23 **Abstract**

24 Detecting the circulation of poliovirus in its early stages is paramount for swift public health action.
25 Environmental surveillance (ES) is the testing of sewage samples for the presence of poliovirus and
26 has the potential to enhance early detection capabilities. However, the establishment and
27 maintenance of ES sites incur costs and necessitate human resources, underscoring the
28 consideration of ES scale and site selection. Here, we aim to assess the early detection ability of ES
29 by varying the number and location of ES sites using the simulation-based approach. We developed
30 a stochastic meta-population model among unimmunised children aged under 5 years old and used
31 geographic and demographic characteristics of South Africa as a case study of a non-endemic
32 country, assuming a single introduction of wild poliovirus serotype 1. We constructed six scenarios
33 by combining three importation risk distributions (predicated on population size, approximations of
34 international inbound travel volume and border crossing volume) with two ES site layout strategies:
35 one proportionate to population size and another focusing on importation risk via land border
36 crossings. We showed that a modest number of strategically positioned ES sites can achieve a high
37 early detection ability when assumed importation risks were geographically confined. In contrast,
38 when importation risks were dispersed, the effectiveness of ES was diminished. Our sensitivity
39 analyses suggested that the strategy to implement ES across large areas with low sampling
40 frequency consistently resulted in a better early detection ability against various importation
41 scenarios than one to implement ES in limited areas with high sampling frequency. Although we
42 acknowledge the challenges of translating our simulated outcomes for real-world situations, our
43 study has implications for deciding the scale and site selection of ES.

45

46 **Author summary**

47 Poliovirus causes paralytic poliomyelitis, a terrible and debilitating disease. Only a small number of
48 infections with poliovirus result in disease. Early detection of these infections can inform public
49 health decision-makers to trigger interventions such as vaccination campaigns. Environmental
50 surveillance (ES) is able to detect poliovirus circulation by capturing virus shedding (even from
51 asymptomatic people) in wastewater. Strategic geographical placements of ES sites may enhance
52 early detection capabilities, but there has been limited exploration of factors that might affect early
53 detection. Here, we investigated the relationship between the scale and site selection of ES and
54 early detection ability by simulating the introduction, spread and detection of poliovirus among
55 unimmunised children aged under 5 years old. We used geographic and demographic
56 characteristics of South Africa as a case study of a non-endemic country, assuming an introduction
57 of wild poliovirus serotype 1. We found that the informed ES placement achieved a high early
58 detection ability when importation risks were geographically limited. In contrast, when importation
59 risks were dispersed, the ES effectiveness was diminished. Our sensitivity results suggested the
60 strategy to expand ES sites was robust against various importation scenarios and better than the
61 strategy to merely increase sampling frequency in limited locations.

65 **Short title:** Early detection ability of environmental surveillance for poliovirus

66

67

68 Introduction

69 Global concerted efforts toward polio eradication have achieved a drastic reduction in the number of
70 poliomyelitis cases [1] and cooperated surveillance systems contributed to this achievement [2].

71 Patients with paralytic poliomyelitis are detected through syndromic surveillance, referred to as
72 acute flaccid paralysis (AFP) surveillance, but a tiny portion of infections can be detected due to a
73 very low paralysis-to-infection rate. It has been estimated that for every 200 wild poliovirus serotype
74 1 (WPV1) infections there will be one paralytic case [3]. To improve surveillance to rule out local
75 transmission of poliovirus, sewage sampling, which is referred to as environmental surveillance
76 (ES), has been developed. After the withdrawal of the trivalent oral polio vaccine (OPV) in 2016 and
77 the emergence of vaccine-derived poliovirus serotype 2 (VDPV2) outbreaks [4,5], ES has been a
78 vital complementary surveillance tool for polio eradication [6–8], especially for the detection of
79 cryptic circulation in subnational areas of endemic countries, and detection of importation or
80 confirmation of polio-free status in non-endemic countries.

81 Detection of poliovirus circulation through ES can trigger swift public health actions to contain
82 outbreaks [9]. Recent examples include the detection of VDPV2 circulation first through the ES in
83 the US [10,11] and the UK [12], which enabled public health authorities to conduct active case
84 finding, supplementary immunisation activity and social mobilisations. On the other hand, delays in
85 detection have been linked to a large number of cases during outbreaks [13]. The long reporting
86 delays of AFP surveillance have been attributable to a delay in sample collection, transport, culture
87 and sequencing as well as the time required to ship collected samples to other countries due to the
88 lack of facilities in resource-limited settings [13,14].

89 Expanding ES sites can enhance early detection capabilities, but the establishment and
90 maintenance of ES sites incur costs and necessitate human resources [15]. To operate ES
91 effectively, the quality assessment is essential, which comprises the appropriateness of sampling
92 site locations [16], importation risk assessment [17], ES-covered population size, non-enterovirus
93 detection [18], and the quality of sample handling and sample processing. Although guidelines for

94 the implementation of ES have been developed by the Global Polio Eradication Initiative (GPEI)
95 [19], specific guidance on the number and location of ES sites is still lacking due to uncertainties in
96 available resources.

97 Quantitative evidence of the early detection ability of ES is needed to design ES layout strategies at
98 the national or subnational level. One study empirically investigated the early detection capabilities
99 using poliovirus genome data in Pakistan, showing that ES can detect the circulation of specific
100 genotypic clusters before AFP surveillance in nearly 60% of sampled clusters [20]. From the
101 perspective of a mathematical modelling approach, one seminal paper quantified the simulated
102 cumulative probability of detecting poliovirus circulation through each AFP surveillance and ES [21],
103 and one paper broadly examined the lead time of the first detection through ES over other
104 surveillance systems assuming various pathogen characteristics [22]. Another study theoretically
105 investigated optimal sampling frequency against emerging pathogens, considering a balance
106 between sampling costs and disease burden [23].

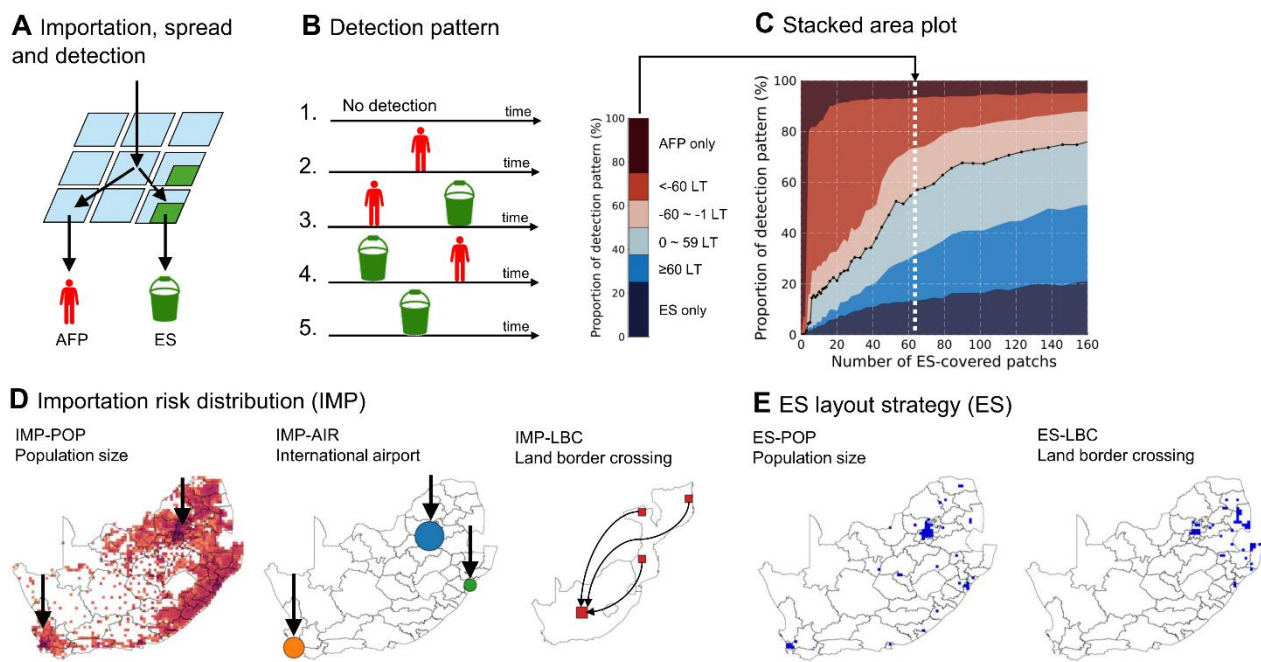

107 There remains a gap in understanding the quantitative relationship between the ES early detection
108 ability and spatial arrangements of ES sites. While laboratory facilities may be constrained by
109 capacity, there is flexibility in the selection of ES sites and we aim to address this point using a
110 simulational approach. Here, we utilised geographic and demographic characteristics of South
111 Africa (where a polio-free status has been maintained since 1989 [24]) as a case study of a non-
112 endemic country. We employed the stochastic meta-population framework (following the basic
113 model structure proposed by Ranta et al. [21]) among unimmunised children aged under 5 years old
114 to assess the first detection timing through AFP surveillance and ES. We assumed that a single
115 patient with WPV1 was imported to a specific 'patch' (a unit of a spatial grid in the meta-population
116 framework) according to the importation risk distribution. Our study setting was motivated by the
117 WPV1 importation event of 2022 into Mozambique, a neighbouring country to South Africa, implying
118 a non-negligible risk of WPV1 importation into South Africa [25].

119 By conducting simulations, we aim to explore the quantitative relationship between the number and
120 location of ES sites and the early detection capabilities of ES over AFP surveillance.

121 **Results**

122 **Study setting.**

123 The overview of our study setting is summarised in Fig 1 and a schematic representation of our
124 model is shown (Fig S3 in S1 text). We refer to a patch as a unit square at 20km spatial resolution
125 (i.e. 400 km²), matched with the actual geographical location within the meta-population framework.
126 The ES site was assumed to be placed within a single patch, covering 25% of the population of that
127 patch. We chose 25% for a patch-level ES population coverage by considering the observed
128 national ES population coverage and district-level ES population coverage (Table S4-5 and Fig S8
129 in S1 text). Our SEIR model is comprised of three components: transmission model, AFP
130 surveillance model and ES surveillance model (Fig S3 in S1 text). We assumed the probability of
131 detecting poliovirus circulation through ES was proportional to the incidence rate of infected
132 individuals. We define 'LT' as the lead time of the first detection (in days) through the ES over AFP
133 surveillance and seven detection patterns were considered: 'No detection', 'AFP only detection',
134 earlier detection through AFP surveillance than ES (i.e. '<-60 LT', '-60 ~ -1 LT'), earlier detection
135 through ES than AFP surveillance (i.e. '0 ~ 59 LT', '≥60 LT') and 'ES only detection' (Fig 1B&C). We
136 used the proportion of each detection pattern among simulations with poliovirus detections (i.e.
137 excluding the 'no detection' pattern) as the main output of simulation results.

138

139 **Fig 1. Schematic illustration of study settings. (A)** Simulated importation of wild poliovirus
 140 serotype 1 to South Africa, spread described by the meta-population model, and detection through
 141 acute flaccid surveillance (AFP) and environmental surveillance (ES). AFP surveillance is carried
 142 out across all patches whereas ES operations are confined to selected patches (in green). A patch-
 143 level ES population coverage is assumed to be 25%. **(B)** Five detection patterns: i) No detection, ii)
 144 AFP only detection, iii) earlier detection through AFP surveillance than ES, iv) earlier detection
 145 through ES than AFP surveillance v) ES only detection. Detection patterns of iii) and iv) are further
 146 classified based on the lead time (LT) of the first detection through ES over AFP surveillance. **(C)**
 147 Stacked area plot of the proportion of each detection pattern against the number of ES-covered
 148 patches. **(D)** Three importation risk distributions: i) IMP-POP corresponds to the 'Population size'-
 149 based importation risk distribution and assumes importation risk is proportional to the population
 150 size of each patch (indicated by orange-red colouration); ii) IMP-AIR corresponds to the
 151 'International airport'-based importation risk distribution and assumes an importation risk is shaped
 152 by international inbound travel volume in 2019 and approximated movement from airports. Each
 153 circle denotes the international airport with a size proportional to the international inbound travel
 154 volume: Blue, O.R. Tambo International Airport; Orange, Cape Town International Airport; Green,

155 King Shaka International Airport; iii) IMP-LBC corresponds to 'Land border crossing'-based
156 importation risk distribution and assumes importation risk is proportional to human mobilisation from
157 outbreak countries, in this study Mozambique. **(E)** Two ES site layout strategies: i) ES-POP denotes
158 'Population size' where allocation of sites is ordered by population size in each patch; ii) ES-LBC
159 denotes 'Land border crossing importation risk' where ES sites are placed according to assumed
160 international travel volume via land border crossings.

161

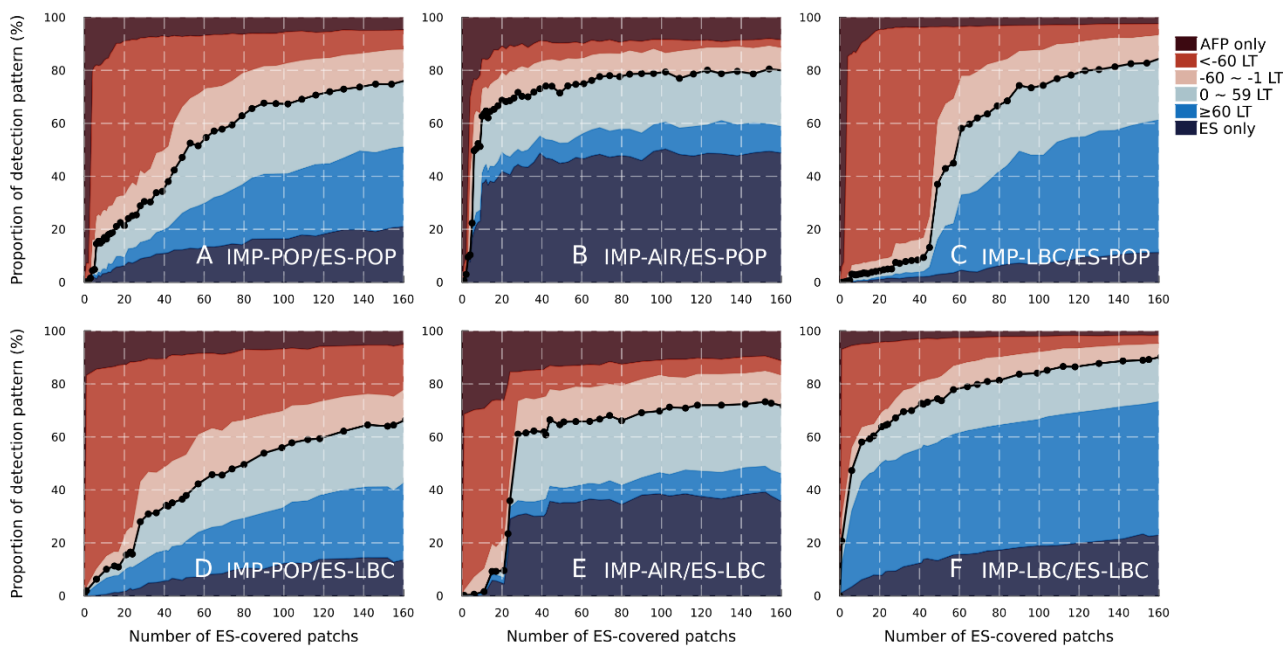

162 Preliminary analysis illustrated that the first detection timing through ES was largely influenced by
163 the assumed route of poliovirus introduction, and ES site layout. Therefore we prepared three
164 importation risk distributions and two ES site layout strategies, totalling 6 scenarios when combined
165 (Fig 1D&E, S7 in S1 text and S1-2 Video). For example, IMP-POP denotes the population size-
166 based importation risk distribution and assumes that an importation risk is proportional to the
167 population size of each patch (Fig 1D and S7A in S1 text). The ES site layout strategy determines
168 the sequence in which patches are covered by the ES. For example, ES-LBC denotes land border
169 crossing importation risk-based ES site layout strategy and assumes that we first cover patches with
170 a high importation risk via land border crossing from Mozambique (Fig 1E, S8C in S1 text and S2
171 Video). Six scenarios are expressed with the combinations of importation risk distribution and ES
172 layout strategy as the following: IMP-POP/ES-POP, IMP-AIR/ES-POP, IMP-LBC/ES-POP, IMP-
173 POP/ES-LBC, IMP-AIR/ES-LBC, and IMP-LBC/ES-LBC.

174

175 **A modest number of targeted ES site implementations can achieve high**
176 **simulated early detection probability.**

177 The proportion of each detection pattern was visualised as the stacked area plot against the number
178 of ES-covered patches for 6 scenarios (Fig 2). We truncated the number of ES-covered patches at
179 160 sites even though the total number of patches for all of South Africa was 1502. The full scale of

180 the figure can be found in Fig S12 in S1 text, in which the x-axis represents the national ES
 181 population coverage. When importation risks were concentrated in confined patches (e.g. IMP-AIR
 182 and IMP-LBC) and an ES site layout strategy was prioritised to cover those high importation risk
 183 areas (e.g. IMP-AIR/ES-POP and IMP-LBC/ES-LBC, shown in Fig 2B and 2F), 6–8 ES-covered
 184 patches were sufficient to achieve 50% simulated early detection probability. In comparison, in the
 185 scenario where the ES site layout strategy failed to prioritise patches with high importation risks
 186 (e.g. IMP-LBC/ES-POP and IMP-AIR/ES-LBC, shown in Fig 2C and 2E), covering only 10 to 20
 187 patches by ES resulted in low simulated early detection probability.

188

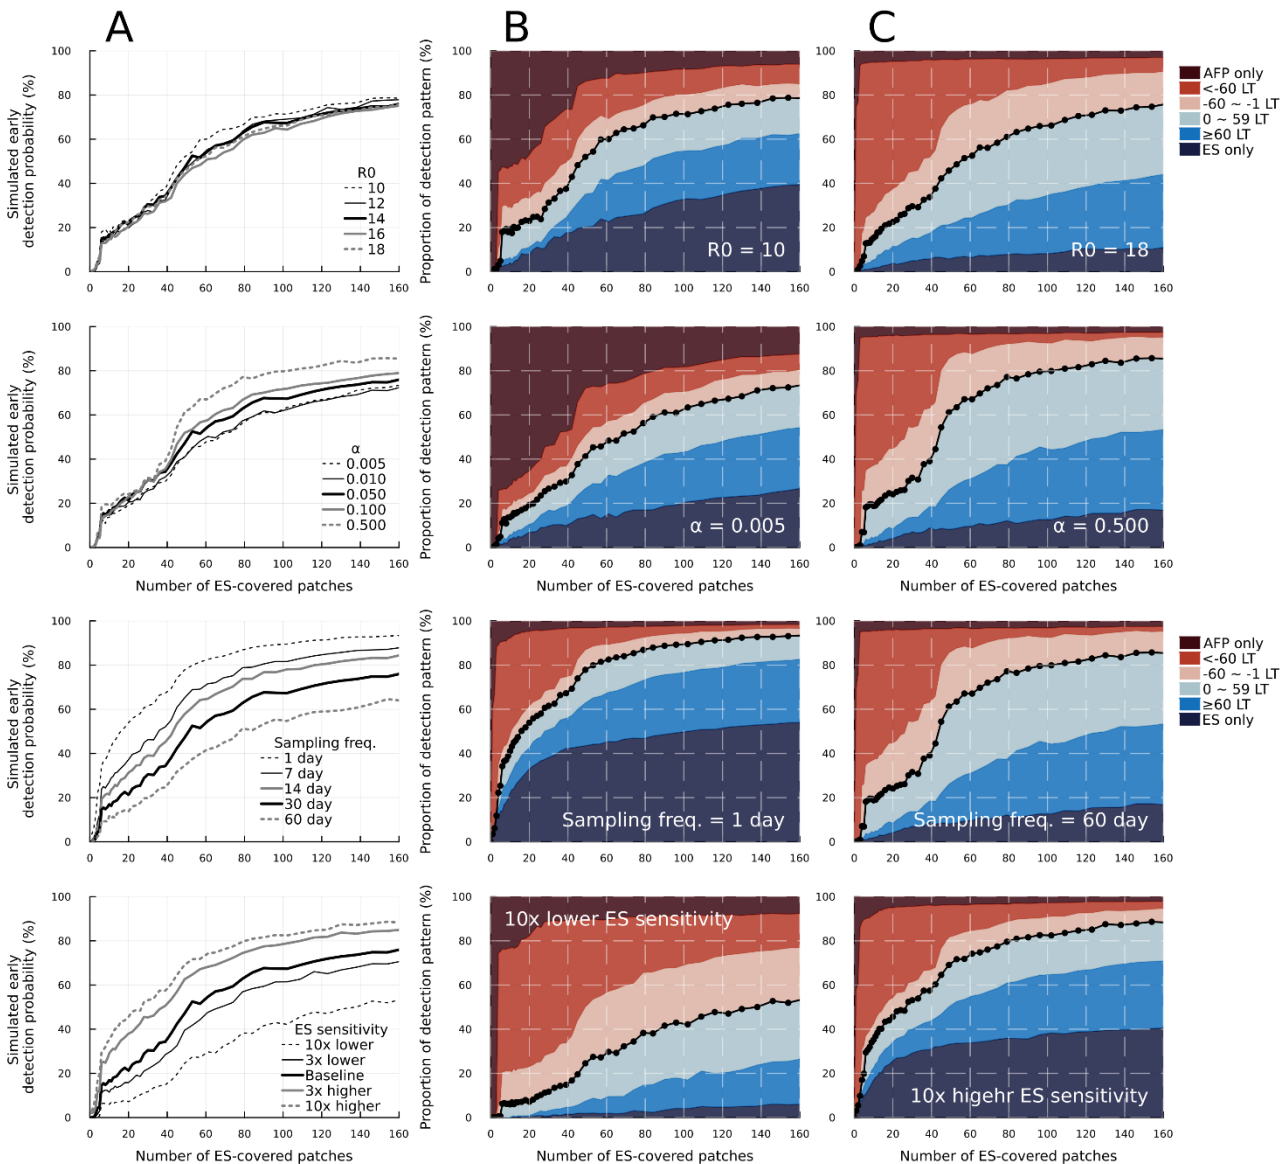

189 **Fig 2. Proportion of each detection pattern (%) against the number of ES-covered patches for**
 190 **6 scenarios.** The blue-coloured area under the black dotted lines represents the simulated early
 191 detection probability, consisting of the early detection through ES over AFP surveillance and the ES
 192 only detection pattern. It is noted that the maximum number of ES-covered patches is 1502 and the
 193 x-axis is truncated at 160. IMP-POP, 'Population size'-based importation risk distribution; IMP-AIR,
 194 'International airport'-based importation risk distribution; IMP-LBC, 'Land border crossing'-based
 195 importation risk distribution; ES-POP, 'Population size'-based ES site layout strategy; ES-LBC,
 196 'Land border crossing importation risk'-based ES site layout strategy. LT denotes the lead time of
 197 the first poliovirus detection through ES over AFP surveillance.

198

199 According to the wastewater plant data provided by the National Institute of Communicable Disease
200 in South Africa on 27 November 2023, ES for poliovirus was operating at 17 wastewater plants,
201 covering ~11.3% of the national population (if the wastewater-served population was imputed with
202 the median value for two wastewater plants; see S1 text for details). Under our model assumptions,
203 the closest number of ES-covered patches to match the current ES capacity in South Africa (i.e. the
204 number of ES-covered patches required to achieve 11.3% national ES population coverage) was 58
205 for ES-POP and 154 for ES-LBC. To investigate the impact of the exclusion of the ‘no detection
206 pattern’ on the proportion of detection patterns, we visualised those proportions including the ‘no
207 detection’ pattern in Fig S13 in S1 text. We found significant differences in the simulated probability
208 of at least one detection of poliovirus either through ES or AFP surveillance (coloured areas), which
209 would be attributable to heterogeneity in the effective immunisation proportions.

210 **Sensitivity analysis showed sampling frequency and ES sensitivity were key**
211 **parameters for enhancing early detection ability.**

212 We conducted a sensitivity analysis of the basic reproduction number (R_0), travelling rate between
213 patches (α), sampling frequency, ES sensitivity, and patch-level ES population coverage (p_c) for the
214 IMP-POP/ES-POP scenario (Fig 3 and 4). The basic reproduction number of poliovirus (R_0) did not
215 influence the simulated early detection probability in the entire region of the number of ES-covered
216 patches, whereas a lower basic reproduction number resulted in a large proportion of AFP only or
217 ES only detection patterns. This tendency was consistent with the sensitivity analysis under the
218 single patch setting (Fig S10 in S1 text).

219

220 **Fig 3. Sensitivity analysis of the basic reproduction number (R_0), travelling rate between**
 221 **patches (α), sampling frequency and ES sensitivity for the IMP-POP/ES-POP scenario. (A)**

222 Simulated early detection probability for different parameters against the number of ES-covered
 223 patches. Thick black lines represent results with the same parameter value as in the main analysis.

224 (B, C) Stacked area plot for the smallest and largest sensitivity parameter values. LT corresponds to
 225 the lead time of the first poliovirus detection through ES over AFP surveillance and 'sampling freq.'
 226 corresponds to the sampling frequency.

227

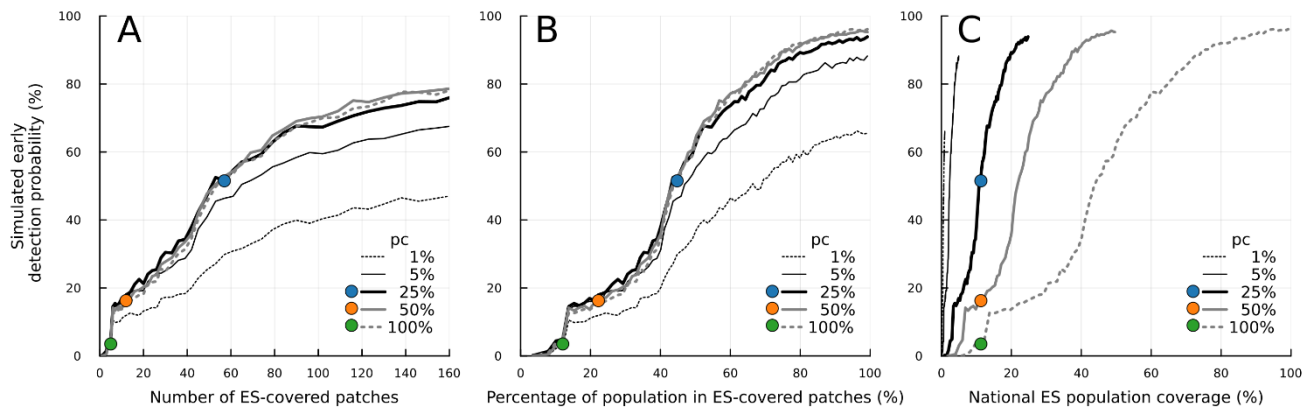

228 The simulated early detection probability remained consistent across different travelling rates (α) for
229 a small number of ES-covered patches (i.e. up to 40 patches) whereas increasing the value of α by
230 tenfold, from the baseline value of 0.050 to 0.500, yielded a 15% increase in simulated early
231 detection probability after the number of ES-covered patches exceeded 50. Notable disparities were
232 consistently observed when focusing on the proportion of AFP only or ES only detection patterns.
233 Setting high travelling rates resulted in smaller proportions of ES only detection patterns whereas
234 setting low travelling rates resulted in higher proportions.

235 Both sampling frequency and ES sensitivity (which is governed by two parameters of lognormal
236 distribution) influenced the simulated early detection probability in the order of 10 to 25%, and these
237 differences were consistently observed across the entire region of the number of ES-covered
238 patches. It is noted that either with the higher sampling frequency or higher ES sensitivity, ES only
239 detection pattern accounted for more than 30% among simulations excluding no detection pattern.

240

241 **Simulated early detection ability largely depends on the choice of patch-level**
242 **ES population coverage (p_c).**

243 We explored the impact of the patch-level ES population coverage (p_c) on simulated early detection
244 ability for the IMP-POP/ES-POP scenario. The parameter p_c modulated the balance between the
245 concentration of ES placement in a single patch and the dispersion of ES sites across patches
246 under a fixed national ES population coverage. The simulated early detection ability remained
247 nearly consistent for p_c values greater than 5%, given the same number of ES-covered patches (Fig
248 4A). Considering the observed district-level ES population coverages in South Africa all exceeding
249 10% (with a median of 22.5%), the early detection ability would be robust despite large variations in
250 ES coverage in those districts (Table S3 in S1 text).

251

252 **Fig 4. Sensitivity analysis of the patch-level ES population coverage (p_c) for IMP-POP/ES-POP**

253 **scenario.** (A, B, C) Simulated early detection probability is plotted (A) against the number of ES-

254 covered patches, (B) against the percentage of the population in ES-covered patches, and (C) the

255 national ES population coverage. Black lines represent simulation results for each of p_c and the

256 number of ES-covered patches. The coloured data points in (A-C) represent simulations where the

257 simulated national ES population coverage aligned with the observed national ES population

258 coverage in South Africa (11.3%), under p_c of 25% (blue), 50% (orange) and 100% (green). The

259 national ES population coverage is given by the product of p_c and the percentage of the population

260 in ES-coverage patches. It is noted that the maximum number of ES-covered patches is 1502 and

261 the x-axis for (A) is limited to a maximum value of 160.

262

263 Since the higher p_c value leads to a larger ES-covered population with limited ES-covered sites, we

264 plotted the coloured points representing the simulation results where the simulated national ES

265 population coverage matched the observed coverage (Fig 4A). Under such a constraint, when p_c

266 =100%, only 5 sites were required to achieve the observed national ES population coverage but the

267 combined sensitivity of these sites resulted in a low simulated probability of early detection (Fig 4A,

268 green circle). Lower p_c values correspond with many ES-covered patches, which in turn increased

269 simulated early detection probability (Fig 4A, blue circle).

270 To further illustrate the role of the patch-level ES population coverage parameter, the same

271 simulation results are displayed in two different x-axes. First, we employed the percentage of the

272 population in ES-covered patches, which was calculated by the sum of the population in ES-
273 covered patches divided by the total population size (Fig 4B). It is noted that $(1 - p_c)\%$ of the
274 population was not covered by ES but counted in the denominator. The tendency of simulated early
275 detection probability was similar to Fig 4A. Second, we considered the national ES population
276 coverage as the x-axis, which was calculated by multiplying p_c with the “percentage of the
277 population in ES-covered patches” to correctly account for the population covered by ES. Even
278 though the same national ES population coverage was maintained (Fig 4C, coloured points), the
279 simulated early detection ability largely depended on the choice of p_c . This large variation implies
280 the national ES population coverage would be an unreliable measurement to evaluate the spatial
281 arrangements of the ES sites for the early detection ability. This tendency was consistent across the
282 sensitivity analyses under the other 5 scenarios (Fig S14-15 in S1 text).

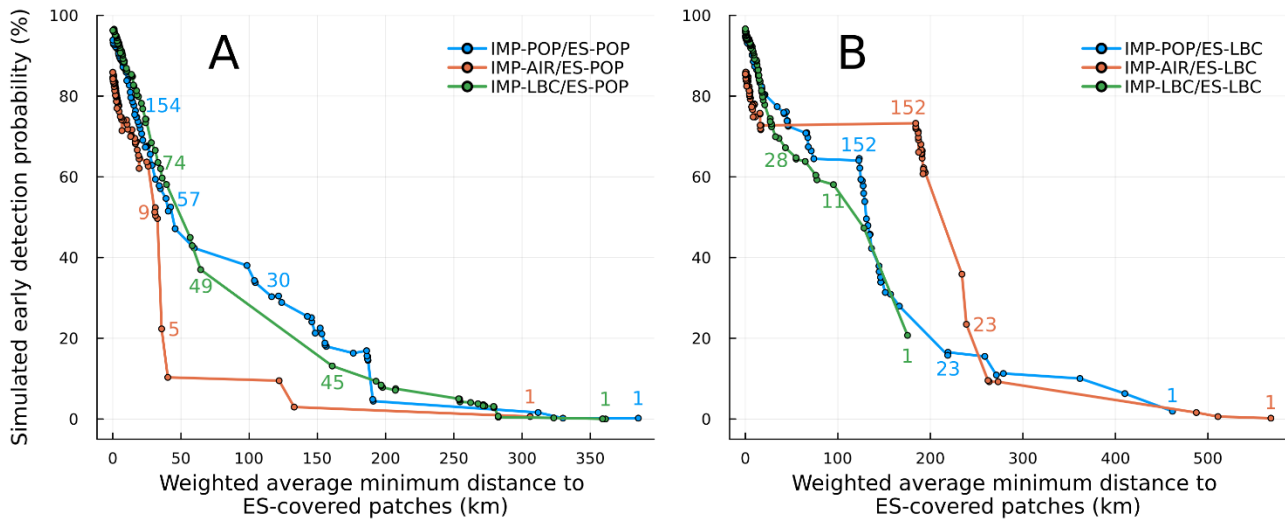

283

284 **Correlations between simulated early detection probability and weighted** 285 **average minimum distance to ES-covered patches**

286 We explored more parsimonious assessment measurements for the ES site layout across the
287 countries since our stochastic simulations required a long computation time. We calculated the
288 average minimum distance from patches with importation to ES-covered patches weighted by
289 outbreak probability. The outbreak probability in the present study is defined as the probability of 10
290 or more infections occurring given a single introduction, considering the effective immunisation
291 proportion (EIP) in each patch (Fig S9 in S1 text). This metric can be calculated if importation risks
292 and ES site layout are available. Intuitively, early detection probability is likely to be higher if ES-
293 covered patches are placed near locations for importation. In this exercise, we wanted to explore
294 whether assumptions on importation and ES placement consistently influenced this property.

295 The relationship between simulated early detection probability and weighted average minimum
296 distance showed a shape similar to an exponential curve for the IMP-POP and IMP-LBC scenarios
297 (Fig 5A&B). Once the simulated early detection probability surpassed 50%, this relationship

298 transitioned towards a nearly linear trend. Although the shape for these relationships was similar for
 299 ES-POP and ES-LBC scenarios, the scale of weighted average minimum distance was different.

300

301 **Fig 5. Relationship between the weighted average minimum distance to ES-covered patches**
 302 **and simulated early detection probability (%).** (A) Under ES-POP scenarios. (B) Under ES-LBC
 303 scenarios. Minimum distances to ES-covered patches were weighted by importation risk and
 304 outbreak probability of 10 or more infections occurring, considering the effective immunisation
 305 proportion. The coloured numbers next to points correspond to the number of ES-covered patches
 306 for each importation risk distribution.

307

308 In contrast, the relationship between simulated early detection ability and weighted average
 309 minimum distance showed an irregular pattern in IMP-AIR scenarios. We observed a sharp increase
 310 in simulated early detection probability despite a small difference in weighted average minimum
 311 distance in both ES-POP and ES-LBC. Conversely, only a small difference in simulated early
 312 detection probability was present despite a large difference in weighted average minimum distance.
 313 Notably, in the IMP-AIR/ES-LBC scenario, when the number of ES-covered patches exceeded 152,
 314 there was no increase in simulated early detection probability despite a more than 100km decline in
 315 the weighted average minimum distance to ES-covered patches.

316 Discussion

317 In this study, we assessed the quantitative relationship between early detection ability and the scale
318 and locations of ES sites by employing a meta-population framework. We simulated the importation,
319 spread and detection process, varying the number of ES-covered sites under different importation
320 risk distributions and ES site layout strategies. By applying stochastic simulations, we successfully
321 considered the partial detection patterns (i.e. ES only detection or AFP surveillance only detection)
322 to align with real-world observations. The results provided here illustrated the potential of strategic
323 positioning of ES sites to enhance early detection capabilities and clarified key ES-related
324 parameters to be considered. Our results also highlight the importance of poliovirus importation risk
325 assessment and how infectious disease surveillance should be tailored to perceived threats.

326 We found that simulated early detection probability exhibited a monotonic increase with the number
327 of ES sites, but distinct variations in slope and plateau points were observed across six different
328 scenarios. When importation risks were concentrated in confined patches, the modest number of
329 strategic and targeted ES positioning can be highly efficient in the early detection of poliovirus
330 circulation. Conversely, if importation risk was geographically dispersed, the effectiveness of ES
331 was diminished, and many ES sites were required for a high early detection ability. It is noted that in
332 our simulation study, we did not consider delays in reporting from the onset of AFP or delays in
333 processing environmental samples. The reporting delays in patients with AFP were substantial in
334 resource-limited settings, which could be around 29–74 days [22], and those delays should be
335 considered in practice.

336 Our sensitivity analysis showed large variations in simulated early detection probability depending
337 on the patch-level ES population coverage given the same national ES population coverage, which
338 poses the challenge of translating our simulation results into the practical ES implementation
339 strategy. Although national ES population coverage can be easily calculated, this measurement
340 would poorly reflect early detection ability for the ES layout unless a patch-level ES population
341 coverage is precisely specified. On the other hand, it is difficult to relate a patch in our simulations to

342 real-world geographical settings. We roughly assumed the spatial resolution of each patch was
343 equal to 20 x 20 km (i.e. 400 km²) regardless of urban and rural areas and made homogenous
344 mixing assumptions within a patch. This assumption led to unreasonable model-based conclusions
345 that ES sites should cover as small a proportion of the population within a patch as possible and as
346 many patches as possible, resulting in high early detection probability with low national ES
347 population coverage (requiring fewer resources) (Fig 4C). This result is an artefact of assuming that
348 all individuals within a patch mix homogeneously, and therefore a tiny ES area coverage within a
349 patch would have an unreasonably high probability of detecting poliovirus. Thus, crucial information
350 for connecting models with real-world settings is needed to identify areas where homogenous
351 mixing is held, and in other words, to identify the fragmentation level of patches, as is historically
352 pointed out by several authors [26–29]. One study of COVID-19 provided some insights into the
353 homogenous mixing assumptions. This study used virus genome data with corresponding resident
354 addresses in Danne, Scotland, suggesting around a 5km radius circle was well mixed in terms of
355 genetic distance [30]. An alternative approach would have been to reduce patch size, for example to
356 5 x 5 km, which may align better with the size of ES catchments and assumptions on homogenous
357 mixing. However, this procedure results in a large increase in computation time, and the catchment
358 size of environmental sites is typically unavailable in low- and middle-income settings and we are
359 therefore trying to align simulations with a uncertain value. An improved understanding of catchment
360 sizes in real-world settings is warranted because our study illustrates the sensitivity to assumptions
361 on catchment (or patch) size on early detection ability.

362 The sampling frequency is a parameter of interest to optimise the ES site layout [17,23]. By
363 employing a daily sampling strategy in our study, the ES early detection ability increased
364 significantly. However, this strategy resulted in an increased proportion of the ES only detection
365 pattern, which might cause overacting against such an importation that does not lead to secondary
366 infections. Assuming an equal number of environmental samples can be taken for each month,
367 extending ES sites can be more efficient in improving early detection ability and be robust against
368 various importation risk distributions. For example, if we assumed 20 ES-covered sites and monthly

369 sampling for the IMP-POP/ES-POP scenario, doubling sampling frequency led to a 10% increase in
370 simulated early detection probability while doubling ES-covered sites resulted in the same increase
371 and more resilience against multiple importation risk distributions. Moreover, the latter strategy can
372 minimise the proportion of the ES only detection pattern. One concerning point is that expanding ES
373 sites requires much more cost and additional human resources for transportation than increasing
374 sampling frequency [16,31].

375 The basic reproduction number (R_0) for poliovirus is difficult to determine due to the small number of
376 reported paralytic cases per outbreak and the impact of changes in hygiene. Our sensitivity analysis
377 of R_0 showed small differences in simulated early detection probabilities, supporting the high
378 robustness of results in the present study. Our assumed R_0 for the main analysis was based on a
379 review of transmissibility by Fine et al. from 1999 [32], and the hygiene level in the African continent
380 has since greatly improved. We therefore expect the current R_0 value in South Africa will be lower,
381 but the sensitivity analysis would be well within the bounds of potential R_0 values. One study
382 quantitatively investigated the early detection ability varying R_0 and other pathogen characteristics
383 using a branching process [22] and found that the lead time for wastewater surveillance was
384 different depending on R_0 . Two reasons can be considered. First, our model assumed an effective
385 reproduction number of around one by considering vaccination coverage. So, the variation of the
386 effective reproduction number was smaller compared to the range of R_0 investigated in Andrew, et
387 al. [22]. Second, we considered ES only detection patterns as early detection, which did not
388 happen in the branching process model.

389 Our study is not free from limitations. First, we considered the country where OPV and inactivated
390 polio vaccine (IPV) are routinely administered. The large outbreak of VDPV2 was caused by
391 switching from trivalent OPV to bivalent OPV [33], and many countries are planning to cease OPV
392 usage except for outbreak response [34,35]. Moreover, in many developed countries, IPV is only
393 included in their routine immunisation schedule. Those vaccinated with only IPV could spread
394 poliovirus to others due to lack of mucosal immunity and could be detected through ES, but they
395 would be less likely to develop AFP due to the humoral immunity, implying increased utility of the ES

396 compared to our study (where an IPV-OPV schedule is assumed). Second, we only focused on
397 WPV1 and did not consider other serotypes (such as cVDPVs) or transmission from immune-
398 compromised individuals shedding (iVDPVs).

399 Third, we limited transmission dynamics in children under 5 years old, assuming those aged 5 or
400 more were completely immunised. However, the reported age distribution of poliomyelitis patients is
401 skewed towards older groups in non-endemic countries [36], and multiple reasons for being
402 unvaccinated were considered such as migration, poverty and conflict [37–39]. We ignored those
403 pocket populations considering the size of that population and the paucity of historical vaccine
404 coverage data in South Africa. Fourth, our importation risk distributions were essentially based on
405 the population size of each patch and the approximated mobilisation pattern by the radiation model,
406 which could make the ES performance better when compared to reality. Quantitative data about
407 international traveller movement from airports and border crossing populations could improve
408 predictions that support risk assessment. Furthermore, research on the importation pathway is
409 demanding for prevention, detection and response. The importation routes to reported outbreak
410 sites were often unknown and one to three years of cryptic circulation was suspected for some
411 outbreaks [25]. Lastly, parameters for ES sensitivity, which was described by the lognormal
412 distribution, were estimated using the wastewater surveillance data for COVID-19 in the US [40].
413 Considering differences in virus shedding characteristics between poliovirus [41] and COVID-19
414 [42,43] as well as differences in ES site system and quality between the US and other low- and
415 middle-income countries, the ES sensitivity will be inherently different, underscoring the need for
416 region-specific data to assess site-specific ES sensitivity.

417 In conclusion, several countries are planning to initiate, expand and optimise the ES for poliovirus.
418 We varied the number and location of the ES sites under different importation risk distributions to
419 quantify the ES early detection ability over AFP surveillance. Our results showed that risk-targeted
420 ES site layout could achieve high early detection capabilities. Further research is required to
421 optimise resources for the ES to monitor the progress toward polio eradication.

422 **Material and Methods**

423 **Data**

424 We collated population data for children under 5 years old and for all age groups in 100m spatial
425 resolution in South Africa and Mozambique from WorldPop, respectively [44]. We aggregated each
426 dataset to obtain a 20km spatial resolution and called each unit of area a 'patch' within a meta-
427 population framework. We removed patches with less than 100 children under 5 years old for
428 computational efficiency, resulting in 1502 patches in South Africa (Fig S1 in S1 text).

429 We collated the district-level vaccination coverage from the Expanded Programme on Immunisation
430 National Coverage Survey Report 2020 in South Africa [45]. South Africa included both bivalent
431 OPV and IPV in their routine immunisation schedule. In South Africa's vaccine schedule, OPV is
432 administered at birth and 6 weeks after birth, and IPV is administered as a part of the hexavalent
433 vaccine (HEXA) at 6 weeks, 10 weeks, 14 weeks, and 18 months after birth.

434 To quantitatively validate the choice of patch-level ES population coverage (p_c), we obtained the
435 wastewater plant information about the location and their served-population size from the National
436 Institute for Communicable Diseases (NICD). The details of the wastewater data description and
437 validation process can be found in Table S3-4 and Fig S8 in S1 text.

438 **Proportion of immunised children under 5 years old**

439 We assumed those vaccinated with at least one IPV also completed two doses of OPV in our
440 simulation, and classified children into immunised and unimmunised ones. Immunised children are
441 assumed to have no susceptibility and transmissibility because of mucosal immunity induced by
442 OPV and they are assumed not to develop AFP because of serum antibody induced by IPV.
443 Therefore, we removed immunised children from the transmission dynamics. Since the last known
444 polio patient in South Africa was documented in 1989 [24], immunity from natural infection was not
445 considered.

446 We calculated the proportion of children under 5 years old who were effectively immunised, which
447 we called the effective immunisation proportion (EIP), with the district-level coverage of IPV and
448 assumptions of vaccine effectiveness against transmission. Let VE_p be the vaccine effectiveness per
449 dose (0.63 against serotype 1 [46–48]) and the probability of immunisation after n doses of IPV
450 (VE_n) is calculated as $1 - (1 - VE_p)^n$. Considering the IPV coverage for n th dose ($C_{v,n}$), the EIP can be
451 estimated considering VE_n and the IPV coverage for n th dose ($C_{v,n}$), which is described by $C_{v,4}VE_4 +$
452 $(C_{v,3} - C_{v,4})VE_3 + (C_{v,2} - C_{v,3})VE_2 + (C_{v,1} - C_{v,2})VE_1$. When $C_{v,n} < C_{v,n+1}$, we assumed $C_{v,n} - C_{v,n+1}$ to be
453 zero. We calculated the district-level EIPs (Table S1 and Fig S2 in S1 text) and assigned them as
454 the corresponding patch-level EIP. The average EIP weighted by the population size of children
455 under 5 years old in each patch in South Africa was 91.9%.

456 **Modelling framework**

457 We constructed a stochastic meta-population model among unimmunised children under 5 years old
458 considering the detection process of poliovirus through AFP surveillance and ES. The model
459 comprises three components: the transmission model, the AFP surveillance model, and the ES
460 model. In each simulation, we randomly chose one patch to introduce WPV1 proportional to the
461 assumed importation risks of each patch and ran the stochastic SEIR meta-population model until
462 one of the following criteria was met: the first poliovirus was detected through both surveillance, no
463 polio patients were present, or 3 years had passed from the beginning of the simulation.

464 Since the first detection timing through ES is largely influenced by the distribution of importation
465 risks and ES site layout strategy, we prepared three importation risk distributions and two ES site
466 layout strategies as follows (Fig 1, Fig S7-8 in S1 text and S1-2 Video):

- 467 - IMP-POP denotes ‘Population size’-based importation risk distribution and assumes the
468 importation risk of each patch is proportional to the population size of each patch.
- 469 - IMP-AIR denotes ‘International airport’-based importation risk distribution and assumes the
470 importation risk of each patch is proportional to international inbound travel volume in 2019 and
471 further considers mobilisation from airports.

- 472 - IMP-LBC denotes ‘Land border crossing’-based importation risk distribution and assumes the
473 importation risk of each patch is proportional to travelling volume from Mozambique, which is
474 approximated by the radiation model.
- 475 - ES-POP corresponds to ‘Population size’-based ES site layout strategy, and assumes the ES is
476 implemented in the descending order of population size of each patch.
- 477 - ES-LBC corresponds to ‘Land border crossing importation risk’-based ES site layout strategy
478 and assumes the ES is first implemented in a patch with a high importation risk via land border
479 crossing from Mozambique.

480 We considered the combination of each importation risk distribution and ES site layout strategy,
481 totalling 6 scenarios: IMP-POP/ES-POP, IMP-AIR/ES-POP, IMP-LBC/ES-POP, IMP-POP/ES-LBC,
482 IMP-AIR/ES-LBC, and IMP-LBC/ES-LBC. We included the land border crossing scenarios to assess
483 the early detection ability against the poliovirus introduction in rural settings with an informed ES
484 layout strategy (i.e. IMP-LBC/ES-LBC scenario).

485 In each scenario, we ran 10,000 simulations and calculated the proportion of each detection pattern,
486 varying the number of ES-covered patches. All analyses were performed in Julia v1.8.3.

487 **Transmission model**

488 We employed a stochastic meta-population SEIR model among unimmunised children under 5
489 years old (Fig S3 in S1 text). The SEIR model simulates the process in which susceptible individuals
490 (S) get infected, passing through a latent period (E) and infectious period (I), and then recover from
491 infection (R). The daily hazard rate for newly infected individuals in patch i at day t is expressed as

$$492 \quad \lambda_{i,t} = \frac{\beta}{N_{i,c}} \left[(1 - \alpha)(I_{i,c,t} + I_{i,nc,t}) + \alpha \sum_{j \neq i} \pi_{ji}(I_{j,c,t} + I_{j,nc,t}) \right], \quad (1)$$

493 where β corresponds to the transmission rate, $N_{i,c}$ is the population size of children under 5 years
494 old of patch i regardless of immunity status, α corresponds to the travelling rate between patches
495 and π_{ji} denotes the rates of moving from origin j to destination i . The moving rates (π_{ji}) were

496 approximated by the radiation model, which showed an improved fit to data than the gravity model
497 in the polio context [49–51]. We classified the infectious individual compartment into two classes:
498 infectious individuals at patch i covered by the ES at day t ($I_{i,c,t}$) and not covered by the ES ($I_{i,nc,t}$).
499 Infected individuals in the latent period (E) are randomly assigned to $I_{i,c,t}$ or $I_{i,nc,t}$ proportional to the
500 patch-level ES population coverage (p_c) and $1 - p_c$, respectively. However, assumptions on
501 infectiousness did not differ between groups.

502 **AFP surveillance model**

503 Patients with WPV1 develop AFP with a probability of 1/200, and we assumed those patients seek
504 healthcare on the same day as the paralysis onset. The incubation period of developing AFP was
505 assumed to be 16.5 days [52,53] and we prepared 6 compartments with transition rates of 0.329
506 days⁻¹ to be aligned with the incubation period distribution [47].

507 To be correctly diagnosed and reported as AFP cases, patients should visit health care, be tested,
508 and get a positive result. We assumed the probability of correctly reporting AFP cases followed the
509 Binomial process considering the above three steps.

510 **Environmental surveillance model**

511 ES was implemented in limited patches and its number was varied in each scenario. ES is assumed
512 to cover a portion of the population (p_c) in each patch. We chose a default p_c of 25% by considering
513 the observed ES location and ES-covered population (Table S3-4 and Fig S8).

514 We modelled the detection process through ES as a binomial process. Let $n_{i,t}$ be an index variable
515 for sampling at location i at day t (taking 0 or 1), and $P_{ES,test}$ be a test sensitivity given a collected
516 sample contains a detectable level of virus. The number of polio-positive samples in the ES site at
517 patch i at day t ($w_{i,t}$) is given by

$$518 \quad w_{i,t} \sim \text{Binomial} \left(n_{i,t}, G \left(100,000 \frac{I_{i,c,t}}{N_i p_c}; \mu_{ES}, \sigma_{ES} \right) P_{ES,test} \right), \quad (2)$$

519 where N_i denotes the population size of all age groups in patch i , and G denotes the cumulative
520 density function of the log-normal distribution with parameters of μ_{ES} and σ_{ES} , which represents the
521 ES sensitivity against the incidence rate of polio patients per 100,000 population. The ES sensitivity
522 parameters were estimated based on the wastewater surveillance study on COVID-19 [40]. To
523 ensure the consistent quality of ES in each sampling site for estimation, we used sampling sites with
524 both positive and negative samples, where daily newly reported cases on the day with positive
525 samples were consistently higher than on the day with negative samples. The estimated dose-
526 relationship for the ES sensitivity can be seen in Fig S6 in S1 text.

527 **Sensitivity analysis and weighted minimum distance to ES-covered patches**

528 We performed the sensitivity analyses of the basic reproduction number (R_0), travelling rate
529 between patches (α), sampling frequency and ES sensitivity for the IMP-POP/ES-POP scenario. For
530 a patch-level ES population coverage (p_c), sensitivity analysis was conducted for all 6 scenarios.
531 Additionally, we conducted the sensitivity analysis under a single patch setting (i.e. simulations were
532 performed without spatial structures). This analysis aimed to differentiate between the effects of
533 parameters on the ES early detection ability attributable to spatial components and those stemming
534 from model behaviours in a single patch (Fig S10 in S1 text).

535 Since our stochastic meta-population model requires a huge computational burden, we explored an
536 alternative parsimonious assessment measurement for the ES early detection ability. Assuming the
537 importation risk distributions and EIPs are known at a patch level, we calculated the average
538 minimum distance to ES-covered patches weighted by importation risk and outbreak probability of
539 10 or more infections occurring ($d_{ave,w}$). The outbreak probability was based on the branching
540 process considering the effective reproduction number in patch i ($R_{e,i}$) while the effective
541 reproduction number was given by the product of R_0 and EIP in patch i (Fig S9 in S1 text). We
542 calculated the probability of 10 or more infections occurring given the effective reproduction number,
543 $P(X \geq 10; R_{e,i})$, assuming the off-spring distribution follows the Poisson distribution [54–56]. Then,
544 the average minimum distance $d_{ave,w}$ is described as

545
$$d_{ave,w} = \frac{\sum_i r_i P(X \geq 10; R_{e,i}) \min(\{d_{ij}; j \in S_{ES}\})}{\sum_i r_i P(X \geq 10; R_{e,i})}, \quad (3)$$

546 where r_i denotes the importation risk at patch i and S_{ES} denotes the set of patches covered by the
547 ES. The detailed explanations can be found in S1 text.

1 Supplementary Methods

1.1 Data

We collated the population size data from the WorldPop [1] at 100m spatial resolution for 5 bin age categories and created population size data for children under 5 years old and for all ages in South Africa. We aggregated the population data into a 20km spatial resolution (precisely 21.31km x 19.74km), resulting in 3,193 patches. We removed patches with less than 100 children under 5 years old and finally obtained 1502 patches (Fig S1). Through this process, we removed 0.61% population of children under 5 years old. We kept patch spatial resolution constant for all patches so that ES-covered areas in each patch were fixed. We applied the same procedure to create the population data for children under 5 years old in Mozambique at the same resolution.

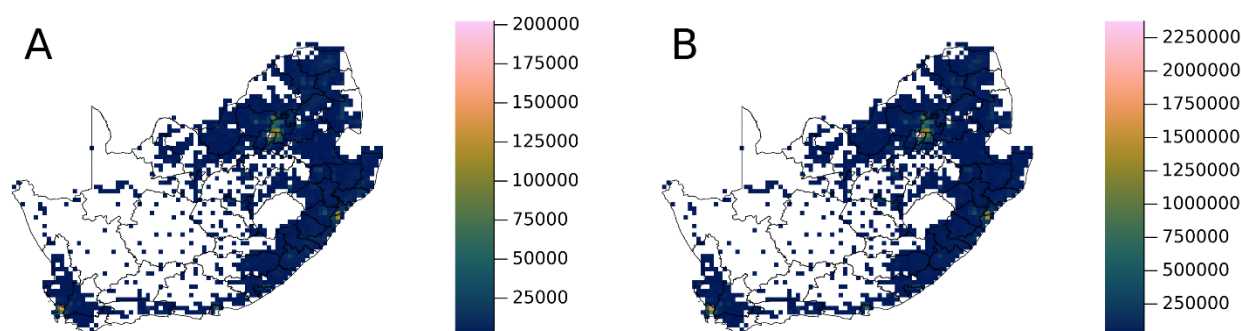

Fig S1. Heatmap of population size in South Africa. (A) Children under 5 years old and (B) All ages. Patches with <100 children under 5 years old were removed from the analysis.

We collated the district-level vaccination coverage from the Expanded Programme on Immunisation National Coverage Survey Report 2020 in South Africa [2]. We summarised the coverage of oral polio vaccine (OPV) and hexavalent vaccine (HEXA) including inactivated polio vaccine (IPV) for each district in Table S1 with the district-level effective immunisation proportions (EIPs), which were calculated using the equation described in the main text. We visualised the district-level EIPs in Fig S2.

1.2 Ethical statement

This study was assessed by the Research Governance & Integrity Office at the London School of Hygiene & Tropical Medicine as not requiring ethical approval due to its study design as a secondary data analysis on 9 May 2023 (MSc ethics reference number: 29004). The location and population size covered by each wastewater plant were provided by the National Institute of Communicable Diseases (NICD) in South Africa. All other data are publicly available.

1.3 Modelling framework

To assess the early detection ability of environmental surveillance (ES) over acute flaccid paralysis (AFP) surveillance, we constructed the stochastic spatiotemporal model among unimmunised children under 5 years old considering the detection process through the AFP surveillance and ES (Fig S3). We utilised South Africa as a case study of a non-endemic country and assumed a single introduction of a patient with wild poliovirus serotype 1 (WPV1). Following other modelling studies on polio [3–5], our model comprises three components: transmission model, AFP surveillance model and ES model (Fig S3), which will be explained in later sections. We used the detection patterns and first detection timing by ES and AFP surveillance as outcomes to quantify the early detection ability while we varied the number of ES-covered patches. We prepared three importation risk distributions and two ES site layout strategies, totalling six scenarios, to account for limited knowledge of importation risks (Fig 1).

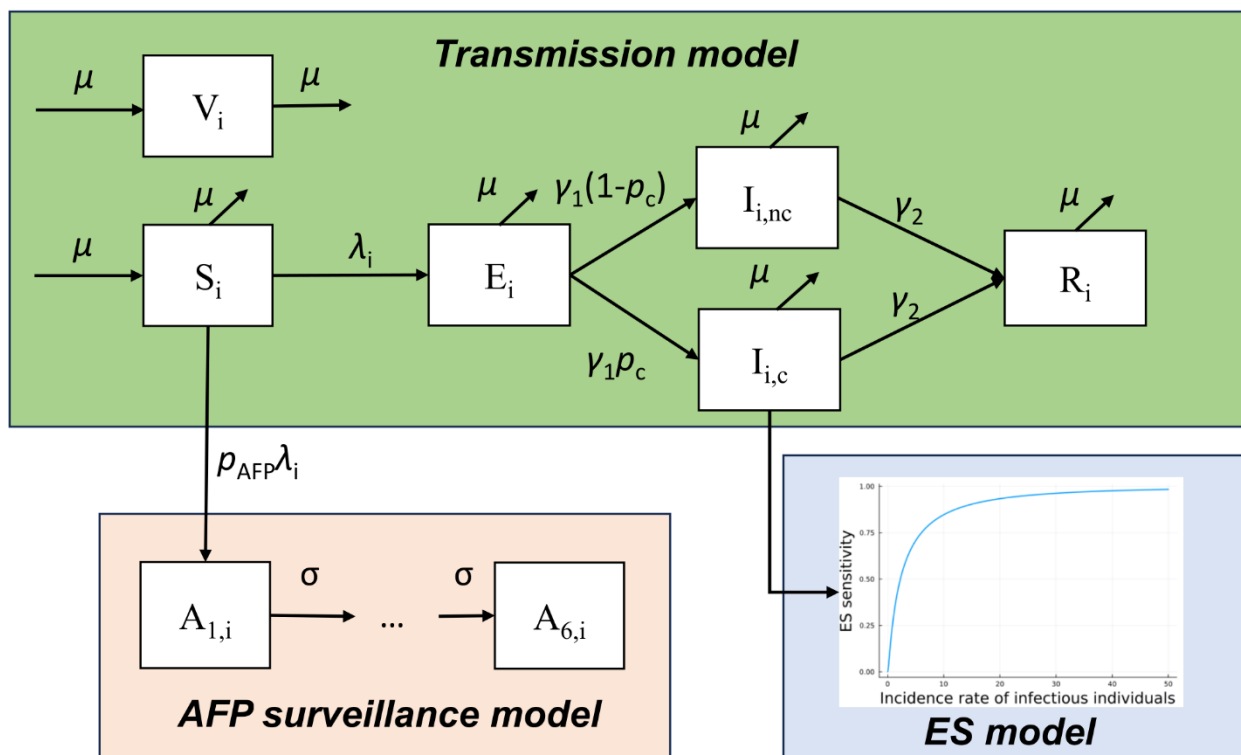

Fig S3. Schematic representation of our model, comprising of three parts: transmission model, AFP surveillance model and ES model. Each compartment is defined as follows: S, susceptible population; E, latent population; I, infectious population; R, recovered population; V, immunised population; and A_1 through A_6 , population who are developing AFP. ES sensitivity is dependent on the incidence rate of infectious polio patients. The subscript of i corresponds to the location. Abbreviations: ES, environmental surveillance; AFP, acute flaccid paralysis.

1.3.1 Transmission model

We employed the stochastic spatiotemporal SEIR model to describe the transmission dynamics. The SEIR model simulates the process in which susceptible individuals (S) get infected, passing through a latent period (E) and infectious period (I), and then recover from infection (R). We only considered unimmunised children under 5 years old since most reported patients with AFP were

within this age group [6]. We assumed no waning of immunity from vaccination or natural infection. Considering our simulation length (i.e. 3 years), we introduced the birth and removal rate (μ) to reflect the population dynamics. We classified infectious compartments into the one covered by the ES (I_c) and the one not covered by the ES (I_{nc}) but assumptions on infectiousness did not differ between groups.

The force of infection at patch i at day t ($\lambda_{i,t}$) corresponds to the rate at which susceptible individuals at patch i at day t get infected and is described by

$$\lambda_{i,t} = \frac{\beta}{N_{i,c}} \left[(1 - \alpha)(I_{i,c,t} + I_{i,nc,t}) + \alpha \sum_{j \neq i} \pi_{ji}(I_{j,c,t} + I_{j,nc,t}) \right], \quad (S1)$$

where β corresponds to the transmission rate, and α corresponds to the travelling rate between patches, which represents the proportion of travellers per day from one patch. The population aged under 5 years old at patch i is denoted as $N_{i,c}$. It is noted that immunised populations (V_i) contributed to herd immunity and its population size was given by $N_{i,c}$ multiplied by the EIP at patch i (EIP_i). Then, the initial susceptible population at patch i (S_i) was given by $N_{i,c} (1 - EIP_i)$, and the effective reproduction number at patch i at the beginning of the simulation ($R_{e,i}$) was given by the product of the basic reproduction number ($R_0 = \beta/\gamma_2$) and the EIP at patch i .

The second term of Equation S1 corresponds to the hazard from other patches, considering the travelling rate (α) and moving rates of travellers from origin j to destination i among all travellers moving from patch j (π_{ji}). We adopted the frequency-dependent model for between-patch transmission, which was theoretically investigated [7,8], while another modelling study on poliovirus employed density-dependent transmission [5]. We used the radiation model to approximate moving rates (π_{ji}):

$$\pi_{ij} = \frac{N_{i,c} N_{j,c}}{(N_{i,c} + N_{ij,c}^S)(N_{i,c} + N_{j,c} + N_{ij,c}^S)}, \quad (S2)$$

where $N_{ij,c}^S$ denotes the aggregated population aged under 5 years old within the circular area with a radius extending from patch i to patch j , centred at patch i but excluding the source and destination population. The histogram and heatmap of moving rates (π_{ij}) of the top 3 populous patches are shown in Fig S4. The previous study suggested in the context of polio disease, the radiation model not only outperformed the gravity model [9–11], but also excelled when compared to the gravity model calibrated to mobile phone data [9].

We adopted the discrete Markov process with daily time steps for our stochastic simulations. Transition events, effects and sampling ways of new states were summarised in Table S2.

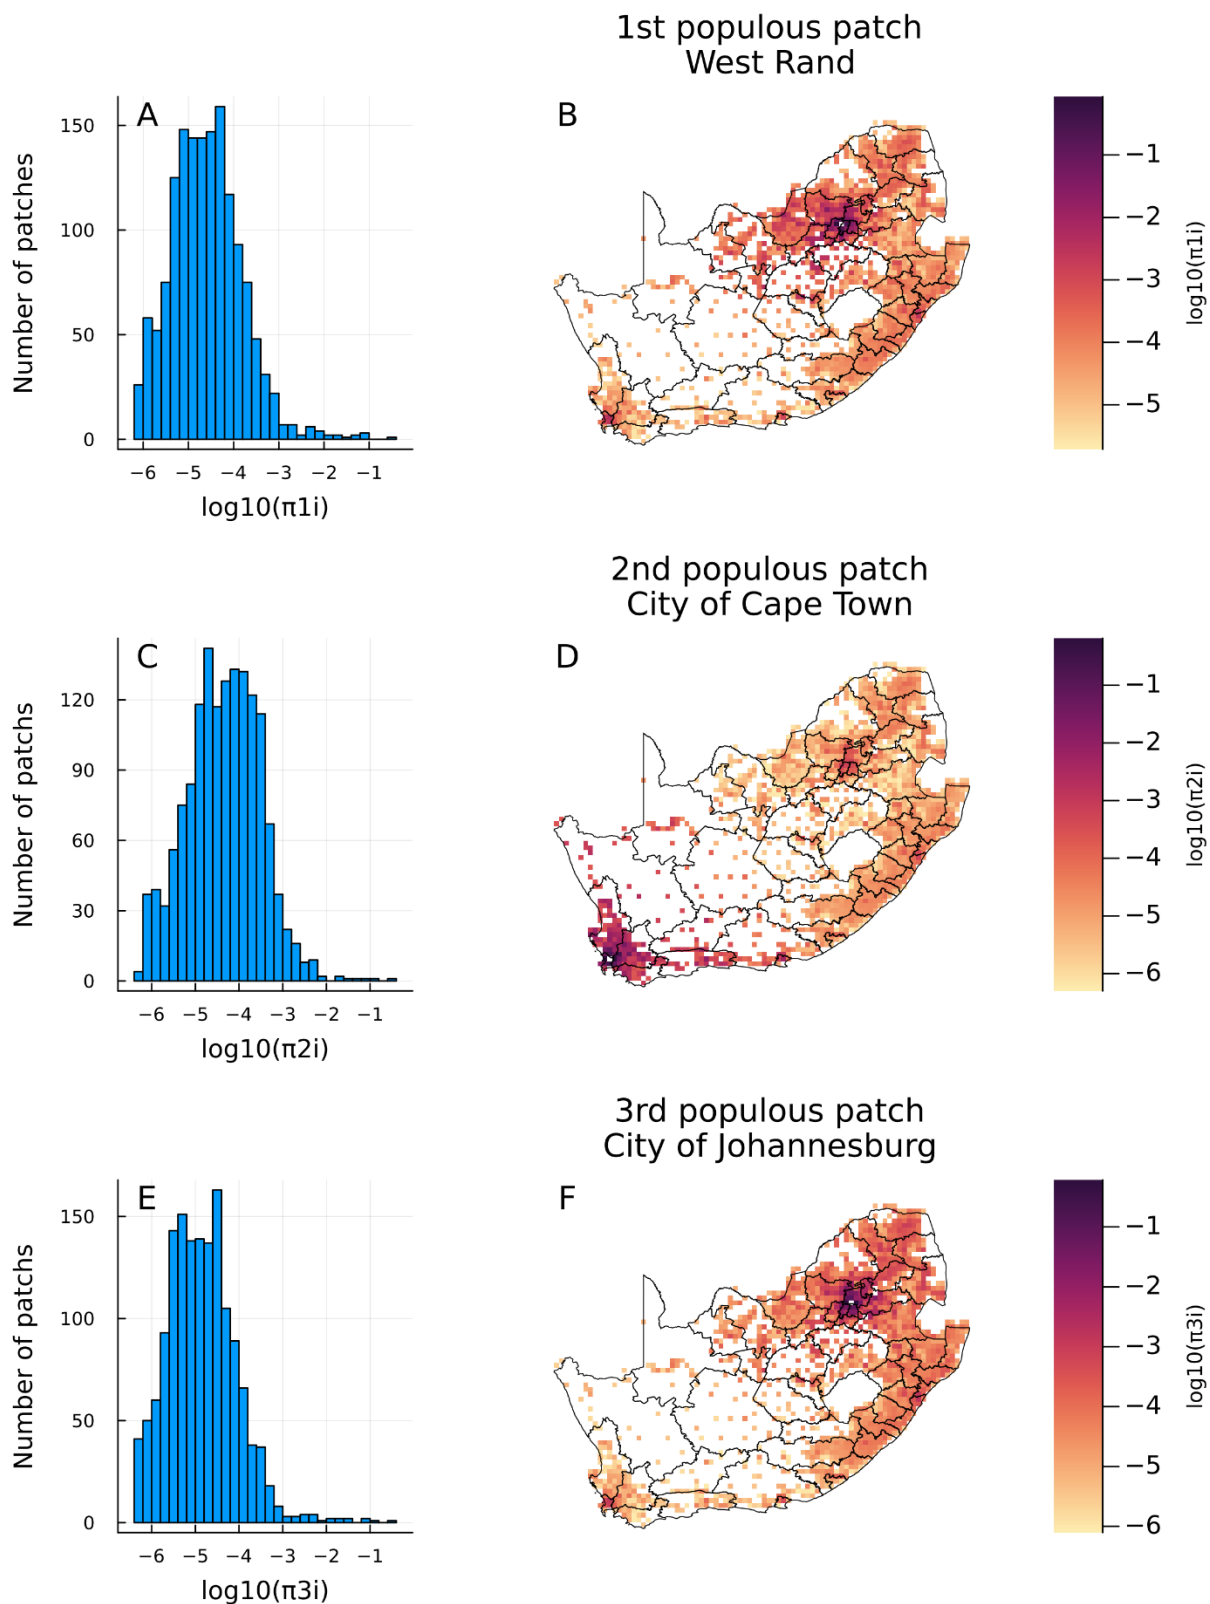

Fig S4. Moving rates from origin i to destination j (π_{ij}) approximated by the radiation model for the three most populous patches. (A, C, E) Histogram of π_{ij} and (B, D, E) heatmap of π_{ij} with colour bar values on a \log_{10} scale for (A, B) West Rand, (C, D) City of Cape Town and (E, F) City of Johannesburg.

Table S2. Discrete Markov process for each time step.

Event (patch i)	Effect	Sampling way
Birth of susceptible individuals	$(S_{i,t+1}) \leftarrow (S_{i,t} + Z_{i,t}^{(N_{i,u})})$	$Z_{i,t}^{(N_{i,u})} \sim \text{Binomial}(N_{i,u}, 1 - e^{-\mu})$
Removal of susceptible individuals because of age eligibility	$(S_{i,t+1}) \leftarrow (S_{i,t} - Z_{i,t}^{(S_{i,t})})$	$Z_{i,t}^{(S_{i,t})} \sim \text{Binomial}(S_{i,t}, 1 - e^{-\mu})$
Infection of susceptible individuals	$(S_{i,t+1}, E_{i,t+1}) \leftarrow (S_{i,t} - Z_{i,t}^{(S_{i,t}, E_{i,t})}, E_{i,t} + Z_{i,t}^{(S_{i,t}, E_{i,t})})$	$Z_{i,t}^{(S_{i,t}, E_{i,t})} \sim \text{Binomial}(S_{i,t}, 1 - e^{-\lambda_{i,t}})$
New individuals who will develop AFP	$(A_{1,i,t+1}) \leftarrow (A_{1,i,t} + Z_{i,t}^{(A_{1,i,t})})$	$Z_{i,t}^{(A_{1,i,t})} \sim \text{Binomial}(Z_{i,t}^{(S_{i,t}, E_{i,t})}, p_{AFP})$
Removal of latent individuals because of age eligibility	$(E_{i,t+1}) \leftarrow (E_{i,t} - Z_{i,t}^{(E_{i,t})})$	$Z_{i,t}^{(E_{i,t})} \sim \text{Binomial}(E_{i,t}, 1 - e^{-\mu})$
Becoming infectious	$(E_{i,t+1}, I_{i,t+1}) \leftarrow (E_{i,t} - Z_{i,t}^{(E_{i,t}, I_{i,t})}, I_{i,t} + Z_{i,t}^{(E_{i,t}, I_{i,t})})$	$Z_{i,t}^{(E_{i,t}, I_{i,t})} \sim \text{Binomial}(E_{i,t}, 1 - e^{-\gamma_1})$
Removal of infected individuals because of age eligibility	$(I_{i,t+1}) \leftarrow (I_{i,t} - Z_{i,t}^{(I_{i,t})})$	$Z_{i,t}^{(I_{i,t})} \sim \text{Binomial}(I_{i,t}, 1 - e^{-\mu})$
Recovery from infection	$(I_{i,t+1}, R_{i,t+1}) \leftarrow (I_{i,t} - Z_{i,t}^{(I_{i,t}, R_{i,t})}, R_{i,t} + Z_{i,t}^{(I_{i,t}, R_{i,t})})$	$Z_{i,t}^{(I_{i,t}, R_{i,t})} \sim \text{Binomial}(I_{i,t}, 1 - e^{-\gamma_2})$
Removal of recovered individuals because of age eligibility	$(R_{i,t+1}) \leftarrow (R_{i,t} - Z_{i,t}^{(R_{i,t})})$	$Z_{i,t}^{(R_{i,t})} \sim \text{Binomial}(R_{i,t}, 1 - e^{-\mu})$
Progression of the incubation period of AFP from stage k to $k+1$	$(A_{k,i,t+1}, A_{k+1,i,t+1}) \leftarrow (A_{k,i,t} - Z_{i,t}^{(A_{k,i,t}, A_{k+1,i,t})}, A_{k+1,i,t} + Z_{i,t}^{(A_{k,i,t}, A_{k+1,i,t})})$	$Z_{i,t}^{(A_{k,i,t}, A_{k+1,i,t})} \sim \text{Binomial}(A_{k,i,t}, 1 - e^{-\sigma})$

^a $N_{i,u}$ denotes unvaccinated individuals at patch i , calculated as the product of population aged under 5 years old and effective immunisation proportion at patch i .

We estimated the infectious period ($1/\gamma_2$) using the proportion of infected individuals shedding any amount of virus over time, which was provided by expert opinions [12]. Formally, the time course of infectiousness can be obtained by the product of the proportion of individuals shedding any amount of virus and non-linear transformation of the amount of virus shedding given a person excretes the virus each day since infection [12]. Since we do not know the functional form for the latter data, we regarded the first one as the infectiousness for simplicity.

Since the compartment model implicitly assumes the transition process from one compartment to another follows the exponential distribution, the distribution of infectiousness over time can be described as the convolution of two exponential distributions:

$$f(t) = \int_0^t \gamma_1 e^{-\gamma_1(t-s)} \gamma_2 e^{-\gamma_2 s} ds = \frac{\gamma_1 \gamma_2}{\gamma_2 - \gamma_1} (e^{-\gamma_1 t} - e^{-\gamma_2 t}), \quad (\text{S3})$$

where the reciprocal, $1/\gamma_1$, corresponds to the mean incubation period and is assumed to be 4 day, and $1/\gamma_2$ corresponds to the mean infectious period. We minimised the Kullback-Leibler divergence between the observed distribution and $f(t)$, estimating $1/\gamma_2$ to be 15.02 days. The fitted curve is shown in Fig S5.

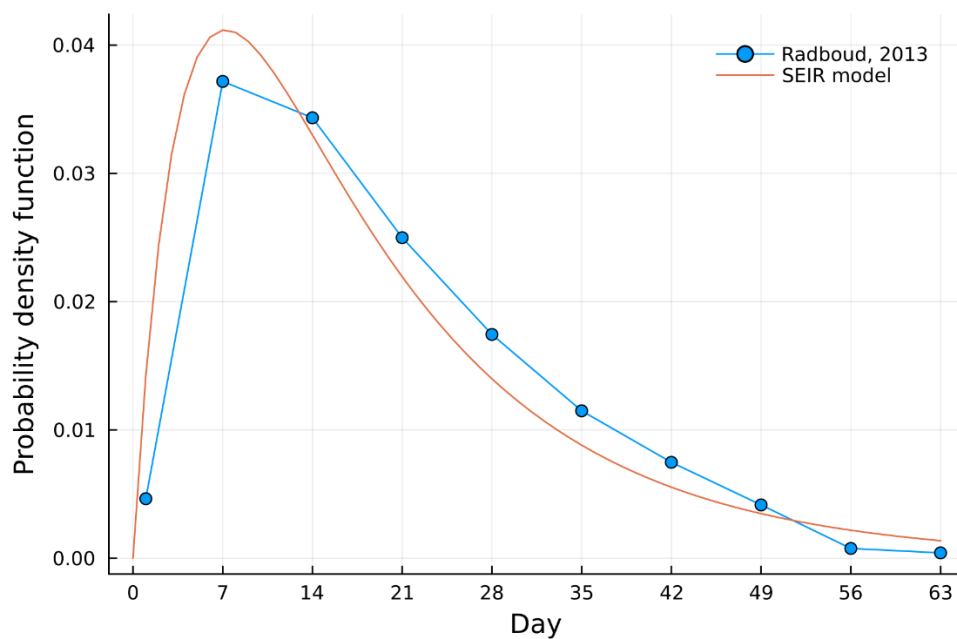

Fig S5. The proportion of individuals excreting the poliovirus regardless of the amount of virus shedding over time, which was scaled to be one for the probability density function and the fitted probability density function.

1.3.2 AFP surveillance model

We assumed the probability of developing AFP given infection with poliovirus to be 1/200, which was denoted as p_{AFP} . Patients developing AFP are correctly reported if they successfully undergo the following process: seeking healthcare, being tested, and getting a positive result. We denoted P_H , $P_{AFP, sample}$, and $P_{AFP, test}$ as the probability of each process. Then, the number of reported patients with AFP at patch i at time t , $O_{i,t}$, was described as

$$O_{i,t} \sim \text{Binomial} \left(Z_{i,t}^{(A_{5,i,t}, A_{6,i,t})}, P_H P_{AFP, sample} P_{AFP, test} \right), \quad (S4)$$

where the number of individuals who newly develop AFP at patch i at day t is denoted as

$$Z_{i,t}^{(A_{5,i,t}, A_{6,i,t})}.$$

The incubation period of developing AFP was assumed to be 16.5 days [13,14] and we prepared 6 compartments with transition rates of 0.329 days⁻¹ to be aligned with the incubation period distribution [5]. The number of compartments and transition rates were estimated in the previous study [5] by fitting an Erlang distribution to 36 independent data intervals from poliovirus exposure to the onset of AFP. In the present study, we did not consider a delay in medical consultations, conducting tests and notifications to authorities. These processes usually take time [15] and should be accounted for when results are interpreted.

1.3.3 Environmental surveillance model

There are limited empirical data to compare the incidence of poliovirus against the probability of a positive ES sample, which is a required parameter in this analysis. Instead, we opted to assume that ES sensitivity for poliovirus was comparable to that observed for COVID-19, and used the wastewater surveillance data in the US, published by Fuqing Wu et al. [16]. The data for COVID-19 is more amenable to analysis because of the intensity of clinical testing for SARS-CoV-2 and the (comparatively) low proportion of asymptomatic infections. To ensure the consistent quality of ES in each sampling site for estimation, we used sampling sites with both positive and negative samples, where daily newly reported cases on the day with positive samples were consistently higher than on the day with negative samples. Finally, 27 out of 353 sampling sites were eligible for the estimation.

We employed the log-normal distribution to estimate the dose-response curve for the ES sensitivity against the incidence rate of COVID-19 (thus also of poliovirus infection). Let $x_{i,t}$ be the number of newly reported COVID-19 cases at sampling site i on day t , $y_{i,t}$ be the indicator variable for an observed positive sample at sampling site i on day t , and $p_{i,t}$ be the probability of detecting a positive sample at site i on day t . We minimized the following likelihood function to estimate the parameters of the lognormal distribution (μ_{ES} and σ_{ES}):

$$L = \prod_i \prod_t p_{i,t}^{y_{i,t}} (1 - p_{i,t})^{1 - y_{i,t}}, \quad (S5)$$

$$p_{i,t} = G \left(100,000 \frac{x_{i,t}}{N_{i,FW}}; \mu_{ES}, \sigma_{ES} \right) = \Phi \left(\frac{\log \left(100,000 \frac{x_{i,t}}{N_{i,FW}} \right) - \mu_{ES}}{\sigma_{ES}} \right)$$

where G denotes the cumulative density function of the log-normal distribution, $N_{i,FW}$ denotes the population in the state with sampling site i , which was given in Fuqing Wu et al. [16], and Φ

corresponds to the cumulative density function of the standard normal distribution. We obtained 0.818 for μ_{ES} and 1.45 for σ_{ES} .

The estimated parameters here will be inappropriate in terms of differences in the amount and length of virus shedding between SARS-CoV-2 and poliovirus in addition to differences in diagnostics for the detection of virus. In the main text, we conducted the sensitivity analysis ranging the ES sensitivity from 10 times higher to 10 times lower. We multiplied $1/k$ for previous data to obtain parameters for k times higher ES sensitivity. The dose-response curves for those ES sensitivity parameters are shown in Fig S6. σ_{ES} was estimated to be constant across different ES sensitivity assumptions and μ_{ES} was estimated to be 3.121, 1.917, -0.281 and -1.485 for 10 times lower, 3 times lower, 3 times higher, and 10 times higher ES sensitivity, respectively.

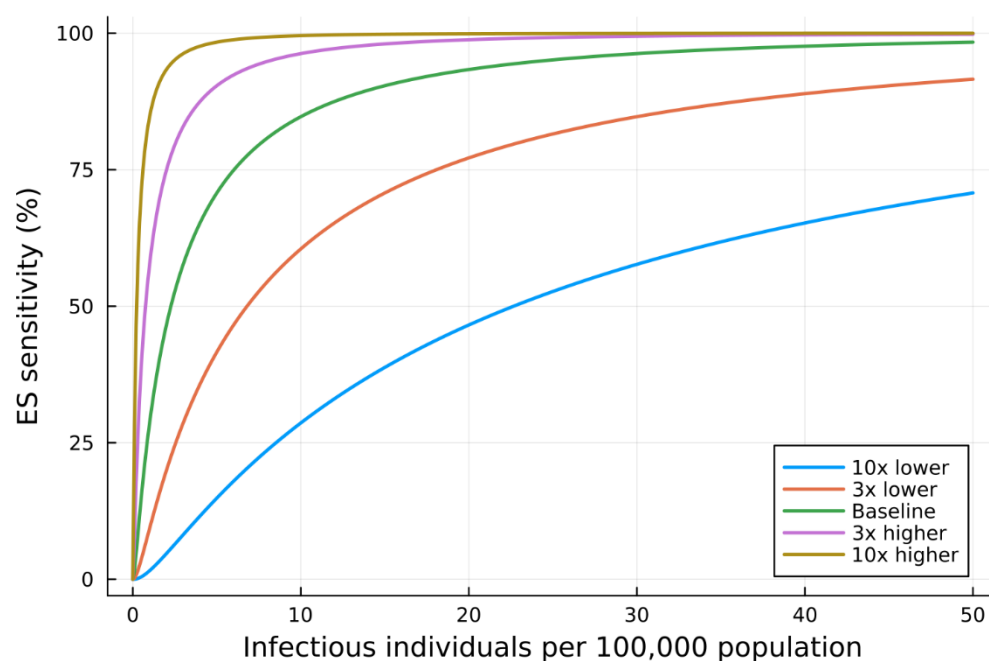

Fig S6. Dose-response curve for the ES sensitivity parameter against the number of infectious individuals per 100,000 population in a single patch.

We modelled the detection process through ES as the binomial process in our simulation study. Let $n_{i,t}$ be the indicator variable for conducting environmental sampling at patch i at day t (e.g. given monthly sampling, $n_{i,t}$ takes 1 on a single day, and takes 0 for the remaining days within a month), and $P_{ES, test}$ be the test sensitivity given a collected sample contains a detectable level of virus. The number of polio-positive samples in wastewater ($w_{i,t}$) is given by

$$w_{i,t} \sim \text{Binomial} \left(n_{i,t}, G \left(100,000 \frac{I_{i,c,t}}{N_i p_c}; \mu_{ES}, \sigma_{ES} \right) P_{ES, test} \right). \quad (S6)$$

It is noted that in each patch, $p_c\%$ of the population was assumed to be covered by the ES, and we separately considered the infectious individuals covered by ES ($I_{i,c,t}$) or not ($I_{i,nc,t}$) in the compartment model. Here N_i denotes the population of all ages at patch i (not limited to children under 5 years old).

1.3.4 Importation risk distributions

Importation risk at patch i refers to the probability that WPV1 is introduced to that specific patch and importation risk distribution refers to the distribution of importation risk across patches. We considered three importation risk distributions, which are denoted as IMP-POP, IMP-AIR, and IMP-LBC.

The IMP-POP refers to the ‘Population size’-based importation risk distribution and assumes importation risk is proportional to the population size of each patch. Let r_i be the importation risk at patch i for the IMP-POP scenario and be described as

$$r_i = \frac{N_{i,c}}{\sum_i N_{i,c}}, \quad (S7)$$

where $N_{i,c}$ denotes the population size of children aged under 5 years old at patch i .

The IMP-AIR refers to the ‘International airport’-based importation risk distribution and assumes importation risk is proportional to international inbound travel volume in 2019 and further considers mobilisation from airports, which was approximated by the radiation model given in Equation S2. Without considering mobilisation from airports, importation risks would be too confined to a few patches, which are sometimes very rural areas and we did not think that importation risk distribution is a realistic one. South Africa holds three international airports and their international inbound travel volumes in 2019 were 4,342,611 for O.R. Tambo International Airport, 1,156,996 for Cape Town International Airport, and 188,243 for King Shaka International Airport (Fig 1D).

We denote l_1 , l_2 and l_3 as the location of a patch with O.R. Tambo International Airport, Cape Town International Airport, and King Shaka International Airport, respectively. Let w_i be the proportion of the inbound travel volume at patch i with international airport i . The importation risk at patch i for the IMP-AIR is described as the average of moving rates from three international airports weighted by their inbound travel volumes:

$$r_i = w_{l_1}\pi_{(l_1)i} + w_{l_2}\pi_{(l_2)i} + w_{l_3}\pi_{(l_3)i}. \quad (S8)$$

The IMP-LBC refers to the ‘Land border crossing’-based importation risk distribution and assumes importation risk is proportional to travelling volume from Mozambique. Here, we assumed poliovirus was circulating in Mozambique and importation from Mozambique to South Africa happened via land border crossing. Since mobilisation volume data between Mozambique and South Africa is not available, we approximated those mobilisations with the radiation model.

The probability of the presence of poliovirus in patch j in Mozambique was assumed to be proportional to the population size of children under 5 years old, and the movement from patch j in Mozambique to patch i in South Africa is given by the radiation model between the two countries. The importation risk at patch i in South Africa for the IMP-LBC is described as

$$r_i = \frac{\sum_{j \in S_{MOZ}} \alpha_M \pi_{ji} N_{j,c}}{\sum_{k \in S_{ZAF}} \sum_{j \in S_{MOZ}} \alpha_M \pi_{jk} N_{k,c}} = \frac{\sum_{j \in S_{MOZ}} \pi_{ji} N_{j,c}}{\sum_{k \in S_{ZAF}} \sum_{j \in S_{MOZ}} \pi_{jk} N_{k,c}}, \quad (S9)$$

where S_{MOZ} and S_{ZAF} represent the set of patches in Mozambique and South Africa, respectively. The travelling rate from Mozambique to South Africa (α_M) would be different from the travelling rate between patches in South Africa (α) but is cancelled out in Equation S9.

The importation risk distributions explained above are visualised in Fig S7.

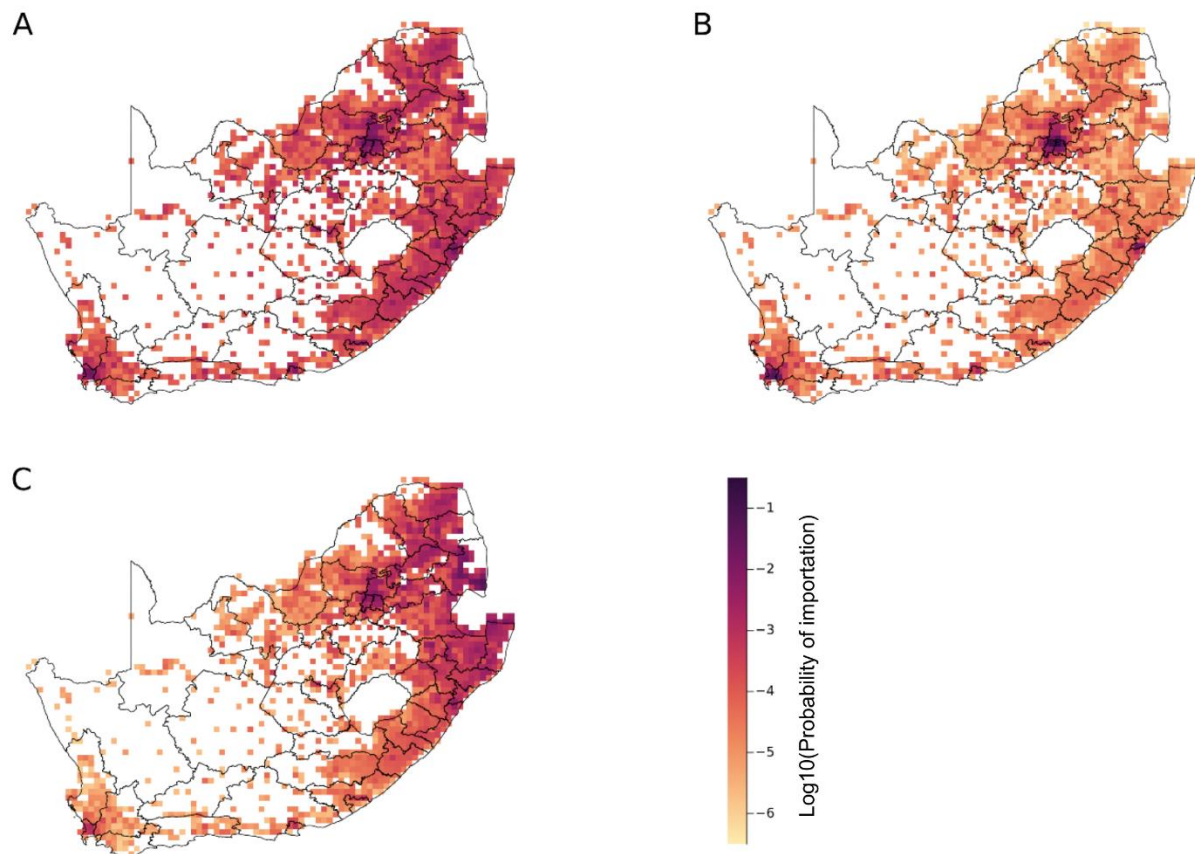

Fig S7. Importation risk distributions in a log₁₀ scale (A) for IMP-POP, (B) IMP-AIR, and (C) IMP-LBC.

1.3.5 ES site layout strategies and a patch-level ES population coverage (p_c)

ES site layout strategy determines a sequence of which patches are covered by the ES when we increase the number of ES-covered patches. We considered two ES site layout strategies: ES-POP and ES-LBC. The ES-POP refers to the 'Population size'-based ES site layout strategy, and assumes the ES is implemented in the descending order of population size of each patch. Hence, this strategy can cover the largest population size by the ES given the same number of ES-covered patches.

The ES-LBC refers to the 'Land border crossing importation risk'-based ES site layout strategy, and assumes the ES is first implemented in a patch with a high importation risk via land border crossing from Mozambique. The importation risk from Mozambique is given as the same in Equation S9. The motivation to prepare the ES-LBC is to quantify the effectiveness of the strategic positioning of the ES sites against the high importation risks in rural areas. The animations of the incremental ES implementation from a single patch to all patches were prepared for both ES-POP and ES-LBC in gif-files (S1-2 Video). It is noted that the maximum national ES population coverage was set at 25% since we assumed the ES-population coverage in each patch (called a patch-level ES population coverage, p_c) to be 25%, which reason is explained below.

We aimed for our simulated ES site layout under the ES-POP to be closely aligned with the observed one. The ES site is generally prioritised to be placed in populous areas in the real-world

setting. To quantify the similarity between simulated and observed ES layouts in South Africa, we first calculated the observed national and district-level ES population coverage (Table S3). Then, we varied a patch-level ES population coverage (p_c) fixing the simulated national ES population coverage to be the same as the observed one, and descriptively compared the simulated number of districts with ES sites and the corresponding district-level ES population coverage with the observed ones (Table S4).

We calculated the observed national and district-level ES population coverage using the location and ES-covered population of each wastewater plant, which was provided by the National Institute of Communicable Diseases in South Africa as of 27 November 2023. The ES-covered population was missing for Rooiwal Eastern and Daspoort wastewater plants and we imputed the median ES-covered population size of 350,000. We finally estimated the observed national ES population coverage in South Africa to be 11.3% (Table S3). The median and mean of the district-level ES population coverage among districts with ES sites were 30.6% and 22.5%, respectively.

We simulated the ES layout varying the patch-level ES population coverage (p_c) while fixing the simulated national ES population coverage to be the observed one of 11.3% (Table S4). When we set p_c at 100%, the ES sites were too concentrated and simulated district-level ES population coverages were much higher than observed ones. We chose p_c to be 25% for the main analysis considering the dispersion of ES sites and district-level ES population coverages (Table S4 and Fig S8).

Table S3. Approximated ES-covered population size in districts with ES sites in South Africa as of 27 November 2023.

Province	District	District-level population size	Wastewater plant name	ES-covered population size	District-level ES population coverage (%)

^a Blank in those columns represents no ES-covered patches.

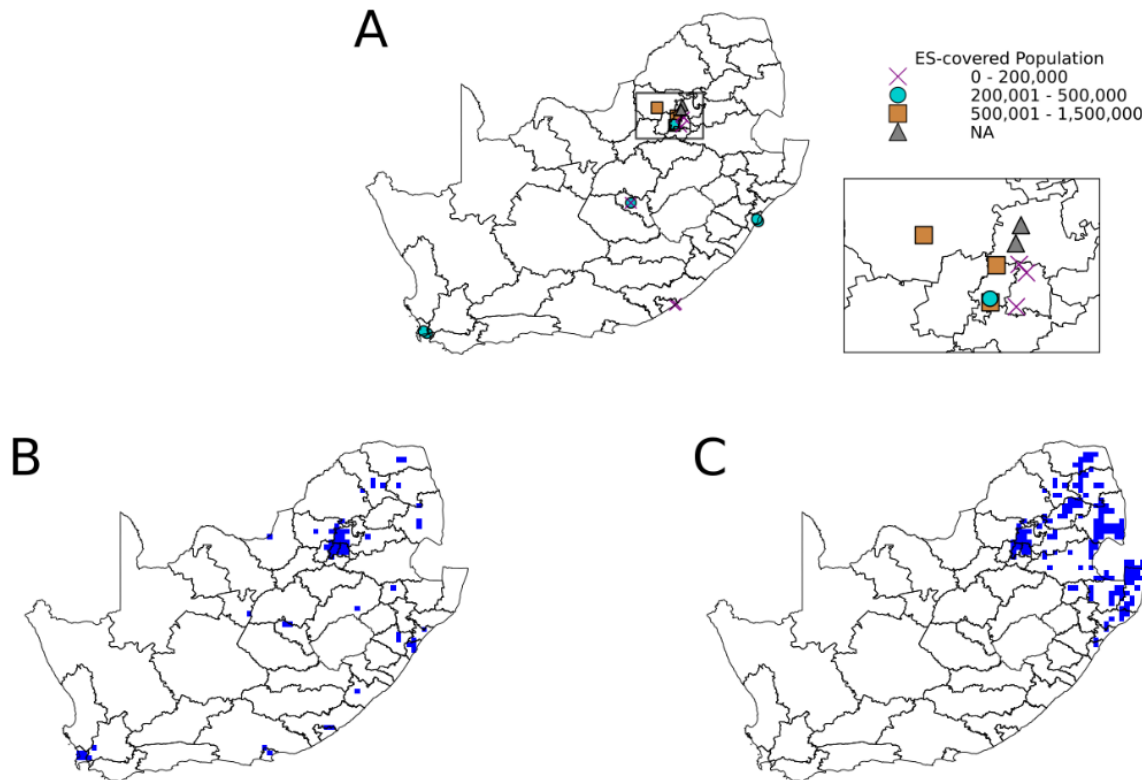

Fig S8. Environmental surveillance (ES) location maps. (A) Observed 17 ES sites in South Africa. Data points represent the location of observed ES sites, with each marker style indicating a specific range of ES-covered population sizes. The inset displays the expanded view of the areas with a high density of ES sites. (B, C) Simulated ES site layout when the simulated national ES population coverage was matched with the observed coverage given the patch-level ES population coverage was set at 25% (B) for ES-POP and (C) for ES-LBC. Blue squared areas represent patches with simulated ES sites. The number of ES-covered patches was 58 for ES-POP and 154 for ES-LBC.

1.3.6 Model parameter specification

Parameter values used in our simulations are summarised in

Table S5. We explained the rationale for the choice of several parameters.

We chose the basic reproduction number (R_0) to be 14 based on the estimation for developing countries by Fine et al. 1999, which used age-stratified seroprevalence data [17]. This estimated value would be higher considering the current hygiene situation in South Africa. In our transmission model, the population who were successfully vaccinated and immunised were removed from the dynamics. We define the transmissibility accounting for the initial susceptible population as the effective reproduction number at the beginning of the simulation for South Africa, $R_e(0)$. We calculated $R_e(0)$ by the product of R_0 and EIP in each district and averaged them across districts weighted by the population size of each district, and we obtained 1.13 for $R_e(0)$.

Regarding the AFP surveillance-related parameters, the stool adequacy rate refers to two stool specimens of sufficient quantity for laboratory analysis, collected at least 24 hours apart, within 14

days after the onset of paralysis. The stool adequacy rate in South Africa was reported 53% from 2016 to 2019 [18]. The procedures of handling samples from polio patients in the laboratory in South Africa followed the WHO Polio Laboratory Manual and supplement [18] and its sensitivity of polio detection was reported to be 0.97 [19].

We assumed monthly sampling (every 30 days) from the ES site in each patch for our simulation. Most African countries use a grab method to collect samples from wastewater and the sampling frequency is often 30 days due to manual labour burdens [20]. Some countries adopted a composite method for the ES, allowing daily or weekly sampling. GPEI recommends daily or weekly sampling but also accepts monthly sampling [21].

Table S5. Model Parameters used for our simulation.

Parameter description	Values	Reference
Per-dose vaccine effectiveness for IPV assessed by seroconversion	0.63	[22–24]
Average effective immune proportion (EIP) weighted by population size of children under 5 years old	91.9%	Estimated from the population data (WorldPop) and vaccine coverage data
Basic reproduction number, R_0	14	Assumed
Effective reproduction number at time 0 at a national level, $R_e(0)$	1.13	Estimated
Latent period, γ_1	1/4 days ⁻¹	[25]
Infectious period, γ_2	1/15.02 days ⁻¹	Estimated [12]
Transmission rate, β	0.93	Estimated by $R_0 \gamma_2$
Travelling rates, α	0.05	Assumed
Age criteria for population	Less than 5 years old	Assumed
Birth and removal rate, μ	1/(365*5)	Assumed
Transition rate of the incubation period for 6 compartments, σ	1/3.04 days ⁻¹	Estimated [5,13,14]
Patch-level ES population coverage, p_c	0.25	Assumed
Paralysis-to-infection ratio, p_{AFP}	1/200	[26]
Probability of seeking healthcare, P_H	0.9	Assumed
Probability of stool sampling when a patient visits a hospital, $P_{AFP, sample}$	0.53	[18,27]
Sensitivity of poliovirus detection when stool is tested, $P_{AFP, test}$	0.97	[19,28]

Sensitivity of poliovirus testing of samples from sewage water, $P_{ES, test}$	0.97	[19,28]
ES sensitivity	LogNormal($\mu=0.82, \sigma=1.45$)	Estimated [16]
Sampling frequency	Every 30 days	[20,21]

1.4 Outcome measures

The detection pattern for each simulation falls into one of the following five patterns (Fig 1).

1. No detection: neither AFP surveillance nor ES detected the poliovirus circulation.
2. AFP surveillance only detected polio patients.
3. AFP surveillance detected the poliovirus circulation earlier than ES.
4. ES detected the poliovirus circulation earlier than AFP surveillance.
5. ES only detected the poliovirus circulation.

Let t_{AFP} and t_{ES} be the timing of the first detection through AFP surveillance and ES, respectively. The lead time of the first detection through ES over APF surveillance (denoted as LT) is defined as $t_{AFP} - t_{ES}$, meaning that a positive value of LT corresponds to the early detection by ES (pattern 4) and a negative value of LT corresponds to the early detection by AFP surveillance (pattern 3). The lead time can only be calculated for patterns 3 and 4.

We used the proportion of each detection pattern among simulations with any poliovirus detection as the main outcome and excluded no detection pattern to match simulation outcomes with the real-world observations. To inform the quantitative aspect of early detection, we further classified pattern 3 into “< -60 LT” and “-60 ~ -1 LT” categories and pattern 4 into “0 – 59 LT”, and “≥60 LT” categories. We refer to the “simulated early detection probability” as the proportion of “0 – 59 LT”, “≥60 LT” and ES only detection patterns given the poliovirus circulation is detected.

1.5 Average minimum distance to ES-covered patches and simulated early detection probability.

We quantified the simulated early detection probability varying the number and location of the ES. However, our stochastic simulation took a long time and implementation was complex. We therefore explored a simple alternative measurement to inform the ES site layout strategy. Given importation risk distribution and EIPs in each patch were known, we calculated the weighted average minimum distance to the closest ES-covered patch and quantified the relationship between this measure and the simulated early detection probability.

The average minimum distance to the closest ES-covered patches (d_{ave}) weighted by the importation risks is given as

$$d_{ave} = \sum_i r_i \min(\{d_{ij}; j \in S_{ES}\}), \quad (S10)$$

where r_i is the importation risk at patch i for each scenario, d_{ij} is the distance between patch i and patch j , and S_{ES} is the set of patches with the ES.

Since the regional heterogeneity in vaccination coverage can influence the timing of detection, we also consider the average minimum distance weighted by the importation risks and the outbreak probability in each patch ($d_{ave,w}$):

$$d_{ave,w} = \frac{\sum_i r_i P(X \geq 10; R_{e,i}) \min(\{d_{ij}; j \in S_{ES}\})}{\sum_i r_i P(X \geq 10; R_{e,i})}, \quad (S11)$$

where $P(X \geq 10; R_{e,i})$ denotes the outbreak probability of 10 or more infections occurring given the effective reproduction number at patch i at the beginning of the simulation ($R_{e,i}$), which is given by the product of the effective immunisation proportion at patch i (EIP _{i}) and the basic reproduction number (R_0). We visualised the relationship between $d_{ave,w}$ and the simulated early detection ability in the main analysis (Fig 5). We arbitrarily chose the value of 10 infections for the cutoff. Assuming the branching process and the Poisson distribution as the offspring distribution (i.e. no overdispersion), the probability of observing x cases given $R_{e,i}$ follows the Borel-Tanner distribution [29–31].

$$P(X = x; R_{e,i}) = \frac{x^{x-2} R_{e,i}^{x-1} e^{-x R_{e,i}}}{(x-1)!}. \quad (S12)$$

Then, the probability of 10 or more infections occurring is calculated by considering the complement of less than 10 infections occurring.

$$P(X \geq 10; R_{e,i}) = 1 - \sum_{i=1}^9 P(X = i; R_{e,i}). \quad (S13)$$

The histogram of $R_{e,i}$ in South Africa and the corresponding probability of at least 10 infections happening given a single introduction is shown in Fig S9.

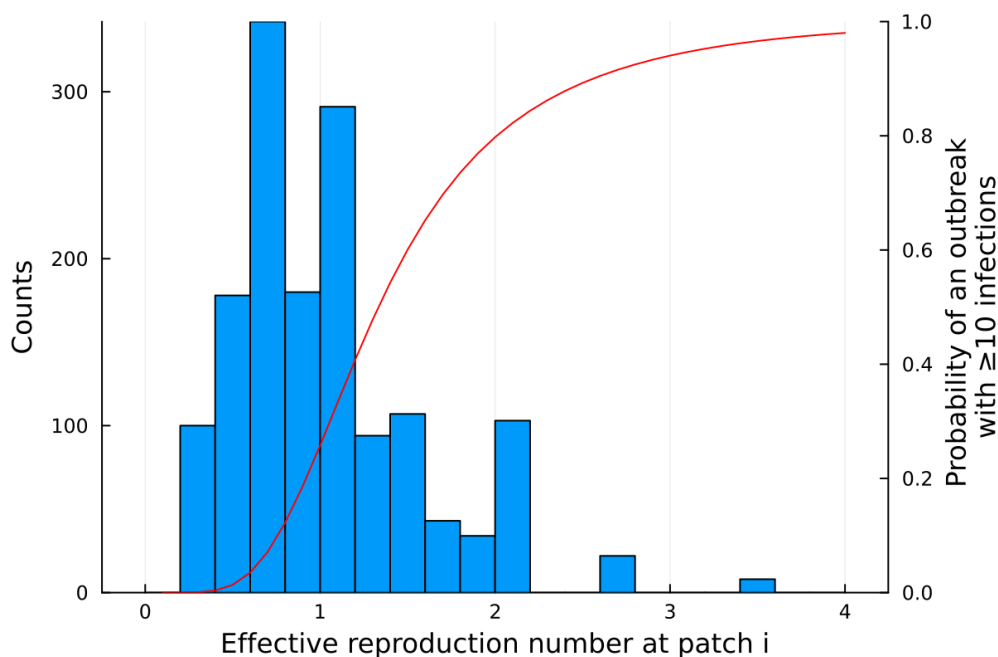

Fig S9. Histogram of the effective reproduction number for each patch and corresponding outbreak probability with ≥ 10 infections.

1.6 Simulation implementation.

We randomly chose a patch for an introduction of WPV1 and simulated the stochastic meta-population model for 3 years 10,000 times for each scenario. We recorded the number of individuals

at each patch in every compartment every day. Using those numbers in each compartment, we repeatedly applied the detection process through AFP surveillance and ES, varying the number of ES sites. We ended the simulation when one of the following criteria was met: the first poliovirus was detected through both surveillance, no polio patients were present, or three years had passed from the beginning of the simulation.

All the analysis was performed in Julia v1.8.3. It took around 5 to 8 hours to complete 10,000 simulations for one scenario from running the transmission model to running AFP surveillance model and ES model. The data and code are deposited on GitHub (https://github.com/toshiakiasakura/polio_environmental_surveillance).

^a Closest patch to King Shaka International Airport among the patches in this table. The rank of population size in King Shaka International Airport's patch is 61st.

^b Cape Town International Airport is in this patch.

^c Tambo International is in this patch.

^d Effective immunisation proportion.

2.2 Simulation results under a single patch setting.

We simulated a stochastic SEIR model in a single patch to differentiate between the effects of parameters on the simulated early detection ability of ES attributable to spatial components and those stemming from model behaviours in a single patch. We employed the same model without a meta-population framework using the parameters listed in Table S5. We chose 100,000 population size of children aged under 5 years old and set the population size of all ages as 100,000 divided by the patch-level ES population coverage (p_c).

We visualised the simulated cumulative detection probability over time for the AFP surveillance (dotted lines) and ES (solid lines) in Fig S10. Additionally, we visualised the proportion of any detection of the poliovirus circulation among all simulations including no detection pattern, and the proportion of each detection pattern given poliovirus circulation is detected (excluding no detection pattern).

Theoretically, ES-related parameters (sampling frequency, ES sensitivity, patch-level ES population coverage) do not influence the simulated cumulative probability of detection for AFP surveillance, which was confirmed by our simulations. Regarding population size, as the population size of children under 5 years old increased, the simulated cumulative probability for AFP surveillance also increased since the absolute value of patients with poliovirus became larger. On the other hand, the simulated cumulative probability for ES decreased because we assumed ES sensitivity was dependent on the incidence rate and a larger denominator resulted in the lower incidence rate.

We re-estimated ES sensitivity parameters with the simulated first detection timing through ES using Equation S5 to validate our assumption that ES sensitivity is proportional to the incidence rate of infectious individuals (Fig S11). We did not include simulated negative environmental samples for the estimation. Through this procedure, we illustrated higher ES sensitivity estimates for a large population size and lower ES sensitivity estimates for a small population size. This model behaviour is consistent with other estimates using the wastewater sample data [32].

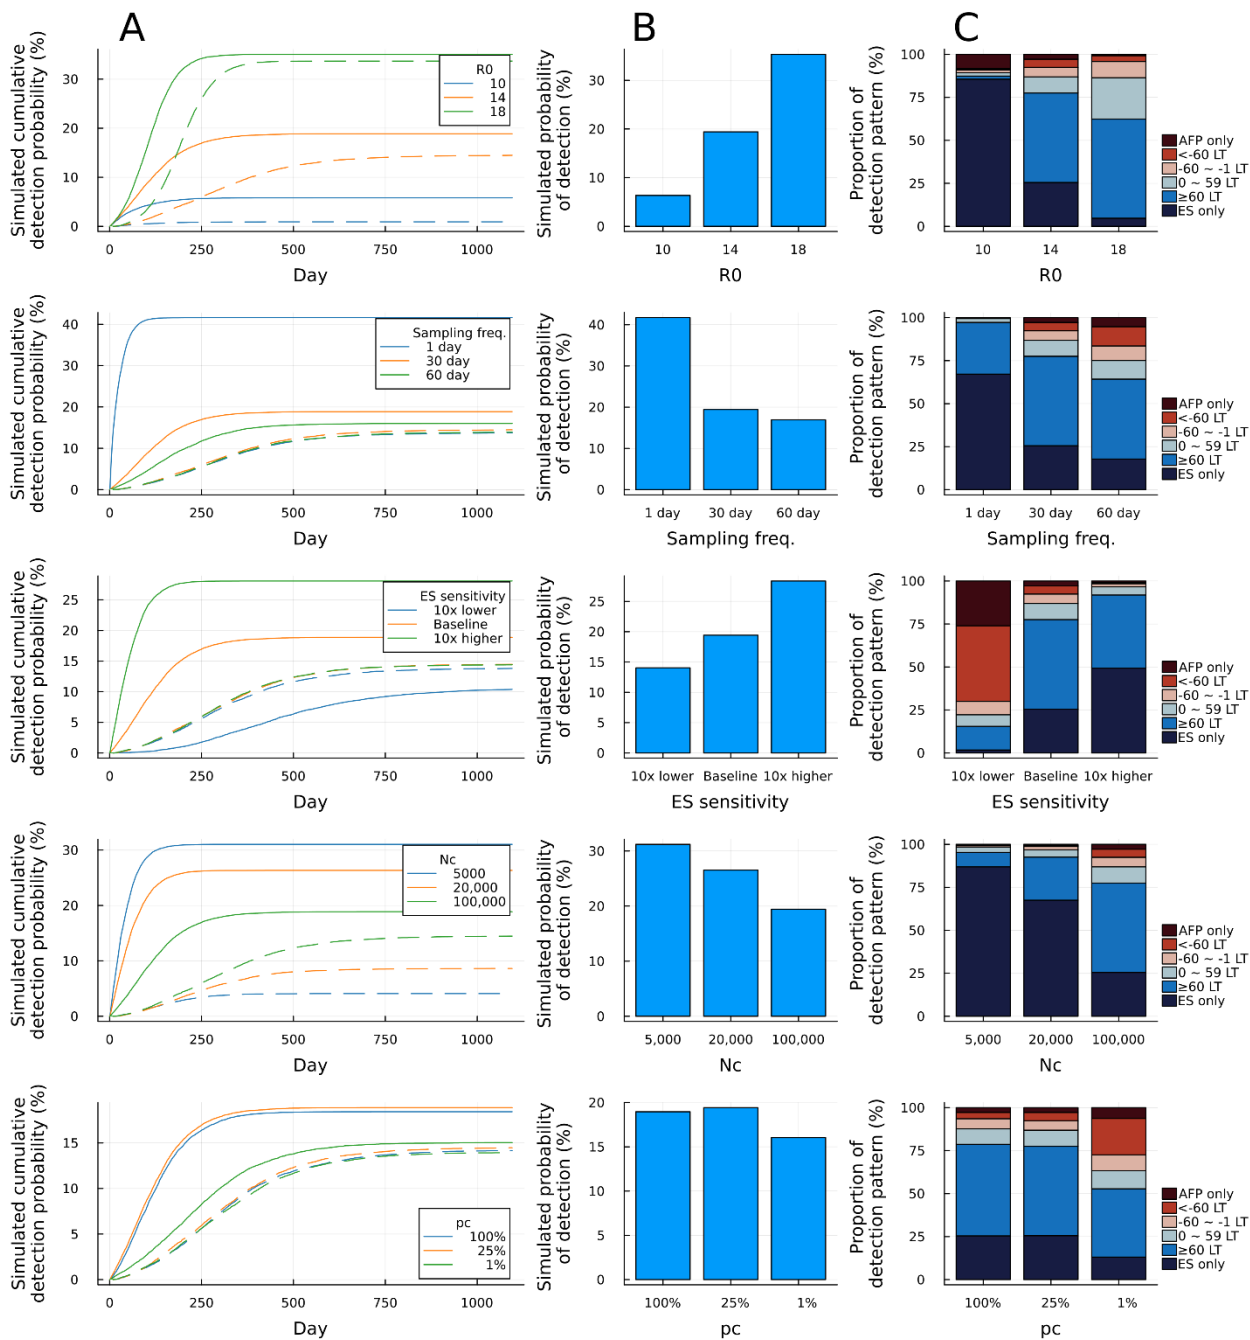

Fig S10. Sensitivity analysis of parameters in a single patch setting. (A) Simulated cumulative detection probabilities. Solid lines and dotted lines represent simulated probability for ES and AFP surveillance, respectively. (B) Simulated probability of detection through either AFP surveillance or ES among all simulations including no detection pattern (%). (C) The proportion of each detection pattern (%) given poliovirus circulation was detected.

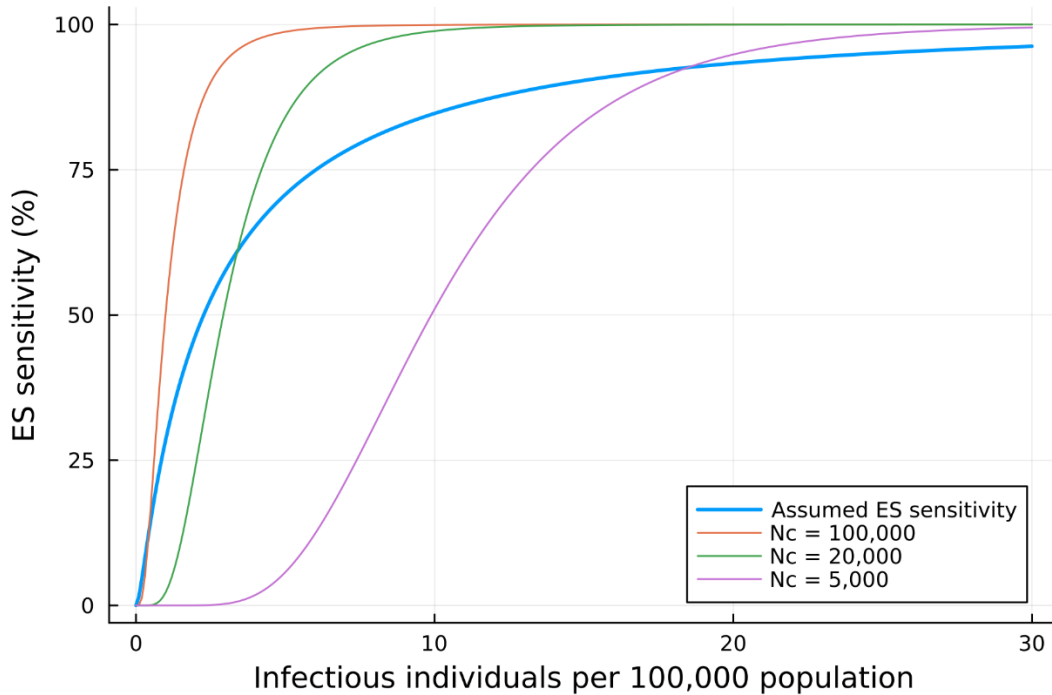

Fig S11. Dose-response curves for estimated ES sensitivity parameters under different population sizes of children under 5 years old (N_c) in a single patch setting.

2.3 Two alternative visualisations for the main analysis

We limited the x-axis for Fig 2 to 160 for the interpretability of the results, and here we visualised the same results where the x-axis represents the national ES population coverage (Fig S12). The national ES population coverage was obtained by the product of the percentage of the population in ES-covered patches and the patch-level ES population coverage (p_c). Therefore, the maximum value of the ES population coverage is matched with our parameter choice for p_c (i.e. 25%). It is noted that the maximum number of ES-covered patches of 1502 corresponds to the national ES population coverage of 25%, and 160 ES-covered patches were close to the plateau of the simulated early detection probability.

We further calculated the proportion of each detection pattern by including the “no detection” pattern (Fig S13) whereas we did not include the “no detection” pattern in the main text figures. Differences in the proportion of the “no detection” pattern would be attributable to the ES layout strategy and heterogeneity in the effective reproduction number in each path (Fig S9).

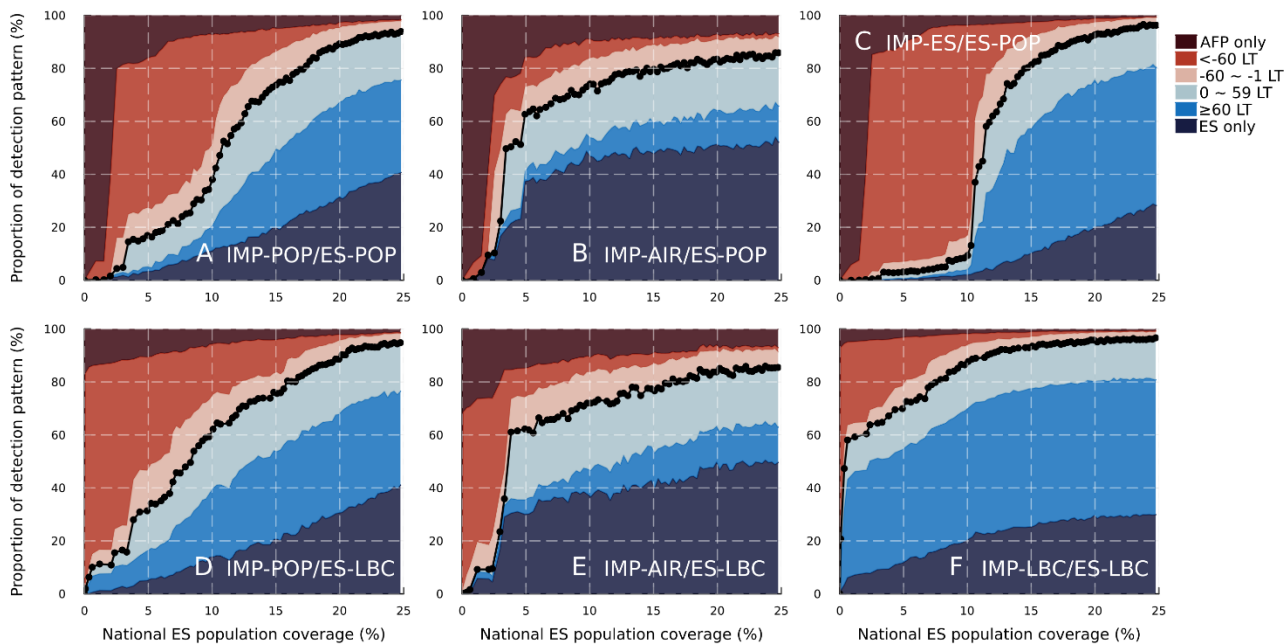

Fig S12. Proportion of each detection pattern (%) against national ES population coverage for 6 scenarios. The blue-coloured area under the black dotted lines represents the simulated early detection probability, consisting of early detection of ES over AFP surveillance and ES only detection. LT denotes the lead time of poliovirus detection through ES over AFP surveillance.

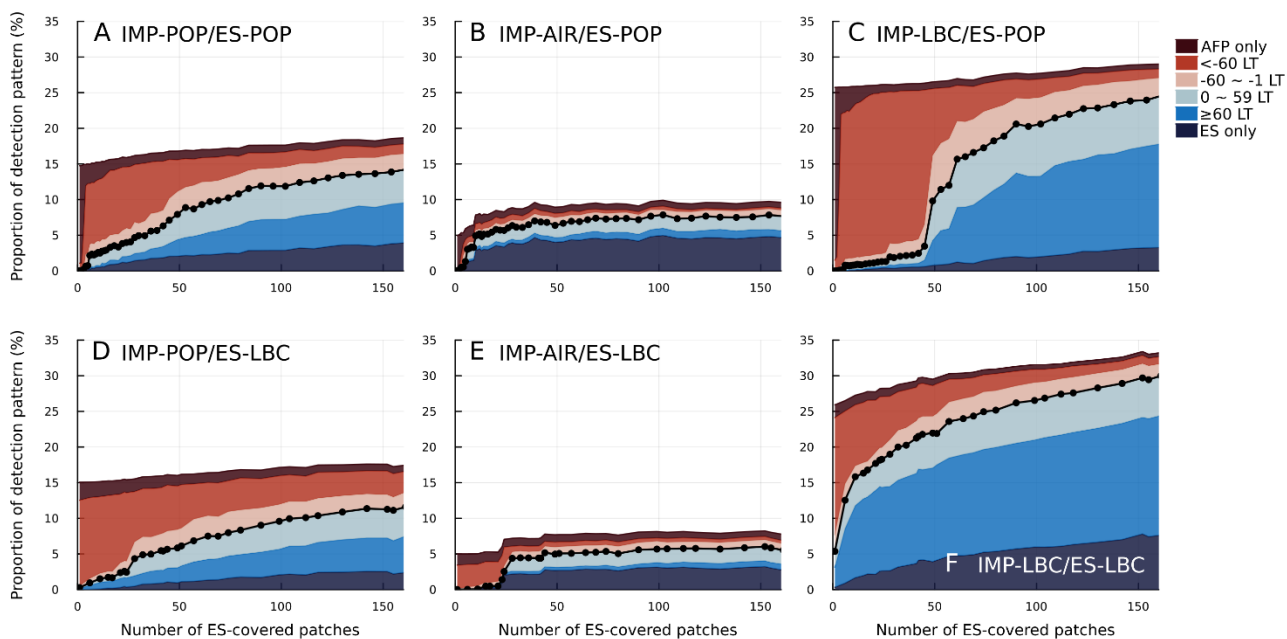

Fig S13. Proportion of each detection pattern (%) including the no detection pattern against the number of ES-covered patches for 6 scenarios. The non-coloured area represents the simulated probability of detecting poliovirus circulation neither through AFP surveillance nor ES. The blue-colours area under the black dotted lines represents the simulated early detection probability. LT denotes the lead time of poliovirus detection through ES over AFP surveillance.

2.4 Sensitivity analysis on the patch-level ES population coverage for different scenarios

We conducted the sensitivity analysis of the patch-level ES population coverage (p_c) for the other 5 scenarios as well as the main text (Fig 4). We found a similar trend in Fig S14-S15 as in Fig 4. That is, the simulated early detection probability was robust against the number of ES-covered patches but had a large variation against the national ES population coverage.

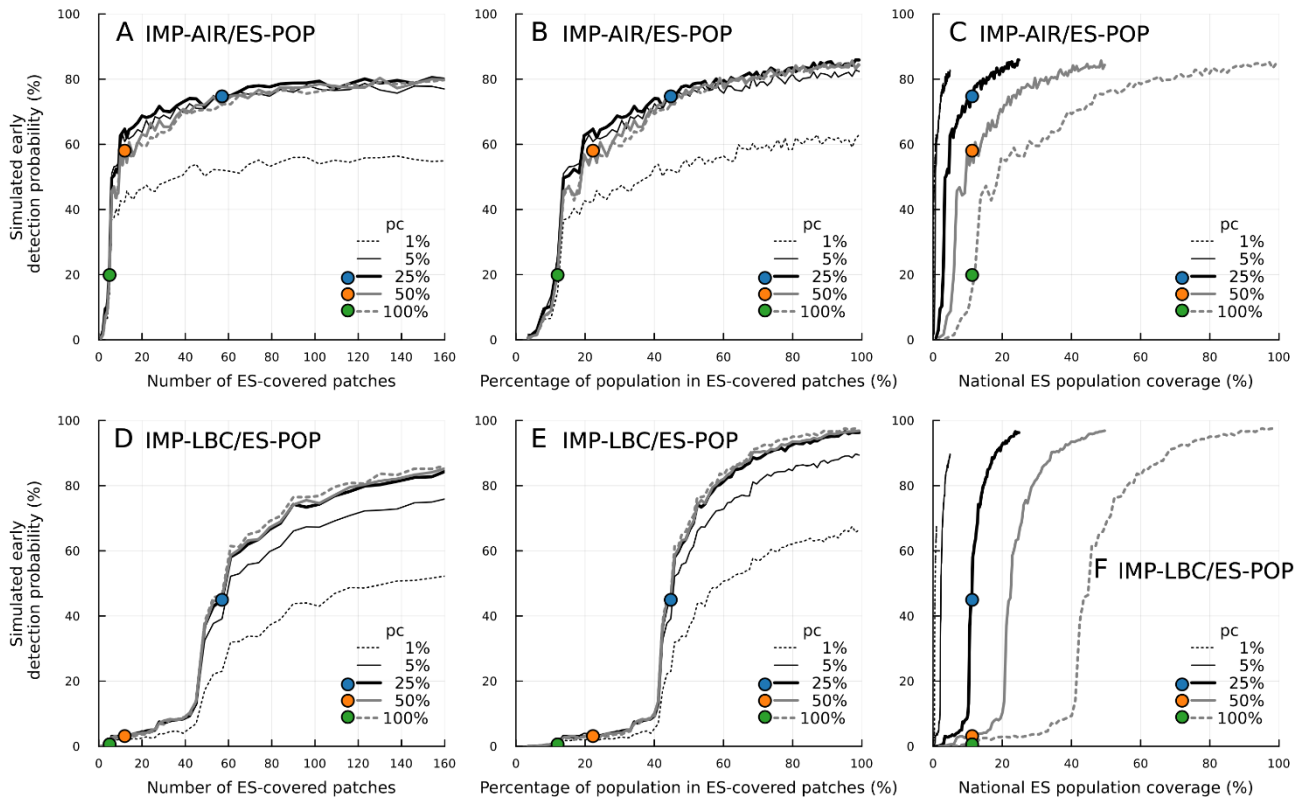

Fig S14. Sensitivity analysis of the patch-level ES population coverage, p_c , for the ES-pop scenarios. (A, B, C) For the IMP-AIR/ES-POP scenario. (C, D, F) For the IMP-LBC/ES-POP scenario. Simulated early detection probability is plotted (A, D) against the number of ES-covered patches, (B, E) against the percentage of the population in ES-covered patches, and (C, F) against the national ES population coverage. The data points represent simulations where the national ES population coverage of the simulated ES layout aligns with the current coverage in South Africa (11.3%), under p_c of 25% (blue), 50% (orange) and 100% (orange). The national ES population coverage is given by the product of p_c and the percentage of the population in ES-coverage patches. It is noted that the maximum number of ES-covered patches is 1502 and the x-axis for (A, D) is limited to a maximum value of 160.

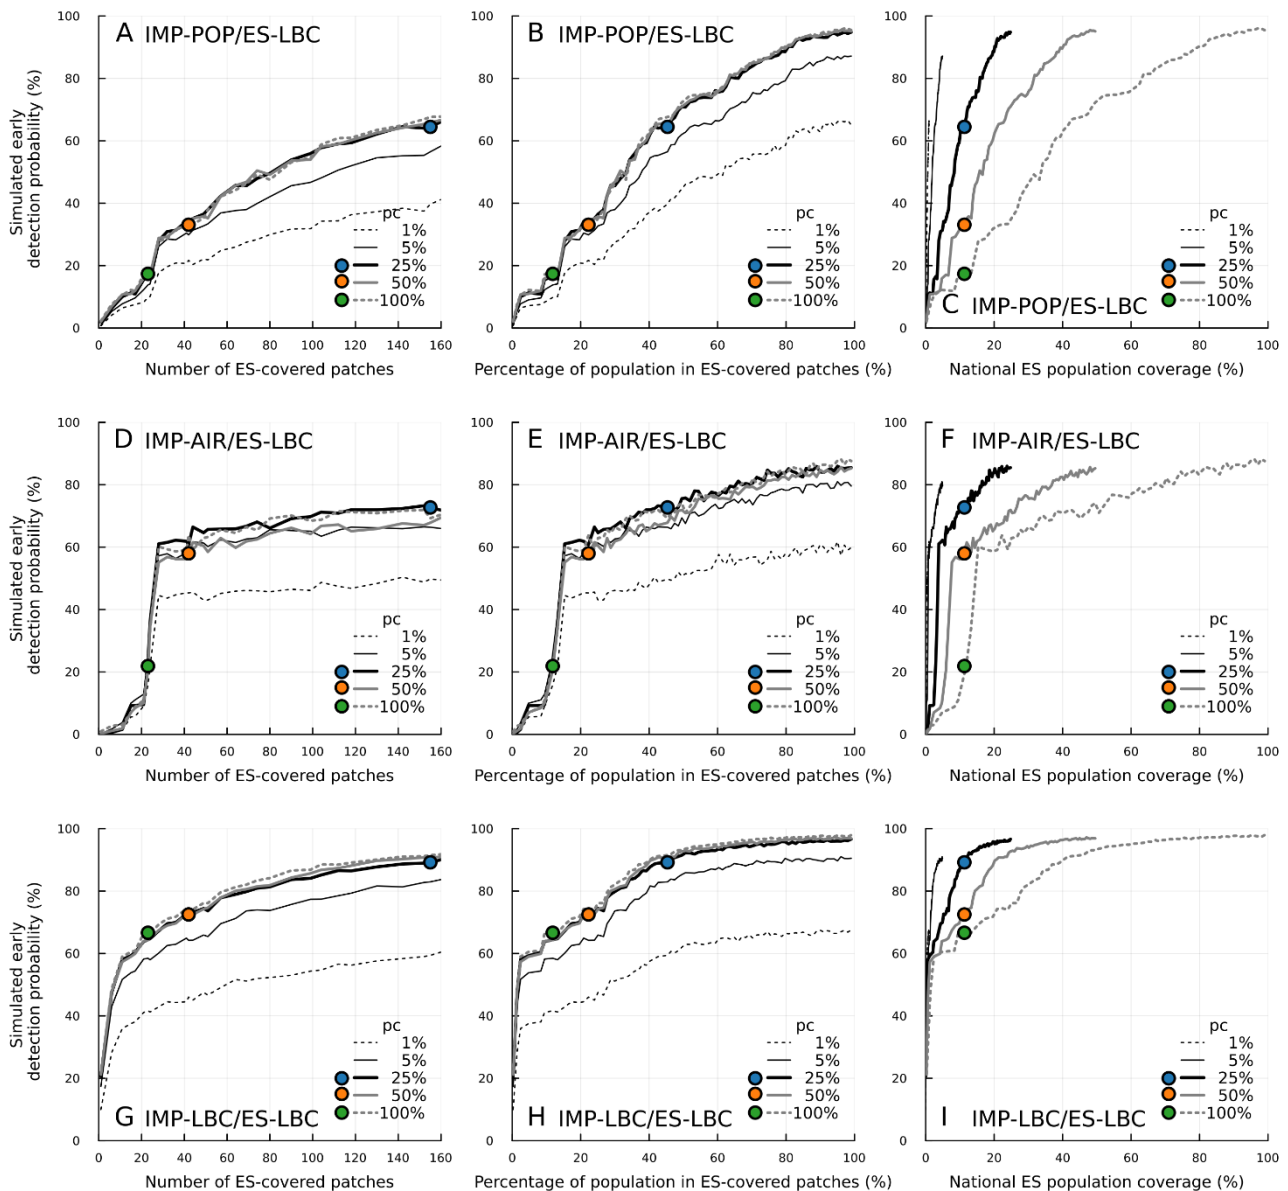

Fig S15. Sensitivity analysis of the patch-level ES population coverage, p_c , for the ES-LBC scenarios. (A, B, C) For the IMP-POP/ES-LBC scenario. (D, E, F) For the IMP-AIR/ES-LBC scenario. (G, H, I) For the IMP-LBC/ES-LBC scenario. Simulated early detection probability is plotted (A, D, G) against the number of ES-covered patches, (B, E, H) against the percentage of the population in ES-covered patches, and (C, F, I) against the national ES population coverage. The data points represent simulations where the national ES population coverage of the simulated ES layout aligns with the current coverage in South Africa (11.3%), under p_c of 25% (blue), 50% (orange) and 100% (orange). The national ES population coverage is given by the product of p_c and the percentage of the population in ES-coverage patches. It is noted that the maximum number of ES-covered patches is 1502 and the x-axis for (A, D, G) is limited to a maximum value of 160.
