters. The biopsies were compared to the biopsies of 10 152 patients who underwent elective thoracic surgery for a small, primary pulmonary nodule. The 153 groups were matched for age, body mass index, and sex (Table 1). Due to the limited size of 154 155 the biopsies, not every biopsy was used in every experiment. Table S1 details which biopsies 156 were used for each experiment.

157 Transcriptomics reveals upregulation of apoptotic pathways in the diaphragm

158 To investigate the mechanisms underlying diaphragm weakness and atrophy, we performed next-generation RNA-sequencing of whole tissue samples cut from the biopsies. Table S2 159 shows the clinical characteristics of the patients included in this experiment. Principal 160 component analysis (PCA) revealed clear clustering in the control patients, while the ICU 161 group showed a more variable clustering pattern (Fig. 1A). We identified 2977 differentially 162 expressed genes (1741 upregulated in the ICU group and 1236 downregulated (Fig. 1B) 163 164 between control and ICU patients. A heatmap of the top 50 differentially expressed genes was generated (Fig. 1C). Next, we performed Panther pathway enrichment analysis of 165 significant (FDR < 0.2, dashed line represents p-value of 0.05) differentially expressed genes 166 (Fig. 1D). Consistent with our hypothesis of increased apoptosis in ICU patients, the top 167 168 upregulated pathways in the ICU group were the p53, apoptosis, and integrin signaling pathways. Thus, in mechanically ventilated ICU patients, the p53 and apoptosis pathways 169 are upregulated (Fig. 1E, S1A), providing a potential mechanism underlying weakness and 170 171 atrophy.

172 Caspase-3-mediated apoptosis of myonuclei

173 As bulk-tissue RNA-sequencing revealed marked upregulation of the apoptotic pathway, next we performed analyses on muscle cross-sections to allow for the identification of different 174 cell types that may be undergoing apoptosis. We used multiple markers to distinguish 175 176 myonuclei from non-myonuclei (e.g. pericentreolar-material-1 (PCM1) (24) and dystrophin/laminin immunolabeling), as previously it was suggested that much of the 177 apoptosis that occurs during muscle atrophy can be attributed to the non-myonuclear cell 178 pool (24). Tables S3 and S4 show the characteristics of the patients included in these 179 180 experiments. The percentage of myonuclei undergoing apoptosis was determined using terminal deoxynucleotidyl transferase dUTP nick end labeling (TUNEL) of double-stranded 181 DNA breaks (Fig. 2A). Representative images of TUNEL labeling of a DNase-I treated 182 diaphragm section (positive control) are shown in Fig. S2. The mean TUNEL-index (number 183 of TUNEL-positive myonuclei divided by the total number of myonuclei) in the ICU group was 184 almost double that of the control group (Fig. 2B). There was no difference in TUNEL-index 185 for other cell types (Fig. S3A). Furthermore, we used an antibody for cleaved (i.e. activated) 186 187 caspase-3 to investigate the role of caspase-3 mediated nuclear apoptosis (Fig. 2C) (25). 188 The mean activated caspase-3 index (number of cleaved caspase-3-positive myonuclei 189 divided by the total number of myonuclei) was ~3-fold higher in the ICU group (Fig. 2D). 190 Caspase-3-index for other cell types was also higher in the ICU group (Fig. S3B). 191 Next, to investigate whether our findings are specific to the diaphragm, we obtained 192 guadriceps muscle biopsies (n = 10) and compared them to healthy controls (n = 5). Tables 2 193 and S5 show the clinical characteristics of these groups. Note that the duration of mechanical 194 ventilation and disease severity is similar to that of the groups from which diaphragm 195 biopsies were obtained. The percentage of myonuclei undergoing apoptosis was determined 196 using the same activated caspase-3 immunofluorescence protocol used for the diaphragm 197 biopsies (Fig. S4A). In the ICU group, the activated caspase-3 index of both myonuclei and other cell types was almost double that of the control group, but still more than two-fold lower 198 than in the diaphragm (Fig. S4B, C, S5). The mean myofiber CSA was similar in the ICU and 199

control groups (Fig. S4D), suggesting that in the quadriceps of MV ICU patients, caspase-3
 activation occurs before the onset of atrophy.

Thus, both our transcriptomic and immunofluorescence data support a mechanism where caspase-3-mediated apoptosis is increased during critical illness-associated diaphragm weakness and is increased in quadriceps muscle before the onset of atrophy.

205 Decreased myonuclear number and myonuclear domain in atrophic diaphragm fibers

206 To investigate whether the upregulation of apoptosis in myonuclei resulted in a reduced 207 myonuclear number, we counted myonuclei in 8-12 myofibers per biopsy that were randomly 208 selected and manually isolated. This method allows for a precise determination of myonuclear number per myofiber volume. Myonuclear domain was determined by dividing 209 210 myofiber volume by myonuclear number. Immunofluorescent staining of myonuclear marker PCM1 revealed that the proportion of PCM1 positive myonuclei within the isolated myofibers 211 212 (n = 3 control and n = 3 ICU. Table S6) was >98% in both groups, showing that the number of non-myonuclei included in the preparations did not impact nuclear number (Fig. S6). Fast 213 214 and slow-twitch fibers were identified by immunoreactivity for fast-twitch myosin heavy chain 215 isoform and data were segregated according to fiber type.

216 Myofiber volume and myonuclear domain size were lower in the ICU group, but nuclear 217 number was not significantly lower (Fig. S7). We hypothesized that we did not observe a difference in myonuclear number due to the presence of patients in the ICU group with a 218 myofiber volume similar to that of the controls. Therefore, to investigate whether myonuclear 219 number was reduced specifically in ICU patients with atrophy, we separated the ICU group 220 into two groups: one with atrophy (ICU A+) and one without atrophy (ICU A-). To this end, 221 we used myofiber CSA data derived from cryosections (mean size of ~450 myofibers). For 222 the ICU A-- group, the lower limit of the CSA was set at the median CSA of the control group 223 224 (CSA of 2500 μ m²). To ensure minimal overlap between the groups, the upper limit of the

225 ICU A+ group was set at a CSA of 2000 μ m². Clinical characteristics of all groups are shown 226 in Table 1.

227 As expected, the volume of the isolated myofibers in the ICU A+ group was ~50% smaller 228 compared to the ICU A- and control groups, and this difference was similar for both fiber types (Fig. 3C). In the ICU A+ group, myonuclear number was reduced by about 35% in both 229 fast and slow myofibers when compared to the ICU A- and the control group (Fig. 3D). To 230 verify whether our findings in single myofibers were representative of a larger sample, we 231 232 validated these findings by analyzing the number of myonuclei per myofiber in diaphragm muscle cross-sections with an average size of 498 myofibers per section. Myonuclei were 233 identified using PCM1 labeling in combination with localization within the dystrophin barrier 234 (note that we did not stain for myofiber type). In muscle cross-sections, average myonuclear 235 236 counts per fiber were reduced by about 39% in the ICU A+ group compared to the control group (Fig. S8B), which was consistent with the results from the isolated myofibers (Fig. 3D). 237 Next, we counted the myonuclei present in the quadriceps cross-sections, and found that 238 there was no difference in the number of myonuclei per myofiber between the control and 239 240 ICU patients (Fig. S8C). In the isolated myofibers, myonuclear domain size was smaller in the ICU A+ group when compared to the control group, but not when compared to the ICU 241 A- group (Fig. 3E). When we examined the relationship between myofiber CSA and 242 myonuclear number, we found a comparable positive correlation in all three groups (Fig. 243 244 S9A). Myonuclear domain size and myofiber CSA showed a similar positive correlation, but the elevation of the regression line in the ICU A+ group was significantly lower, indicating 245 246 smaller myonuclear domains for the same CSA. The slope of the regression line of the fibers isolated from the biopsies of ICU A- patients had a significantly steeper relationship between 247 248 myonuclear domain and cross-sectional area compared to the ICU A- group (Fig. S9B). In 249 conclusion, myonuclear number is reduced in myofibers in the atrophic diaphragm of 250 mechanically ventilated ICU patients, and myonuclear domain is smaller, indicating relatively

251 more atrophy than myonuclear loss. Furthermore, the reduction in myonuclear number was 252 absent in the diaphragm of similar ICU patients without established atrophy. 253 Thus, atrophic diaphragm myofibers have a reduced number of myonuclei. In the diaphragm, 254 loss of myonuclei appears to commence before the onset of atrophy, and before changes in myonuclear number in limb muscle. This may have profound implications for weaning and 255 recovery after ICU and hospital discharge, as it has been proposed that myofibers depend on 256 their myonuclear content for recovery after atrophy (26). 257 258 Changes in myonuclear morphology 259 In addition to myonuclear number, myonuclear size is known to scale with myofiber size (27). 260 Based on the changes we observed in myonuclear number, we sought to study changes in myonuclear morphology by segmenting every 3D-rendered nucleus present within the Z-261 stacks of the myofibers (Fig. 4A). Myonuclear volume was reduced in ICU A+ patients (Fig. 262

4B), and the cumulative fluorescence intensity of the nuclear lamina (lamin A/C) within each

264 nucleus was increased (Fig. 4C). An increased total fluorescent intensity of the nuclear

265 lamina may indicate increased nuclear wrinkling or increased thickness of the nuclear

lamina. To further study this, we determined the wrinkling index of each nucleus by

267 measuring the standard deviation of the fluorescence intensity within each segmented

nucleus in maximum intensity Z-projections of the Z-stacks (Fig. 4D) (28). Nuclear wrinkling

was increased in the ICU A+ and A- groups, when compared to the control group (Fig. 4E).

270 Mean ellipticity or sphericity, two shape descriptors of sphere-like objects, were not different

between the groups (Fig. S10 A-B). Thus, nuclear volume was lower in the ICU A+ group

and myonuclear wrinkling was increased in in both ICU A+ and ICU A- patients.

273 Diminished transcriptional activity of myofibers in the atrophic diaphragm of mechanically

274 ventilated ICU patients

Myonuclear number has been shown to influence myonuclear transcription, with transcription
levels increasing with decreasing nuclear number (29, 30). Thus, we aimed to determine
whether changes in myonuclear number and morphology resulted in changes in myonuclear

278 transcription in ICU patients. We hypothesized that diminished transcriptional activity 279 contributes to atrophy in ICU patients. Furthermore, transcriptional activity may be 280 downscaled with the reduced myonuclear domain size in ICU A+ patients, because the 281 cellular volume to regulate is smaller. The transcriptional activity of each nucleus was determined by measuring the fluorescent intensity of phosphorylated Serine 5 on RNA-282 polymerase-2. This phosphorylation occurs shortly after the initiation of transcription, before 283 the capping of the mRNA (31, 32) (Fig. 5A), and strongly correlates with transcriptional 284 285 activity (33, 34). We measured the intensity of the immunofluorescence of activated RNApolymerase-2 within each nucleus (Fig. 5B) from ten randomly selected myofibers of 5 286 patients from the ICU group and 5 controls (Table S7). Total transcriptional activity per fiber 287 288 was calculated by summation of the fluorescence intensity of RNA-pol-II Ser5 labeling within 289 each nucleus present in the myofiber and was on average almost two-fold lower in the ICU A+ group compared to the control group (Fig. 5C). This was explained by the lower 290 myonuclear number in ICU myofibers, because the fluorescence intensity of RNA-Pol-II Ser5 291 292 per nucleus did not differ between the groups (Fig. 5D). After normalization to fiber volume, 293 the difference in transcriptional activity per fiber was absent (Fig. 5E). Thus, based on these 294 findings, insufficient transcriptional activity of individual nuclei is unlikely to contribute to 295 atrophy, whereas the reduced myonuclear number in the ICU group with atrophy may reduce 296 total transcriptional activity per myofiber.

297 Decreased muscle stem cell number in the diaphragm of ICU patients

After muscles undergo atrophy that is accompanied by loss of myonuclei (Fig. 3) and transcriptional capacity (Fig. 5), myonuclear number could be restored by the contribution of satellite cells, the resident stem cells present adjacent to myofibers that contribute to myofiber homeostasis (35). Interestingly, muscle stem cell activity is particularly high in the diaphragm (36, 37). Thus, we aimed to investigate whether the muscle stem cell population in the atrophic diaphragm is affected, as this could further impair muscle recovery after atrophy. First, in our RNA-seg data set, we found a lower relative expression of *PAX7*, a

305 transcript uniformly expressed in muscle stem cells (38), in both ICU groups compared to the control group (Fig. S1B). Next, immunofluorescent labeling of PAX7 was performed to 306 307 determine the number of muscle stem cells in diaphragm cross-sections (Fig. 6A). Patient 308 characteristics of the groups used in these experiments are shown in Table S8. In ICU patients with atrophy, satellite cell content was reduced when normalized for either the 309 310 number of myofibers present within the section (Fig. 6B) or when normalized for total section area (Fig. 6C). In conclusion, satellite cell content is reduced in the atrophic diaphragm of 311 312 mechanically ventilated patients, potentially impeding the restoration of myonuclear number during recovery. 313

314

315 Discussion

316 In this study, transcriptome profiling identified apoptotic pathway activation as a potential 317 mechanism underlying critical illness-associated diaphragm weakness. Increased apoptosis of myonuclei was confirmed by using staining of cross-sections. Furthermore, this is the first 318 study to reveal reduced myonuclear number in mechanically ventilated ICU patients. We 319 show that myonuclear loss is associated with a reduction in transcriptional activity within 320 321 myofibers. Having lost a significant number of myonuclei may put patients at a disadvantage during ventilator weaning and also may have long-term consequences after ICU discharge, 322 323 because muscle growth and recovery is associated with myonuclear number (19, 20). Reduced myonuclear number in atrophic myofibers implies that recovery of strength requires 324 325 the addition of new myonuclei from satellite cells, instead of solely increasing protein 326 synthesis to recover lost contractile material (Fig. 7) (39). Importantly, we discovered a reduced number of satellite cells in the diaphragm of ICU patients, possibly leading to further 327 impairment of recovery after atrophy. Discovery of this underlying mechanism may pave the 328 329 way for new treatments to prevent diaphragm atrophy.

330

331 Myonuclear apoptosis in the diaphragm

The fate of myonuclei in muscles undergoing atrophy is subject to debate (40-42). The 332 333 changes in myonuclear number and domain during atrophy likely depend on the type of 334 atrophic stimulus (11, 43). Our observation that mechanical ventilation may induce caspase-3-mediated apoptosis of myonuclei is in accordance with the findings of a study investigating 335 diaphragm atrophy in mechanically ventilated rats (6 and 12 h) (44). The authors reported no 336 changes in myonuclear domain size, indicating atrophy that was proportional to myonuclear 337 loss. In our study, the myonuclear domain was significantly smaller in the ICU group with 338 339 established atrophy compared to controls, implying more or faster atrophy than myonuclear loss. There are several potential explanations for this discrepancy. First, we used 3D 340 rendering of Z-stacks of confocal images to measure myonuclear domain volume within 341 342 single myofibers, a more sensitive method compared to the myonuclear domain surface area 343 (2D) measurements done on muscle cross-sections in the rodent study (15). Second, the patients in this study had a median ventilation duration of more than 60 hours, much longer 344 than the 12 hours in the rodent study. In larger clinical studies, duration of ventilation was 345 346 associated with the degree of diaphragm atrophy (45). The longer time on mechanical ventilation in our study may explain the reduction in myonuclear domain size, with atrophy 347 exceeding myonuclear loss. Finally, unlike critically ill patients, the mechanically ventilated 348 rodents were healthy. Common conditions in the ICU such as systemic inflammation and 349 350 increased metabolic demand may independently cause muscle wasting, further accelerating atrophy (46). The pathophysiology of diaphragm atrophy has also been evaluated in 351 352 mechanically ventilated brain-dead organ donors (7). Oxidative stress and mitochondrial 353 dysfunction were suggested to activate the intrinsic pathway leading to caspase-3 activation 354 and apoptosis (18). In diaphragm biopsies of mechanically ventilated ICU patients, a redox 355 imbalance was proposed to underlie diaphragm atrophy in the absence of mitochondrial 356 dysfunction or oxidative stress. This discrepancy may be due to the difference in clinical 357 features between brain-dead organ donors and mechanically ventilated ICU patients.

358 In quadriceps muscle biopsies of ICU patients, we showed increased caspase-3 activity, albeit at a lower level than in the diaphragm, indicating caspase-3 activation before the onset 359 of muscle atrophy and loss of myonuclei, independent of MV. Indeed, in the quadriceps of 360 361 MV ICU patients, atrophy has been shown to occur later (7 days) after ICU admission (47). In this study, we report a transcriptomic profile of the diaphragm of mechanically ventilated 362 ICU patients. Main findings include the upregulation of 20 genes associated with the p53 363 pathway, as well as the upregulation of 16 genes associated with apoptosis. Because p53 is 364 365 subject to redox regulation, a redox imbalance may activate the pathway (48). The p53 366 pathway was upregulated in various animal models of muscle atrophy. In mouse soleus muscle, after 48 of hind limb suspension, the p53 pathway was upregulated and the 367 368 apoptotic index was increased (49). In a recent study in mechanically ventilated rabbits, the 369 p53 pathway was upregulated and was hypothesized to contribute to diaphragm weakness 370 via increased senescence (50). Interestingly, the p53 and apoptosis pathways were not upregulated in a transcriptomics study of the atrophic diaphragm of controlled mechanically 371 ventilated rats (51). This demonstrates the disparity between animal models and clinical 372 373 reality, further underlining the need to study pathophysiology in samples from patients. Finally, 19 genes associated with the integrin pathway were upregulated in the diaphragm of 374 375 ICU patients. This pathway is associated with the transmission of forces from the 376 extracellular matrix to actin and has been shown to be upregulated after eccentric 377 (lengthening) contractions (52). Eccentric contractions of the diaphragm may occur during 378 ineffective efforts, premature cycling or reverse triggering, a ventilator asynchrony that has 379 been shown to contribute to diaphragm dysfunction and myofiber injury in MV pigs with high 380 respiratory effort (53, 54). Therefore, our data support a role for eccentric contractions in the 381 pathophysiology of critical illness associated diaphragm weakness.

382 Decreased number of satellite cells in the mechanically ventilated diaphragm

383 Our results show that the number of *PAX7* expressing cells is reduced in the diaphragm of 384 mechanically ventilated ICU patients. This may be a direct effect of increased apoptosis, but

385 we did not perform a separate experiment to quantify apoptotic satellite cells. Only a small 386 fraction of cells in our cross-sections expressed PAX7 (0.05-0.1%) Therefore, it is technically challenging to capture apoptotic satellite cells, especially because of diaphragm biopsy size 387 388 limitations. Whether satellite cells are required for muscle regeneration depends on the type of atrophy, and on whether myonuclei are lost during atrophy (35, 55, 56). Nevertheless, 389 390 lineage tracing studies demonstrated that satellite cell activity is particularly high in the diaphragm under non-diseased conditions (36, 37). In addition, there are interstitial stem 391 392 cells that can contribute to myofibers that do not express PAX7 (57-60). Future studies should determine the prevalence of non-satellite cell myogenic progenitors in the diaphragm 393 394 of humans, and whether these cells are a significant source of myonuclei during diaphragm 395 muscle homeostasis. Satellite cell content was reduced in the quadriceps of mechanically 396 ventilated patients with sustained atrophy after 6 months, suggesting a crucial role for 397 satellite cells during muscle regeneration in ICU patients (54). However, the exact role of satellite cells during recovery after diaphragm atrophy warrants further investigation. 398

399 Disturbed sarcomeric integrity is accepted as one of the mechanisms contributing to critical 400 illness-associated diaphragm weakness (8). In non-diseased conditions, muscle can repair 401 its sarcomeres, as damage occurs during both exercise and normal use. After sarcomeres are damaged, nuclear movement to a site of injury is required for repair (61, 62). During this 402 403 process, myonuclei migrate toward damaged muscle sections to supply mRNA for 404 sarcomeric proteins, allowing the reassembly of the contractile machinery (61). This 405 mechanism may be disturbed in critical illness-associated diaphragm weakness because 406 sarcomeric damage and reduced myonuclear number are present simultaneously.

407 Clinical implications

The identification of intrinsic apoptotic pathway activation as a mechanism underlying diaphragm atrophy in MV ICU patients may open therapeutic venues to limit diaphragm weakness and weaning failure. The intrinsic apoptotic pathway plays a central role in many pathologies (63). Therefore, many inhibitors targeting the different components of this

pathway have been developed (64). Especially caspase-3 inhibition has been investigated 412 413 extensively, and was shown to prevent diaphragm atrophy in mechanically ventilated rodents (44, 65). To date, none have progressed beyond pre-clinical studies, probably due to 414 415 functions of caspase-3 outside of the intrinsic apoptotic pathway (65). However, there are other strategies to limit apoptosis, such as limiting redox imbalance or inhibiting other 416 constituents of the intrinsic apoptotic pathway, such as BAX or BAK (64, 66). Additionally, 417 increasing the generation of new myonuclei by stimulating satellite cell activation may be a 418 419 strategy to help diaphragm recovery after atrophy and speed up the weaning process. Signaling pathway and immune modulators and various growth factors have been shown to 420 augment satellite cell activation (67). More preclinical research is necessary to further 421 422 explore these targets. Even though our data does not suggest that apoptotic pathway 423 activation is limited to the diaphragm, we only observed myonuclear loss in the presence of myofiber atrophy, suggesting an important role for strategies to prevent atrophy such as 424 diaphragm protective mechanical ventilation or diaphragm pacing (68, 69). 425

426 Limitations

The population of ICU patients included in this is highly heterogeneous, with varying medical 427 histories, reasons for admission, duration of mechanical ventilation and underlying 428 pathophysiology. Therefore, it is not feasible to search for clinical predictors associated with 429 myonuclear apoptosis or myofiber atrophy with our sample size. Nevertheless, this diverse 430 group of patients does adequately reflect the general ICU population. Due to the 431 invasiveness of taking diaphragm biopsies, the controls in this study are patients undergoing 432 surgery for a pulmonary nodule. We cannot rule out an effect of the clinical status of the 433 controls on the diaphragm, even though the in-and-exclusion criteria should minimize this. 434 Finally, due to biopsy size limitations, not all experiments were performed on all biopsies. 435

436 Conclusion

- 437 In mechanically ventilated patients in the ICU, myonuclear apoptosis is a pathophysiological
- 438 mechanism underlying critical illness-associated diaphragm atrophy. Using a combination of
- 439 advanced microscopy and molecular biology techniques, we identified p53 activation as the
- 440 underlying pathway in ICU patients. Myonuclear loss in combination with a reduction of the
- satellite cell population may compromise recovery of the diaphragm, thereby contributing to
- 442 weaning failure.

637

639 Figure legends.

640 Figure 1. RNA sequencing of the diaphragm of mechanically ventilated ICU patients.

641 A: Principal component analysis of sequencing results. Note the clustering of the samples 642 within the CTRL group while this clustering is absent in the ICU groups. This may be due to heterogeneity of patient characteristics within both ICU groups. CTRL N = 8; ICU N = 17. B: 643 Volcano plot and C: top 50 DEG heatmap. Top 50 most significantly differentially expressed 644 DEGs for each contrast (sorted by smallest adjusted p-value). 1714 genes were significantly 645 646 upregulated and 1236 genes were significantly downregulated in the ICU group. Genes with a significance level p < 0.05 and a fold change of >1.5 were deemed differentially expressed. 647 CTRL N = 8; ICU N = 17. **D**: PANTHER gene set enrichment analysis. Top10 gene sets or 648 pathways enriched for up- or down-regulated genes of one database (dashed line: p-value = 649 650 0.05). Only shows pathways that are not significant for both directions (up/down) at the same time to identify on/off situations. Significant gene set enrichment is defined by the false 651 discovery rate. CTRL N = 8; ICU N = 17. E: Schematic of the differentially expressed genes 652 that are involved in the intrinsic apoptotic pathway. Genes in green are significantly 653 upregulated and genes in red are significantly downregulated in ICU patients. 654

655

Figure 2. Caspase-3 mediated apoptosis as a mechanism underlying myonuclear loss
 in the diaphragm of ICU patients.

658 A: Representative images of diaphragm muscle cross-sections stained with TUNEL assay, PCM1 antibody, Dystrophin antibody, and DAPI. Nuclei with a TUNEL-positive signal were 659 660 designated as apoptotic myonuclei when they were PCM1 positive and were located within the dystrophin barrier. Note the difference in PCM1 immunoreactivity of the TUNEL+ non-661 662 myonucleus (left white arrow) and myonucleus (right white arrow). Scale bar top row is 50 663 μm, scale bar bottom row is 20 μm. **B**: Quantification of TUNEL index, calculated as the 664 percentage of TUNEL-positive myonuclei. Total myonuclear count was determined by counting PCM1-positive nuclei. The grey bar represents the mean ± standard deviation 665

within the groups of patients. Each colored symbol represents the value of a single patient. 666 CTRL N = 8; ICU N = 18. Significance level was calculated using an unpaired *t*-test. **C**: 667 Representative images of diaphragm muscle cross-sections stained with Cleaved caspase-3 668 antibody, PCM1 antibody, Laminin antibody and DAPI. Nuclei with a Cleaved Caspase-3 669 positive signal were designated as apoptotic myonuclei when they were PCM1 positive and 670 were located within the laminin barrier. Scale bar top row = $50\mu m$, scale bar bottom row = 20671 µm. D: Quantification of activated caspase-3 index, calculated as the percentage of activated 672 673 caspase-3-positive myonuclei. Total myonuclear count was determined by counting PCM1positive nuclei. The grey bar represents the mean ± standard deviation within the groups of 674 patients. Each colored symbol represents the value of a single patient. CTRL N = 7; ICU N =675 14. Significance level was calculated using a Mann-Whitney-U test. ICU A+ = ICU group with 676 atrophy, ICU A- = ICU group without atrophy, CTRL = Control group, * = p < 0.05, ** = p < 0.01677

Figure 3. Reduced number of myonuclei in atrophic diaphragm fibers of critically ill patients.

A: Representative images of single muscle fibers from control (left) and ICU (right) patients. 680 Myofibers are immunofluorescently labeled for lamin A/C (red) and myosin heavy chain 681 682 (green) Scale bar = 60 µm B: Representative images of 3D rendered single muscle fibers, with segmentation in 3D. Scale bar = $60 \,\mu\text{m}$. C: Quantification of myofiber volume, calculated 683 as volume per mm fiber was normalized to a sarcomere length of 2.5 µm. Every grey dot 684 685 represents the value of a single muscle fiber and the colored symbols represent the mean 686 values of a single patient. Slow-twitch fibers: ICU A+ N = 14, n = 84; N = 10, n = 50; CTRL N = 10, n = 48. Fast-twitch fibers: ICU A+ N = 14, n = 56; ICU A- N = 10, n = 48; CTRL N = 10, 687 n = 46. **D**: Quantification of myonuclear number. Every grey dot represents the value of a 688 689 single muscle fiber and the colored symbols represent the mean values of a single patient. 690 Black bars indicate the median of the whole group. Slow-twitch fibers: ICU A+ N = 14, n = 84; ICU A- N = 10, n = 50; CTRL N = 10, n = 48. Fast-twitch fibers: ICU A+ N = 14, n = 56; ICU 691 692 A- N = 10, n = 48; CTRL N = 10, n = 46. **E** Quantification of myonuclear domain size. Every

693 grey dot represents the value of a single muscle fiber and the colored symbols represent the 694 mean values of a single patient. Significance levels were calculated using linear mixed 695 models with the patients as the random factor. Black bars indicate the median of the whole 696 group. Slow-twitch fibers: ICU A N = 14, n = 84; ICU A - N = 10, n = 50; CTRL N = 10, n = 48. Fast-twitch fibers: ICU A+ N = 14, n = 56; ICU A- N = 10, n = 48; CTRL N = 10, n = 46. ICU 697 A+ = ICU group with atrophy; ICU A- = ICU group without atrophy; CTRL = Control group. * 698 denotes p < 0.05; ** denotes p < 0.01. N = number of patients, n = number of analyzed 699 700 myofibers.

701

702 Figure 4. Altered myonuclear morphology in diaphragm myofibers of ICU patients.

A: Representative images of unsegmented (left) and segmented (right) 3D-rendered 703 704 myonuclei within mounted single muscle fibers that were immunofluorescently labeled for 705 lamin A/C. Note the difference in ellipticity and sphericity between the top and the bottom myonucleus. Scale bar = 5 μ m B Quantification of myonuclear volume. Each grey dot 706 707 represents the value of a single nucleus. Each colored symbol represents the mean value of 708 a single patient. The black bar represents the mean value within the groups of patients. 709 Significance level was calculated using linear mixed models with the patients as the random factor. CTRL N = 10 patients, n = 6270 nuclei; ICU A+ N = 14 patients; n = 5463 nuclei; ICU 710 711 A- N = 10 patients; n = 6330 nuclei. **C** Quantification of lamin A/C fluorescence intensity 712 within each nucleus. Each grey dot represents the value of a single nucleus. Each colored 713 symbol represents the mean value of a single patient. The black bar represents the mean value within the groups of patients. Significance level was calculated using linear mixed 714 715 models with the patients as the random factor. CTRL N = 10 patients, n = 6270 nuclei; ICU 716 A+ N = 14 patients, n = 5463; ICU A- N = 10 patients, n = 6330 nuclei. D: Representative images of maximum intensity Z-projections of Z-stacks of myonuclei. Note the difference 717 between the nuclei with a smooth nuclear lamina (left) and a wrinkled nuclear lamina (right). 718 Scale bar = 5 µm. E: Quantification of the wrinkling index for each nucleus. Wrinkling index 719 720 was calculated as the standard deviation of the fluorescence intensity within the segmented

nucleus. Each grey dot represents the value of a single nucleus. Each colored symbol represents the mean value of a single patient. The black bar represents the mean value within the groups of patients. Significance level was calculated using linear mixed models with the patients as the random factor. CTRL N = 10 patients, n = 1983 nuclei; ICU A+ N =14 patients, n = 2601 nuclei; ICU A- N = 10 patients, n = 2442 nuclei. ICU A+ = 100 group with atrophy; ICU A- = 100 group without atrophy; CTRL = Control group. * denotes p <0.05; ** denotes p < 0.01.

728

729 Figure 5. Total transcriptional activity is reduced in atrophic myofibers of ICU patients. A: Schematic of RNA-polymerase-II with phosphorylation at Serine 5 with antibody binding to 730 phosphorylated Serine. This phosphorylation occurs when RNA-Pol-II starts transcribing 731 732 DNA into mRNA. B: Representative images of RNA-Pol-II-Ser5 (magenta), lamin A/C (yellow), and phalloidin (green) labeling of a single Z-plane of a mounted single muscle fiber. 733 Z-stacks were used to create 3D renders of fiber segments and total RNA-Pol-II Ser5 734 fluorescence intensity was measured within each myonucleus, using lamin A/C to segment 735 736 all nuclei in 3D. Scale bar = 20 µm. C: Total RNA-Pol-II-Ser5 fluorescence intensity was calculated as the sum of the total RNA-Pol-II-Ser5 fluorescence intensity within each nucleus 737 present within three Z-stacks generated from a single myofiber. CTRL N = 5 patients, n = 48738 myofibers; ICU A+ N = 5 patients, n = 48 myofibers. Each grey symbol represents the value 739 740 of a single myofiber. Each colored symbol represents the mean value of a single patient. The black bar represents the mean value within the groups of patients. **D:** Total RNA-Pol-II-Ser5 741 742 fluorescence intensity per segmented nucleus. CTRL N = 5 patients, n = 2817 nuclei; ICU A+ N = 5 patients, n = 2235 nuclei. Each grey symbol represents the value of a single nucleus. 743 744 Each colored symbol represents the mean value of a single patient. The black bar represents 745 the mean value within the groups of patients. E. Total RNA-Pol-II-Ser5 fluorescence intensity 746 per myofiber volume was calculated as the sum of the total RNA-Pol-II-Ser5 fluorescence intensity within each nucleus present within the myofiber divided by the myofiber volume. 747

CTRL *N* = 5 patients, *n* = 48 myofibers; ICU A+ *N* = 5 patients, *n* = 48 myofibers. Each grey symbol represents the value of a single myofiber. Each colored symbol represents the mean value of a single patient. The black bar represents the mean value within the groups of patients. Significance level was calculated using linear mixed models with the patients as the random factor. ICU A+ = ICU group with atrophy; CTRL = Control group; * denotes *p* < 0.05; ** denotes *p* < 0.01

754

755 Figure 6. Decreased abundance of PAX7 positive cells in the atrophic diaphragm A: Representative images of diaphragm muscle cross-sections stained with PAX7 antibody, 756 Laminin antibody, and DAPI. Nuclei with a PAX7-positive signal were designated as satellite 757 cells. Scale bar = 50 µm in the top row and 10 µm in the bottom row. B: Number of PAX7 758 759 positive cells present in diaphragm muscle cross sections, normalized for section size. The grey bar represents the median [IQR] within the groups of patients. Each colored symbol 760 represents a single patient. CTRL N = 6; ICU N = 8. Significance level was calculated using 761 Mann-Whitney U test. C: Number of PAX7 positive cells present in diaphragm muscle cross 762 sections, normalized for the number of myofibers. The grey bar represents the median [IQR] 763 within the groups of patients, brackets represent interquartile ranges. Every colored symbol 764 represents a single patient. CTRL N = 6; ICU N = 8. Significance level was calculated using a 765 Mann-Whitney-U test. 766

ICU = ICU group with atrophy, CTRL = Control group, * = p < 0.05, ** = p < 0.01

776 Data displayed as Median [IQR], p-values calculated with Kruskal-Wallis or chi-squared

tests BMI: Body Mass Index, MVhr: duration of mechanical ventilation before biopsy BMI = 777

778 Body Mass Index APACHE = Acute Physiology And Chronic Health Evaluation, CSA =

Cross-Sectional Area, COPD = Chronic Obstructive Pulmonary Disease, CKD = Chronic 779

Kidney Disease, T2DM = Type 2 Diabetes Mellitus, CID = Chronic Inflammatory Disease, 780

P/F-ratio = arterial partial pressure of oxygen (PaO2) divided by the inspired oxygen 781

concentration (FiO2), A-a gradient = alveolar-arterial gradient. Data shown as Median [IQR]. 782

783 P-values of continuous data calculated with one-way analysis of variance or Kruskal-Wallis

test, depending on distribution of the data. P-values of categorical data calculated with Chi-784

squared test. * indicates a significant difference with the control group calculated with post-785 786 hoc tests.

787

Table 2. Characteristics of individual patients of quadriceps studies

Patient	Age (y)	Se x	BMI (kg/m²)	ICU diagnosis	APACHE-4 score	Duration of MV (h)
1	56-60	М	26	Trauma	139	33.3
2	80-85	Μ	25	Trauma	94	44.3
5	30-35	F	27	Trauma	76	50.5
6	30-35	М	22	Trauma	76	50.8
8	80-85	М	23	Sepsis	130	28.3
