Abstract

Background: Mpox (formerly Monkeypox) virus has affected the lives of thousands of individuals both in endemic and non-endemic countries. Before the May 2022 outbreak, Mpox infections were sporadically endemic in Central and Western Africa, still research into Mpox has been limited and lacking epidemiological data. Thus, identification of potential risk factors to better understand who is at risk of being infected is critical for future prevention and control.

Objective: To synthesize comprehensive evidence on risk factors associated with human Mpox transmission both in endemic and non-endemic countries from inception to March 31, 2024.

Methods: The Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines were followed in conducting the systematic review. Electronic databases were searched. Two reviewers sifted the articles that were included in the review: firstly, by title and abstract, and secondly, by full text. We used the Newcastle-Ottawa Scale (NOS) to assess the risk of bias for included articles. Fixed or random effects meta-analysis were conducted when at least two studies reported odds ratios (OR), relative risks (RR), with 95% confidence intervals (CI). Heterogeneity was assessed using the I^2 statistic and sensitivity analysis was also done. The study protocol has been registered under PROSPERO with ID: **CRD42023459895**.

Results: 947 articles were identified from the database search and 31 articles were eligible to be included in the systematic review. The findings of the meta-analysis showed that interaction with infected animals ($OR = 5.61, 95\%CI = 2.83, 11.13$), HIV ($OR = 4.46, 95\%CI = 3.27, 6.08$), other STIs ($OR = 1.76, 95\%CI = 1.42, 2.91$), sexual contact/activities ($OR = 1.53, 95\%CI = 1.13, 4.82$), contact with an infected person ($OR = 2.39, 95\%CI = 1.87, 3.05$), being identified as men who have sex with men (MSM) ($OR = 2.18, 95\%CI = 1.88, 2.51$), and having multiple sexual partners Mpox ($OR = 1.61, 95\%CI = 1.24, 2.09$), were associated with an increased risk of contracting Mpox. However, patients who were vaccinated against smallpox had a lower risk of Mpox infection ($OR = 0.24, 95\%CI = 0.11, 0.55$).

Conclusion: This study is the first meta-analysis on reported risk factors for Mpox. Our analysis demonstrated that certain factors were associated with increased risk of Mpox, whereas smallpox vaccination had a protective role against contracting Mpox. The study findings could facilitate future strategic public health planning and targeted intervention.

Keywords: Mpox, systematic review, risk factors, meta-analysis, heterogeneity

Key messages of this article

What is already known on this topic

- Mpox (monkeypox) is a zoonotic infectious disease of notable global public health importance due to recent outbreaks in non-endemic countries.
- Prior outbreaks of Mpox have been associated with travel to endemic areas in Western and Central Africa, contact with infected animals, and close contact with infectious lesions, particularly among household members.

What this study adds

- This study is the first meta-analysis on reported risk factors for Mpox. Our study findings add to the body of evidence on Mpox research efforts and could assist in future Mpox global strategic intervention and control.
- Our meta-analysis revealed a strong correlation between increased risk of Mpox infection, HVI, other STIs, physical and sexual contacts, and being identified as MSM.
- While HIV infection may be a risk factor for Mpox, Mpox lesions could also facilitate the transmission of HIV and other STIs.

How this study might affect research, practice or policy

- The results of this systematic review and meta-analysis provide evidence to support policymakers in future Mpox intervention and prevention in both endemic and non-endemic countries based on identified risk factors.

Introduction

The recent re-emergence of human monkeypox (Mpox) infection is a significant concern for global health (1). Mpox is an *Orthopoxvirus*, endemic in West and Central Africa, with a clinical presentation resembling that of smallpox (1, 2). The virus was initially identified in captive monkeys in Denmark in 1959 and later in a 9-year-old male child from the Democratic Republic of the Congo (DRC) in 1970 (2-4).

Over the past forty years, the DRC has persistently reported human Mpox cases, with the number of annual reports surpassing 1000 cases in the past twenty years (3). Since the initial human identification of Mpox in the DRC, there have been intermittent reports of outbreaks across Africa, characterized by a relatively low mortality rate.

Between 1970 and 2003, isolated cases of Mpox were reported in various African countries, including Nigeria, Côte d'Ivoire, Liberia, and Sierra Leone, among others (3, 5, 6). From 2003, human Mpox cases were reported outside Africa due to migration. For example in 2018, human Mpox cases were reported in Israel and the United Kingdom, in 2019 it was reported in Singapore, and in 2003 and 2021 Mpox cases were reported in the United States of America (3, 6, 7). These incidents underscored the potential for Mpox to spread globally through travelers from areas where the disease is endemic to non-endemic regions (3).

In May 2022, the world experienced the first human Mpox outbreaks which were largely reported in regions with no previous history of the disease and began to spread across multiple countries (1). This led the World Health Organization (WHO) to declare it a Public Health

Emergency of International Concern (PHEIC) in July 2022 (1, 8). The latest data indicates over 90,000 confirmed cases of Mpox infections globally, with around 150 fatalities across 110 countries. Non-endemic countries greatly impacted were the USA, Canada, Spain, France, Colombia, the UK, Mexico, Brazil, Peru, and Germany as they represent approximately 86% of the reported global cases (1). Mpox infection has greatly declined globally as a result of several factors including public health intervention, behavioral adjustment, and an increasing level of immunity within the population at risk, either naturally acquired or via effective Mpox vaccination campaigns (9). However, Mpox still remains a major global public health concern needing critical research for future control and interventions (1, 10).

A significant aspect of the Mpox cases in 2022 was the lack of direct epidemiological ties to the importation of animals or migration, with the cases being mostly linked to sexual contacts (1). The individuals affected predominantly identified themselves as gay, bisexual, or other men who have sex with men (1, 11, 12). In contrast, in certain countries, individuals with confirmed Mpox cases reported having traveled to nations within Europe and North America (1, 13). This marks a departure from traditional transmission routes previously observed and points to a new pattern of transmission within specific communities (1). Therefore, this systematic review aims to explore all risk factors associated with the transmission of Mpox both in endemic and non-endemic countries.

Materials and Methods

Study Protocol

This systematic review and meta-analysis were conducted and reported following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (14, 15).

Additionally, the review was registered with the International Prospective Register of Systematic Reviews (PROSPERO) under the registration number CRD42023459895.

Search Strategy

Electronic databases including Scopus, Google Scholar, Cochrane Library, Web of Sciences (WOS), EMBASE, and PubMed were searched systematically for potential publications from inception to March 31, 2024. The key search terms were: “Mpox” OR “Monkeypox” OR “Orthopoxvirus” OR “Monkeypox virus” AND (“risk factors” OR “influential factors” OR “impact factors” OR “exposure”). The search was specifically tailored to select original articles published in the English language, including any study design (case-control, observational (prospective/retrospective), and randomized control studies) with the human population. To streamline the screening process and enhance efficiency, EndNote X9 (16) was employed to keep a record of all articles obtained from the electronic database, duplicates removed, and final studies included in the review.

Eligible Criteria

Articles included were original articles of any study design (randomized control trial, case study, observational study, etc.) that investigated the risk factors of Mpox infection in human subjects. The study must have a minimum sample size of 10 patients and be published in the English language. Articles excluded were review papers, grey literature (like dissertations and thesis), studies with less than 10 participants, and studies on animal and non-human populations.

Study Selection

The study selection was carried out by two reviewers (CLJU and WAW) independently. The reviewers screened all articles obtained from the database (after removing the duplicates) initially by title and abstract, then by full text. The eligible criteria were used in the screening

process. Disagreements were resolved through discussion and mutual agreement and consensus were reached.

Statistical Analysis (Meta-Analysis)

Meta-analyses were conducted for risk factors that were reported in two or more studies and included the estimated odds ratios (ORs), or relative risks (RRs) (17). The degree of heterogeneity was determined quantitatively using I^2 index statistic (18, 19). $I^2 \geq 75\%$ is a measure of highly significant heterogeneity, $I^2 = 50\% - 70\%$ is recognized as moderate heterogeneity, $25\% < I^2 < 50\%$ denotes a low heterogeneity and $I^2 \leq 25\%$ presents homogeneity. Thus, heterogeneity is high when Cochran's Q $p - value < 0.10$, and $I^2 \geq 50\%$ (20, 21). For a better-quality study, we employed the fixed-effects meta-analysis model when heterogeneity was low or homogeneous, opted for the random-effects model if it was highly significant, and conducted sensitivity analysis to identify the sources of heterogeneity (17). To explore possible publication bias, funnel plots with Egger's weighted regression test were used (20). All of the analyses were implemented in the R statistical software version 4.3.2 with R-package *meta* (22, 23). $p - value < 0.05$ were considered statistically significant.

Data Extraction

Authors extracted the following data from the included studies: the author's name, country of study, year of publication, study design, sample size, demographic variables (such as gender, age, sexual orientation, etc.), clinical variables (such as disease presentations, etc.), outcome (Mpox), exposure (risk factors), and odds ratios, or relative risks plus the 95% CIs in an Excel spreadsheet.

Quality Assessment

The evaluation of the study's quality was conducted using the Newcastle-Ottawa Quality Assessment Scale (NOS) (24, 25). The NOS framework examines several aspects: (1) Selection, focusing on the adequacy of case definition, representativeness of cases, selection of controls, and definition of controls. (2) Comparability, assessing whether cases and controls are comparable based on the study's design or analysis. (3) Exposure, checking the ascertainment of exposure, consistency in the method of ascertainment for cases and controls, and the non-response rate. In this study, articles that achieved Newcastle-Ottawa Scale (NOS) scores ≥ 5 were considered high-quality publications.

Results

Literature Search and Study Selection

Initial searches identified 947 studies, and 8 additional studies were identified from citation referencing. Subsequently, 460 studies were obtained after removing duplicate literature, and 291 were excluded after screening titles and abstracts. After a full-text review, a total of 138 texts were further excluded for not meeting the inclusion criteria. Finally, 31 studies were included in the systematic review (**Figure 1**).

Demographic characteristics of the included studies

Of the 31 included studies in this systematic review, seven studies were conducted in DR Congo (26-31), one in Nigeria (6), two in the USA (32, 33), two in the UK (34, 35), four in Spain (36-39), two in Brazil (40, 41), four in Italy (42, 43), two in UAE (26, 44), one in the Netherlands (45), one in Israel (46), one in Chile (47), one in Portugal (48), one in Belgium (49), one in Germany (50), and four multi-country studies for a group of countries (34, 51, 52) (see **Figure**

2). The data included 148,499 Mpox cases involving men, women, cisgender, transgender, and non-binary individuals. A summary of the study characteristics is reported in **Table 1**.

Table 1: Demographic characteristics of the study population (Mpox confirmed cases)

No	Author (year)	Country	Study design	Sample size	Mean age	Sex (M/F)	Sexual Orientation (MSM/gay/bisexual)

Clinical Characteristics of the Included Studies

All risk factors and clinical presentations identified in 31 included articles are reported in **Table 2**. The most common symptoms of Mpox are fever, rash, exanthema, lymphadenopathy, myalgia, lesions, and headache, with fever being the predominant systemic manifestation observed (6, 38, 47). **Figure 3** summarizes the clinical symptoms of mpox reported in the papers included in the review. Individuals with Confirmed Mpox infection were mostly presented with mucocutaneous lesions, most commonly on the genital and anal areas, which support sexual contact as a means of Mpox transmission (6, 47, 52).

The STIs reported among Mpox-infected patients included HIV – being the most prevalent (34, 38, 47, 51, 52, 54). This may be likely due to the relative immunodeficiency associated with HIV infection, even among those receiving treatment (43). Though HIV infection highly increases the risk of contracting Mpox, Mpox lesions could also potentially enhance the transmission of HIV and other STIs (30, 47, 53). A summary of STIs reported in the included studies is presented in **Figure 4**.

Meta-analysis of Risk Factors of Mpox

Interaction with Animals

Among the included studies, two studies in endemic regions (29, 33) identified close contact with wild animals, daily exposure during an animal's illness, contact with rashes or eye crusts, scratching, cleaning cages or handling bedding, and direct exposure to animals susceptible to Mpox infection. Our study has detected a moderate heterogeneity ($I^2 = 42\%$, $p = 0.16$). Therefore, the fixed-effects model was adopted for meta-analysis. From the result of the forest

plot in **Figure 5**, interaction with animals was found to be a statistically significant risk factor for Mpox in endemic areas ($OR = 5.61, 95\%CI = 2.83, 11.13, P - value < 0.0001$). These findings reveal that being bitten by rodents at home, handling Mpox-infected animals, and daily exposure to their excretions and secretions were statistically and significantly linked to higher rates of human Mpox infection. The results indicate that individuals with direct exposure to infected animals are 5.61 times more likely to contract Mpox than those without such exposure (**Figure 5**).

Human Immunodeficiency Virus (HIV)

Five studies (6, 46, 47, 51, 55), identified HIV as both a risk factor and a comorbidity for Mpox infection. Individuals with advanced HIV (who are immunocompromised) have an increased risk of severe Mpox symptoms and mortality. Significant high heterogeneity was detected ($I^2 = 87\%, p < 0.01$), and a random-effects model was employed for meta-analysis of the association between HIV and Mpox infection. The estimate obtained showed that HIV is a risk factor for Mpox ($OR = 4.05, 95\%CI = 2.02, 8.14, P - value < 0.0001$). Individuals living with HIV are 4 times more likely to contract Mpox compared to those without HIV, underscoring the role of HIV as a significant risk factor for Mpox infection (**Figure 6**).

However, to identify the source of high heterogeneity, we conducted a sensitivity analysis and detected that Acevedo, A. et al. (47) was the source of heterogeneity. Removing the study reduced the heterogeneity to ($I^2 = 39\%, p = 0.18$). Subsequently, a fixed effect model was performed for meta-analysis. Our findings still indicate that HIV is a statistically significant risk factor for Mpox ($OR = 4.46, 95\%CI = 3.27, 6.08, P - value < 0.0001$), suggesting that

individuals with HIV are 4.5 times more likely to contract Mpox compared to those without HIV (Figure 7).

Other Sexually Transmitted Diseases (STIs)

Three studies (6, 46, 47), reported syphilis, concomitant varicella-zoster virus infection, chlamydia, hepatitis B and C, gonorrhea, and histories of other STIs as risk factors for Mpox. From the forest plot, an evident moderate heterogeneity was detected ($I^2 = 40.3\%$, 0.19), and a fixed-effects model was performed for meta-analysis. The results indicated that other STIs are risk factors for Mpox ($OR = 1.76$, $95\%CI = 1.42, 2.91$, $P - value < 0.0001$), **Figure 8**.

Presence of Comorbidities

Three studies (6, 45, 47), identified the presence of comorbidities as a risk factor for Mpox infection. The forest plot analysis revealed no evidence of heterogeneity ($I^2 = 0\%$, 0.78), and a fixed-effects model was utilized for the meta-analysis. The result indicated that commodities were a risk factor for Mpox ($OR = 1.58$, $95\%CI = 1.31, 1.91$, $P - value < 0.0001$), **Figure 9**. However, the studies did not specify the types of comorbidities involved, leaving it unclear which specific comorbidities have a greater impact on Mpox infection.

Men Who Have Sex with Men (MSM)

Two studies (41, 45), identified specific risk factors for Mpox infection among a broader population defined as MSM, which includes transgender and non-binary individuals. These studies indicated that the majority of Mpox cases predominantly affected MSM men, with a high incidence of lesions occurring in the anogenital area. With no heterogeneity detected ($I^2 = 0\%$, 0.39), and a fixed-effects model was selected for meta-analysis. Our results indicate that

MSM individuals are at a higher risk of contracting Mpox (OR = 2.18, 95%CI = 1.88, 2.51, P – value < 0.0001), **Figure 10**, with 2.18 times greater odds compared to those who are not MSM.

Sexual Contact/Activities

Two studies (45, 55) reported that unprotected anal sex, or engaging in three or more sexual activities, such as oral, anal, and/or oral-anal, compared to just one or two activities in the 21 days before symptom onset, increased the risk of Mpox infection. No heterogeneity was detected ($I^2 = 0\%$, 0.74), and a fixed-effects model was selected for meta-analysis. From the forest plot, sexual contact was a risk factor for Mpox (OR = 1.53, 95% CI = 1.13, 4.82, P = 0.005). The result indicates that those who engaged in unprotected anal and oral sex had 1.53 times the risk of Mpox compared to those who did not (**Figure 11**).

Multiple Sexual Partners

Four studies (41, 45, 47, 55) reported having multiple sexual partners as a risk factor for Mpox infection. We analyzed the data and found significant heterogeneity ($I^2 = 92\%$, $p < 0.01$), and a random-effects model was performed for the meta-analysis. The results indicated that having multiple sexual partners is a risk factor for Mpox (OR = 1.79, 95%CI = 1.04, 3.11, P – value < 0.0001), **Figure 12**.

To find the source of heterogeneity, we performed sensitivity analysis and found that two studies (47, 55), were the source, and the heterogeneity was significantly reduced to ($I^2 = 35\%$, 0.22), after removing the studies. Finally, a fixed-effects model was employed for the meta-analysis, and having multiple sexual partners was concluded as a risk factor for Mpox (OR =

1.61, 95%CI = 1.24, 2.09, $P < 0.0001$), **Figure 13**. The result indicated that those who engage in multiple sex have about 1.6 times higher risk of contracting Mpox compared to those who do not.

Contact with an Infected Person

Three studies (45, 47, 49), reported previous close contact with a confirmed case, including sharing personal items like glasses and towels as a significant risk factor for Mpox. High heterogeneity was detected ($I^2 = 79\%$, $p < 0.01$), and a random-effects model was employed for meta-analysis. The result confirmed that close contact with an infected person is a risk factor for Mpox (OR = 2.05, 95%CI = 1.10, 3.79, P – value < 0.0001), **Figure 14**.

Based on the results of the sensitivity analysis, the study by van Ewijk, Catharina E. et al. (45), was identified as the source of heterogeneity. Upon its removal, heterogeneity decreased ($I^2 = 36\%$, 0.21), allowing for the use of a fixed-effects model in the meta-analysis. The analysis concluded that close contact with infected individuals significantly increases the risk of Mpox, with (OR = 2.39, 95%CI = 1.87, 3.05, P – value < 0.0001), **Figure 15**.

Younger Age Group

Five studies (6, 41, 45, 49, 54), reported the younger age group as a risk factor for Mpox. We analyzed the data, and no evidence of heterogeneity was detected ($I^2 = 0$, 0.47). Subsequently, a fixed-effects meta-analysis was employed and the results showed that the young age group was a risk factor for Mpox (OR = 2.03, 95%CI = 1.44, 2.85, P – value < 0.0001), **Figure 16**.

Smallpox as a Protective Factor for Mpox

Two studies from Mpox endemic regions (6, 33) identified the smallpox vaccine as a protective factor against Mpox. The forest plot in **Figure 17** showed no evidence of heterogeneity ($I^2 = 0, 0.47$), and subsequent meta-analysis using a fixed-effects model indicated a statistically significant negative association between Mpox and smallpox vaccination (OR = 0.24, 95%CI = 0.11, 0.55, P – value < 0.0001). This result suggested that the smallpox vaccination was a protective effect against Mpox infection.

Higher Educational Level as a Protective Factor for Mpox

Two studies (6, 55) reported that higher education level was a risk factor for Mpox. We analyzed the data, and moderate heterogeneity was detected ($I^2 = 46\%, 0.17$). Subsequently, a fixed-effects meta-analysis was employed, and according to the forest plot, a higher level of education had a negative influence on Mpox infection, however, no statistically significant result was found (OR = 0.52, 95%CI = 0.26, 1.02, P = 0.06), **Figure 18**.

Other Risk Factors

Other remaining risk factors identified in **Table 2** were only reported in one independent study, and therefore not analyzed. The details of these risk factors are shown in **Table 2**.

Table 2: Clinical characteristics of patients, and identified risk factors of Mpox.

	Author (year)	Country	Other clinical Presentations	Other risk factors
1	Acevedo, A. (2022) (47)	Chile	Rash, Lymphadenopathy, Myalgia, Fever, Pustules, Scabs, Umbilicated lesions	(1) Contact with a positive case. (2) Multiple sexual partners. (3) Male gender. (4) History of sexually transmitted disease. (5) HIV.
2	Akilimali, A. (2022)(26)	DR Congo	Systemic illness, fever, asthenia, myalgia, headache, lesions on the genitals, face, arms, hands, and perianal area. Less common lesions included mucosal ulcers (including pharyngeal ulcers	(1) Presence of forested areas (where possible animal reservoirs are plentiful) (2) Lower age groups who were not vaccinated as part of the smallpox eradication program. (3) Sleeping in the same room or bed, particularly between people of the same sex, for example, men sleeping with men. (4) Living in the same household. (5) Drinking or eating from the same dish. (6) HIV (7) Living in the same household
3	Alegre, B.(2022) (36)	Spain	Fever, exanthema, Cutaneous and anal ulcers	(1) Previous unsafe sexual contact had risky oral. (2) Vaginal and/or anal sexual contact in the days.
4	Alhammadi, O. A. (2022) (53)	UAE	Lesions on the genital and anal regions. fever, exanthema, ulcers, and inguinal lymphadenopathy, headache	(1) History of sexual exposure. (2) History of travel abroad. (3) Had a history of contact with animals. (4) Had contact with people with similar symptoms.

				(5) Previous history of sexually transmitted infections
5	Alpalhão, M. (2023) (48)	Portugal	Lesions in the genital, perianal, or perioral areas, Fever, headache, Enlarged lymph, nodes, etc.	(1) Prior history of other STI (other than HIV)
6	Angelo, K. (2022) (34)	15 countries	Perianal rash, Lymphadenopathy, Fever, Headache	(1) Sexual or close intimate contact (2) Household contact. (3) Contact with someone who had confirmed monkeypox.

Discussion

This systematic review and meta-analysis extracted data from published original articles of any study design (randomized control trial, case study, observational study, etc.) that investigated the risk factors of Mpox infection in human subjects and included 148,499 Mpox cases from 31 studies. These studies were rigorously chosen based on the NOS quality assessment to ensure the reliability of the evidence.

Findings from the current meta-analysis identified contact with infected animals, close contact with infected individuals, having multiple sexual partners, sexual contact, being identified as MSM (men who have sex with men), belonging to a younger age group, being HIV positive, having other sexually transmitted infections (STIs), and disease comorbidities as significant risk factors for Mpox infection. Conversely, smallpox vaccination emerged as a protective factor, particularly in endemic regions.

Contact with infected animals emerged as a significant risk factor for Mpox transmission, particularly in endemic regions such as the Democratic Republic of the Congo (DRC) and other parts of Central and Western Africa (26). The DRC reports most cases, where contact with animal reservoirs significantly drives Mpox infections (31). Anthropogenic and demographic changes since the 1980s may have increased local populations exposure to these reservoir species, elevating the risk of animal-to-human transmission (27, 30). In endemic regions, Mpox predominantly affects rural villages near tropical rainforests (29). According to Claire A. Quiner (29), humans primarily acquire Mpox through contact with infected animals or from limited

human-to-human transmission chains. The virus has been isolated from wildlife only twice, highlighting the role of hunting and butchering bushmeat as primary zoonotic transmission activities (29, 30). These practices are widespread in Central Africa and are considered a primary route for several pathogens entering human populations. Findings by Mary G. Reynolds et al. (33) confirm that handling infected animals significantly correlates with Mpox infection, emphasizing the risk posed by direct contact with and exposure to excretions and secretions of infected animals. Adjusted data indicate a substantially higher likelihood of infection in individuals with daily exposure to, or direct contact with, sick animals (33, 57).

The meta-analysis revealed that HIV, other STIs, and the presence of comorbidities are significant risk factors for Mpox. HIV and other STIs are notably prevalent among these comorbidities, strongly influencing the risk of Mpox across various countries (6, 41, 45-47, 51, 55). This correlation highlights a crucial intersection of public health concerns, suggesting that efforts to control HIV and other STIs might also reduce Mpox susceptibility, especially in high-risk groups. These insights could inform broader healthcare strategies that concurrently address multiple infectious diseases, enhancing overall epidemic control.

Our study through meta-analysis identified having multiple sexual partners, close sexual contact, being identified as MSM, contact with a previously positive case, and belonging to a younger age group as significant risk factors for Mpox especially in non-endemic countries. Historically, Mpox cases have been linked to travel to Western and Central Africa where the disease is common, transmission from animals to humans via bodily fluids, and transmission between people via close contact with infectious sores or bodily fluids. (33, 34, 52). This is especially

common among household members and healthcare professionals. However, recent findings suggest a shift towards person-to-person transmission, often through sexual contact, evidenced by the type and location of lesions that are primarily anal, rectal, or genital (58-60). This shift influenced a higher probability of Mpox transmission among younger individuals, particularly in non-endemic regions, who are identified as MSM group (61, 62).

Our meta-analysis found smallpox vaccination as a protective factor against Mpox. This protection may be attributed to immunity in older individuals who were previously vaccinated against smallpox (29, 33). Previous studies in endemic countries indicate that those vaccinated with the first-generation smallpox vaccine were less likely to develop severe Mpox (45, 63). Studies from the DRC also demonstrated the protective influence of smallpox vaccination among those born before the 1980s when smallpox was officially suspended (26, 31, 63).

Strengths and limitations

The strength of our study lies in its robust methodology, which included a comprehensive literature search, study selection, clearly defined inclusion and exclusion criteria, eligibility screening, quality assessment, and the pooled analysis of Mpox data from 31 studies. Additionally, it is noteworthy that no significant unidentified heterogeneity persisted after synthesis. Our study has several limitations. First, no causal relationships between Mpox and risk factors were established. Second, the review included only English-language publications. Third, insufficient data prevented a meta-analysis of all risk factors, potentially due to fear of stigmatization in Mpox-endemic countries. However, the findings could aid clinicians and public health agencies in treatment decisions, supporting future research, and guiding policymakers in developing targeted interventions and control strategies.

Conclusion

Our meta-analysis identified contact with infected animals, multiple sexual partners, sexual contact, younger age, HIV, other STIs, and comorbidities as significant risk factors for Mpox. We also found that the smallpox vaccine was protective against Mpox. As part of strategic control and prevention measures, it is important to prioritize laboratory testing for HIV and other STIs, especially since the recent outbreak among MSM was sustained by direct sexual contact. Additionally, extending Mpox vaccination to include high-risk groups engaging in sexual contact or intimate contact, even at mass gatherings, aligns with WHO guidelines and can reduce Mpox transmission globally.

Ethics approval

This study was entirely based on published data. Therefore, an ethics committee approval or written informed consent was not required as no primary data was collected.

Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

Funding

This research is funded by the Canadian Institute for Health Research (CIHR) under the Mpox and other zoonotic threats Team Grant (FRN. 187246).
