20 Abstract

21 Background

22 The integration of real-world evidence (RWE) from real-world data (RWD) in clinical research
23 is crucial for bridging the gap between clinical trial results and real-world outcomes. Analyzing
24 routinely collected data to generate clinical evidence faces methodological concerns like
25 confounding and bias, similar to prospectively documented observational studies. This study
26 focuses on additional limitations frequently reported in the literature, providing an overview of
27 the challenges and biases inherent to analyzing routine clinical care data, including health
28 claims data (hereafter: routine data).

29 Methods

30 We conducted a literature search on routine data studies in four high-impact journals based
31 on the Journal Citation Reports (JCR) category “Medicine, General & Internal” as of 2022 and
32 three oncology journals, covering articles published from January 2018 to October 2023.
33 Articles were screened and categorized into three scenarios based on their potential to provide
34 meaningful RWE: (1) Burden of Disease, (2) Safety and Risk Group Analysis, and (3)
35 Treatment Comparison. Limitations of this type of data cited in the discussion sections were
36 extracted and classified according to different bias types: main bias categories in non-
37 randomized studies (information bias, reporting bias, selection bias, confounding) and
38 additional routine data-specific challenges (i.e., operationalization, coding, follow-up, missing
39 data, validation, and data quality). These classifications were then ranked by relevance in a
40 focus group meeting of methodological experts. The search was pre-specified and registered
41 in PROSPERO (CRD42023477616).

42 Results

43 In October 2023, 227 articles were identified, 69 were assessed for eligibility, and 39 were
44 included in the review: 11 on the burden of disease, 17 on safety and risk group analysis, and
45 11 on treatment comparison. Besides typical biases in observational studies, we identified
46 additional challenges specific to RWE frequently mentioned in the discussion sections. The

47 focus group had varied opinions on the limitations of Safety and Risk Group Analysis and
48 Treatment Comparison but agreed on the essential limitations for the Burden of Disease
49 category.

50 Conclusion

51 This review provides a comprehensive overview of potential limitations and biases in analyzing
52 routine data reported in recent high-impact journals. We highlighted key challenges that
53 significantly impact analysis results, emphasizing the need for thorough consideration and
54 discussion for meaningful inferences.

55 Keywords: rapid review, limitation, bias, routine clinical care data, real-world evidence, EHR

56

57 Background

58 Real-world evidence (RWE) derived from real-world data (RWD) becomes increasingly
59 important to support clinical evidence. The growing availability of such data opens up new
60 research opportunities to improve our understanding of clinical practice. A recent definition of
61 real-world data includes data sources such as routine clinical care data, frequently called
62 electronic health records (EHRs), disease-specific registries, administrative data, such as
63 claims data or death registries, and data collected through personal devices [1–4].

64 This review is limited to routine clinical care data (hereafter: routine data) derived from the
65 health care system, such as EHR and administrative data including insurance and claims data.
66 We focus on methodological challenges and biases that researchers may face when analyzing
67 routine data. Although routine data are not primarily collected for research purposes, their use
68 and longitudinal linkage with data from other sources such as registries or biobanks has the
69 potential to improve health care and regulatory decision making [2,5]. However, it is not only
70 the linkage to other data sources that is important but also the ability to aggregate data from
71 different hospitals or even across different countries and health care systems given a common
72 data model.

73 Randomized controlled trials (RCTs) are the gold standard for answering questions about
74 treatment efficacy and safety. However, analyzing RWD may be useful to bridge evidence
75 gaps at the interface to clinical practice. Utilizing routine data offers several advantages,
76 including a large number of observations, especially when leveraging and linking multiple
77 clinical data sources. It allows the coverage of different locations, patient populations (e.g.,
78 different age distribution or disease severity), and practice patterns in routine health care
79 [1,3,6]. Routine data analysis can also be valuable when RCTs are not feasible due to ethical
80 or practical reasons. Particularly in the context of treatment comparisons, the use of the target
81 trial emulation framework allows to obtain comparable results to those observed in RCTs when
82 carefully and fully emulated [7–9]. An alternative approach, rather than relying solely on routine
83 data or their linkage for treatment comparison, is to use the data as an external control [2,10].

84 Yet, as routine data are documented for reimbursement or clinical care purposes, the quality
85 of the data from a research perspective is typically lower than that of other prospectively
86 planned studies – including RCTs. Routine data may lack harmonization and interoperability,
87 may often be incomplete and some relevant information may be missing [4]. For instance, body
88 mass index is generally irrelevant for reimbursement purposes but might be a potential risk
89 factor, confounder or effect modifier for several research questions, especially in the field of
90 non-communicable diseases, such as those investigated by Zöller et al. [11] on chronic
91 obstructive pulmonary disease (COPD). The analysis of such data is therefore fraught with
92 methodological challenges, including confounding and several potential biases which are
93 already well-known from clinical epidemiology. Beyond these common concerns, it remains
94 unclear which additional limitations related to routinely collected data, particularly challenges
95 at measurement level – such as how data is collected and translated into variables used for
96 analysis – appear frequently [12].

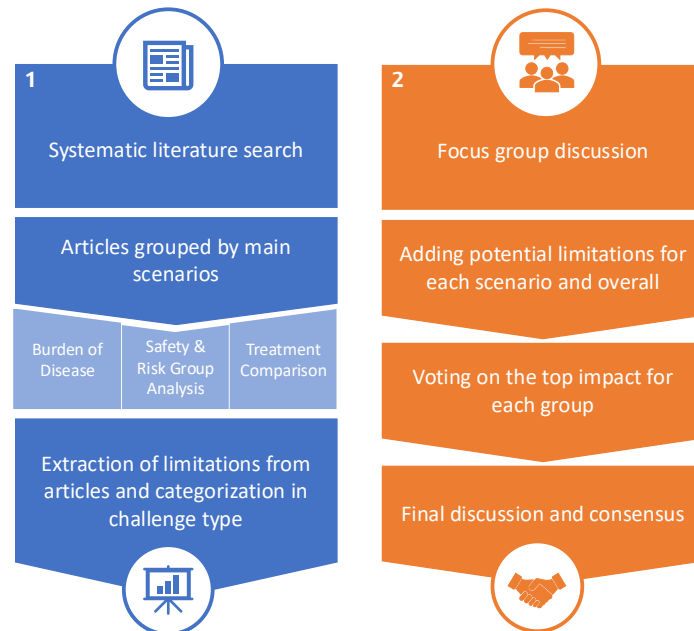

97 For structuring an investigation on limitations, we suggest three scenarios, derived from the
98 field of clinical epidemiology where routine data hold high potential for generating RWE: (1)
99 *Burden of Disease*, (2) *Safety and Risk Group Analysis*, and (3) *Treatment Comparison*.
100 *Burden of Disease* describes the impact of a disease or health problem on a specified

101 population, quantified by metrics such as incidence, prevalence, mortality, morbidity, quality of
102 life, and economic impact [13]. As this scenario typically includes the given health care setting
103 in the definition of the study population, we consider it as the most natural application of routine
104 data. *Safety and Risk Group Analysis* covers adverse events of various medical interventions
105 such as treatments, medications, devices and procedures, with a potential focus on identifying
106 and characterizing subgroups with a higher risk profile in the respective population (e.g., due
107 to comorbidities, genetic predispositions, or general demographic characteristics) [14]. Here,
108 routine data offer the possibility of long-term observations, to study rare subgroups and
109 adverse events, as well as to observe patients with different comorbidities, and co-
110 medications. As this scenario is characterized by time-sensitive and potentially unobservable
111 or undocumented information, it is more complex than the *Burden of Disease* scenario.
112 *Treatment Comparison* deals with the causal effects of medical treatments. This area is and
113 will continue to be dominated by evidence from RCTs. However, with the beginning of 2025, a
114 new EU regulation for health technology assessment will enter into force. Although the process
115 is still in development, health technology developers will need to address a high number of
116 PICOs with diverse comparators [15]. Combined with the tight timelines in the joint clinical
117 assessment process, clinical studies will not be available for all PICOs, creating a high need
118 for additional data sources like routine data. In addition, routine data offer the opportunity to
119 study the effects in a routine setting, including effects of noncompliance, rare subgroups or
120 subgroups not typically eligible for clinical studies, confounding by indication as well as
121 potential effects of site-specific impact factors on treatment outcome. Here, similar issues as
122 in *Safety and Risk Group Analysis* complicate the statistical analysis, especially due to the
123 causal interpretation of the primary outcome.

124 In this work, we aim to provide an overview of the reported challenges and biases inherent in
125 routine data analysis with respect to their potential impact in the three main scenarios. This is
126 accomplished in a step-wise procedure as illustrated in Figure 1. First, a systematic literature
127 search is conducted to extract the limitations outlined in the respective discussion sections.
128 Second, a subsequent focus group discussion with experts is held to supplement and to

129 evaluate the identified list of challenges. Finally, we identified challenges that have a
130 comparably high potential to affect the analysis findings and require thorough consideration
131 and discussion in order to draw meaningful conclusions.

132 *Figure 1 Process Flow Diagram*

133
134 Overview of the process used in this work to identify and evaluate challenges and biases in
135 routine care data analysis. This includes (1) a systematic literature search to extract reported limitations
136 followed by (2) expert focus group discussions to supplement and discuss these challenges regarding
137 their impact on real-world evidence.

138 **Methods**

139 **Data sources and search strategies**

140 In October 2023, we conducted a systematic search of MEDLINE via PubMed. The search
141 focused on English-language publications in the following top-ranked journals based on the
142 Journal Citation Reports (JCR) category “Medicine, General & Internal” as of 2022 [16]: (i) The
143 Lancet, (ii) New England Journal of Medicine, (iii) Journal of the American Medical Association
144 (JAMA) and (iv) British Medical Journal (BMJ). In addition, we included the following oncology
145 journals, based on our experience, as RWE is particularly prevalent in this therapeutic field
146 [17]: (v) JAMA Oncology, (vi) The Lancet Oncology, and (vii) Journal of Clinical Oncology. In

147 order to ensure recency and thereby relevance of the articles, the search included all original
148 articles published between January 2018 and October 2023. The following terms were queried
149 in the title or abstract: “real-world evidence”, “RWE”, “Real-world data”, “real-world”, “routine
150 data”, “routine care data”, “Emulation” and “Electronic health data”. A study was defined as
151 being eligible if routine clinical care data collected by the healthcare system, such as
152 longitudinal claims data or EHR, was analyzed. Other types of publications, such as
153 comments, letters, perspectives or reviews were excluded. Studies were also excluded, in
154 which only registry data or manually collected data were analyzed. In addition, we assessed if
155 any aspect from the three pre-defined scenario categories were investigated in the studies: (1)
156 Burden of Disease, (2) Safety and Risk Group Analysis, and (3) Treatment Comparison. If this
157 was not the case, the study was excluded. The detailed search strategy is described in the
158 Supplementary Material (Supplementary S1). All articles were indexed and organized using
159 Zotero.

160 Three reviewers (MP, KG, KU) independently screened each publication through all stages of
161 the review process. First, titles and abstracts of the search results were screened to ensure
162 relevance and adherence to the inclusion and exclusion criteria. In a second step, the full texts
163 of the included abstracts were assessed to obtain a final decision on inclusion in the review.
164 In case of any discrepancy between two reviewers regarding the eligibility of specific studies,
165 an additional independent reviewer (MB) was consulted to resolve the issue. The review was
166 pre-specified and registered in PROSPERO (CRD42023477616).

167

168 [Data extraction and categorization](#)

169 Methodological challenges and limitations mentioned in the discussion sections of the included
170 publications were extracted as the main outcome. In addition, study characteristics such as
171 design, the underlying data sources, the country from which data was obtained, the methods
172 employed, and the purpose of the published studies were retrieved. Publications were
173 categorized into the three predefined main areas of application (Burden of Disease, Safety and
174 Risk Group Analysis, Treatment Comparison), based on their research question. The extracted

175 limitations were subsequently assigned to the main bias categories in non-randomized studies
176 as defined in the Cochrane Handbook: confounding, selection bias, information bias and
177 reporting bias [18]. We identified five specific categories to highlight potential biases that are
178 specific to the use of routine data. First, as clinical routine data is primarily collected for
179 reimbursement purposes based on clinic-specific coding practices, the category *Coding*
180 *Challenges* is introduced. This category includes for example discrepancies in coding practices
181 between clinics or specificities of the ICD10 (the International Classification of Diseases and
182 Related Health Problems) coding system [19]. This challenge may lead to information bias,
183 specifically misclassification or detection bias, regardless of the already well-known detection
184 bias, which typically result from varying quality in detection methods. Second, as one of the
185 main drivers of documentation quality is again reimbursement as well as patient care rather
186 than research, the category *Operationalization or Availability of Variables* is established to
187 address to which extent studies were restricted by the availability of the data for answering the
188 research question. This type of missing data may lead to unmeasured confounding and
189 potential selection bias. Third, routine data may suffer from other types of missing data, i.e.,
190 missing records in certain variables, as typically known from observational studies, resulting in
191 the category *Missing Data*. Fourth, routine data may also suffer from different lengths of follow-
192 up largely varying between patients, for which we introduce a further category called *Follow-*
193 *up Challenges*. Finally, the category *Validation & Data Quality* is added, which leads to
194 potential bias as large amounts of routine data typically cannot be carefully validated. This also
195 includes the variability of data quality over time arising e.g., due to changes in coding systems,
196 such as transitions between versions of the ICD coding standard, or the ongoing digitalization
197 of hospitals.

198 We did not assess the quality or risk of bias of individual studies since we were not extracting
199 data or outcomes of the studies for subsequent analysis and we were only interested in their
200 stated limitations. Still, we expected that there were challenges not reported in the study
201 publications, e.g., because of limited relevance or lack of awareness. Therefore, a subsequent

202 focus group meeting was initiated for complementing and ranking the identified list of
203 challenges.

204 Focus Group

205 At a four-hour workshop, the results of the systematic literature search were presented in the
206 form of a slide presentation for each scenario to a selected group of co-authors of this
207 manuscript plus one independent expert from the area of health technology assessments. After
208 each scenario was presented, focus group members were asked to add potential additional
209 challenges in a moderated joint discussion. In addition, through a *General* category, we left
210 room for limitations and challenges that can be found in RWD studies not specific to any of the
211 three scenarios. All identified challenges were listed for a subsequent voting on their potential
212 impact within each scenario. Every focus group member had two votes for each of the three
213 main scenarios, plus one additional vote for the *General* category. All challenges with at least
214 one vote were summarized and considered as key challenges deemed to have a high potential
215 to influence the results requiring thorough consideration in analyses.

216 Results

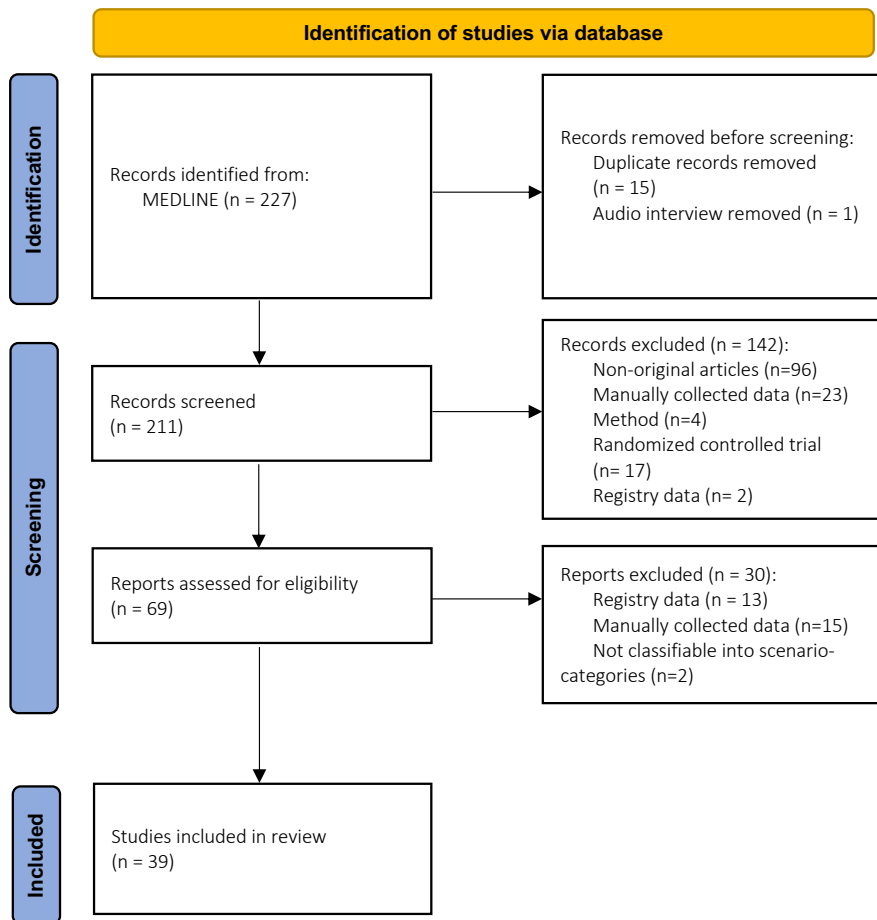

217 Study selection and characteristics

218 In total, 227 records were identified from MEDLINE of which 15 duplicate publications and 1
219 audio interview were removed, leading to 211 records eligible for title and abstract screening.
220 From this first screening, we excluded 142 publications because they were not original
221 research articles, were only methods articles, or did not use routinely collected data from
222 clinical care. In a second step, 69 records were evaluated in a full-text screening for verifying
223 the data source as coming from electronic health records or administrative data, and to be
224 categorizable into the three main scenarios. Finally, 39 studies were included in the review.
225 An overview of the review process and study selection is depicted in Figure 2.

226

227

228 Figure 2 PRISMA flow diagram [20]

229

230 A brief summary of the study characteristics is shown in Table 1. Most of the studies were
 231 published in BMJ (36%), with 55% being published in the past two years (2022 and 2023). This
 232 is supporting our decision to limit the search to the past five years. The majority of extracted
 233 publications (46%) was based on data from the US. While some publications used only EHR
 234 data (59%), other studies linked this information to additional sources, such as biobanks or
 235 registries (28%). The use of data sources varied between studies, from single-country to
 236 multinational studies. The majority of the publications used nation-wide (46%) or multi-center
 237 data (38%), while the remaining studies used multi-national (10%), single-center (3%) and
 238 territory-wide (3%) data.

239 Table 1 Summary of study characteristics

Study Characteristics	n (%)
Journals

240 In this table, the number of studies *n*, along with its percentage in brackets (%), is presented for
241 each category. EHR= Electronic health records

242 * additional linked data include exome sequencing data, hospital admission data, mortality data,
243 data from biobanks, claims data, questionnaire data, and data from registries

244 ** administrative data include insurance information and claims data

245

246 Figure 3 provides a summary of the limitations mentioned in the discussion section of the
 247 extracted studies stratified into the data source types and according to their assigned scenario
 248 category. In total, there are 11 publications in the category *Burden of Disease*, 17 publications
 249 in *Safety and Risk Group Analysis* and 11 publications in *Treatment Comparison*. As expected,
 250 the main bias types are typically mentioned in the publications. However, it is important to
 251 recognize the additional biases that frequently appear. A detailed overview for each publication
 252 is provided in the Supplementary Material S2 – Table S3, including a broad overview of the
 253 study design including the main outcomes and their respective methods, objectives, and the
 254 scope of the analysis in terms of data use.

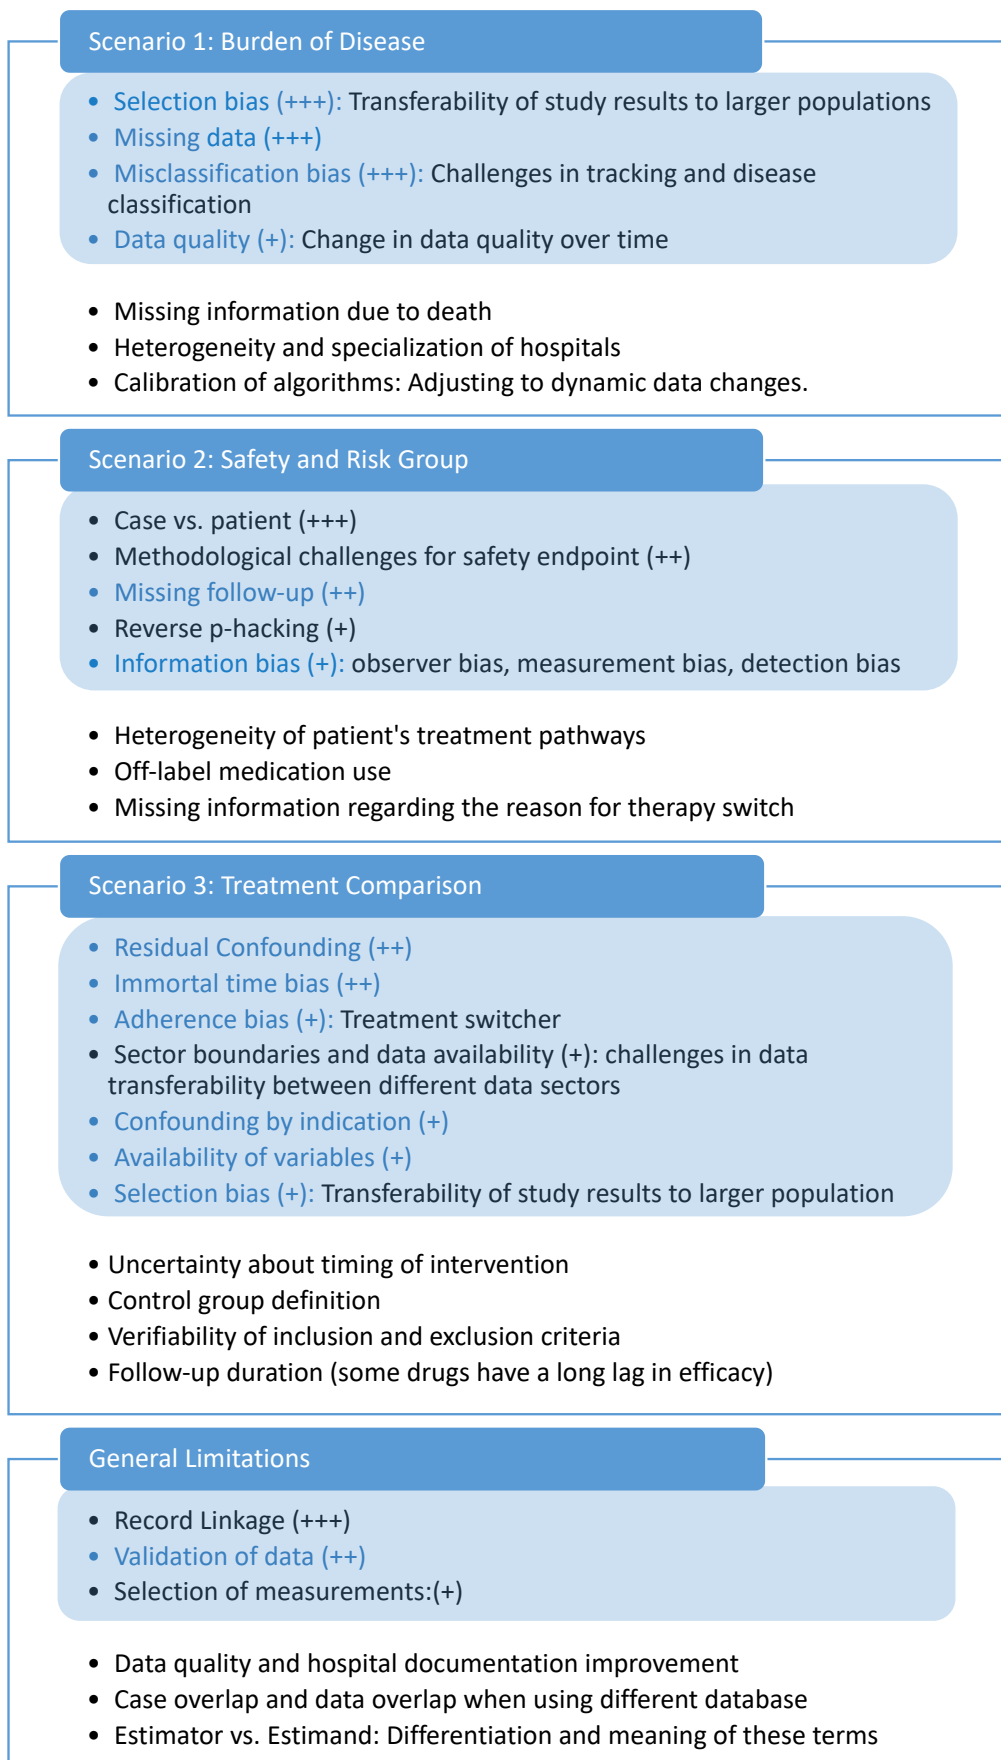

255 *Figure 3 Summary of biases extracted from the studies*

		Main Bias Categories				Additional Bias Categories				
		Confounding	Selection Bias	Information Bias	Reporting Bias	Coding Challenges	Operationalization or Availability of Variables	Missing Data	Follow-up Challenges	Validation & Data Quality
<i>Burden of Disease</i>	EHR	3	4	5	2	2	2	3		
	Linked EHR	2	3	2	1			1	2	2
	Admin. Data		1							
<i>Safety & Risk Group</i>	EHR	7	4	5	2		3	2	3	2
	Linked EHR	4	4	6	4	2	1	2		2

 257 Number of studies facing the main biases and additional identified bias categories grouped
 258 by data source types and the main scenarios: *Burden of Disease*, *Safety and Risk Group Analysis*,
 259 *and Treatment Comparison*. Abbreviations: EHR...Electronic Health Records, Admin. Data...
 260 Administrative Data

261 In the following, we summarize the findings on methodological challenges and limitations from
 262 both the review and the focus group workshop for each main scenario, separately. In Figure
 263 4, all challenges that were added and ranked according to their relevance in the focus group
 264 discussion are summarized.

265 *Figure 4 Overview of Workshop Results*

267 Findings of the focus group discussion divided into the three main scenarios: *Burden of*
268 *Disease, Safety and Risk Group Analysis, and Treatment Comparison*, as well as the additional
269 category *General Limitations*. The content stated within the blue colored areas are the voting result,
270 with the plus signs (+) indicating the importance weighting. The blue font highlights challenges and
271 limitations already occurring in the systematic search. The black font and particularly the content
272 outside the blue area are limitations and challenges added by the focus group.

273 **Burden of disease**

274 Five publications reported limitations potentially leading to confounding. Of these, two studies
275 had limited availability of variables included in the analysis resulting in the possibility of
276 unmeasured confounding [21,22]. However, Kamran et al. [22] argued that with the use of a
277 limited number of variables in the model a reliable identification and validation of all variables
278 even across different institutions was feasible. Limitations related to the risk of selection bias
279 were present in eight studies. On the one hand, in Canavan et al. [21] a volunteer bias could
280 not be ruled out because the data used for the analyses included individuals who opted to be
281 included in the study database. On the other hand, in Witberg et al. [23] the absence of
282 simultaneously enrolled comparison groups was mentioned which could lead to a potential
283 selection bias. Moreover, some studies highlighted the fact that the results might not be
284 transferable to other clinical practices or populations [21,24–26]. The primary type of
285 information bias (n=7) observed was misclassification bias, affecting either the exposure or
286 outcome [21,24,27,28]. Beck et al. [24] highlighted that clinical diagnoses were probably not
287 fully captured due to challenges in diagnostic and physician coding. On the other hand, Manz
288 et al. [28] noted a limitation indicating that they were limited to use only patients with a coded
289 classifier variable for comparing the machine learning model with the commonly used
290 prognostic reference. This limitation resulted from differences in the characteristics of the
291 patients with and without the coded variable. Kamran et al. [22] additionally emphasized that
292 even though a common EHR provider across facilities was implemented, it remains crucial to
293 have in-depth knowledge of the local deployment. Two studies reported limited follow-up time
294 [26,29]. However, Bicler et al. [29] noted that despite the longer follow-up period compared

295 to clinical trials, it was still insufficient to evaluate very long-term effects. The lack of health
296 record validation was reported in two studies [29,30]. While all studies acknowledged
297 limitations in their discussions, only three studies [22,25,27] took an additional step to assess
298 these limitations in the context of their specific study.

299 During the focus group discussion, further limitations were added to those identified in the
300 literature review and are presented in the first part of Figure 4. Some relevant and reasonable
301 limitations added by the experts were the inconsistency of the data quality over time. This
302 challenge is interconnected to the adjustment or calibration of algorithms to dynamic data
303 changes, especially when using a model that continuously uses recent data from routine
304 clinical care. Additionally, the heterogeneity and specialization of hospitals substantially impact
305 the burden of disease. Including only hospitals with specializations in a certain disease
306 treatment would overestimate the burden. Another added limitation was *missing information*
307 *due to death* in situations with death as competing risk, where it would be impossible to
308 diagnose the disease even though the patient may have had it [31].

309 The rating of the limitations of *Burden of Disease* is indicated by the blue area in Figure 4. The
310 transferability of study results to a larger population, which goes hand in hand with the
311 possibilities of selection bias, missing data and misclassification of data, was weighted by the
312 experts to be most important. The importance of data quality in EHR data was also recognized,
313 specifically the variability of data quality over time due to e.g., changes in coding systems,
314 such as transitions between versions of the ICD coding standard, or individual coding behavior.
315 This could potentially introduce bias to the results concerning the burden of a disease,
316 particularly when comparing diagnoses from the present to the past or the burden over an
317 extended period of time.

318 **Safety and Risk Group Analysis**

319 In this category, the information bias was predominantly manifested as the risk for
320 misclassification bias [32–40] with only one study addressing immortal time bias [38].
321 Specifically, certain limitations were connected with coding challenges, since the classification

322 was based on diagnosis codes from the EHR systems [33,35]. In addition, some form of
323 potential information bias occurred because the drug use in an EHR system had been defined
324 as the prescription of the medication and not as the actual drug intake [36,41]. Aspects like the
325 quantification and analysis of information concerning the physician's decision-making process
326 for treatment selection, treatment switching or the effect of pre-treatment were often missing
327 or inadequately explored [38,40,42] which could lead to confounded results. Details regarding
328 adherence or dosage, as well as unstructured free-text information, were not accessible
329 [40,42,43]. Additionally, significant risk factors, such as smoking, were not available, creating
330 a potentially high risk of confounding in the analysis. Selection bias limitations were evident in
331 ten studies including volunteer bias due to the involvement of individuals who volunteered to
332 join the database used for analysis [35,44]. Moreover, several studies highlighted site
333 heterogeneity, noting that certain hospitals with robust programs may have had a higher
334 burden of disease [33–35]. The limitation of missing data was mentioned in five studies
335 [33,36,38,39,45], for instance, in Li et al. [36] who stated that EHR data sources lacked
336 comprehensive coverage of medical events recorded in other healthcare facilities. While only
337 three studies [38,43,44] explicitly stated their limitations without providing further elaboration,
338 the remaining studies either addressed how they mitigated certain limitations through selected
339 methodologies or sensitivity analyses [34,36,37,39–42,45,46]. Alternatively, they presented
340 arguments explaining why certain limitations were unlikely or invalid in the context of their
341 specific study [32,33,35,39,45,47].

342 A few specific challenges were added by the experts in the focus group discussion as displayed
343 in the second section of Figure 4. First, it is considered important to correctly distinguish
344 between the case and patient definition. Given that patients may have multiple cases
345 associated with them in routine clinical data, it is essential for the research question to specify
346 whether the data refers to the patient level or the individual case level. The lack of clarity could
347 potentially violate the i.i.d-assumptions (independent and identically distributed assumption),
348 which is the basis for many commonly used statistical methods.

349 Second, another challenge mentioned is the problem of reverse p-hacking for safety endpoints,
350 where the analysis is manipulated to intentionally favor non-significant results [48]. Third, the
351 focus group emphasized the importance of the limitation related to the lack of follow-up data,
352 especially in health care systems where no linkage with routine outcome information is
353 available. A longer follow-up period is crucial for conducting thorough safety analyses to
354 observe adverse events. This aspect is closely linked to the issue of missing information due
355 to death, as death prevents the observation of subsequent adverse events.

356 Moreover, the experts added several limitations related to medication use. These included
357 insufficient information on the reasons for change in medication and its effect, as well as
358 information on dosage. Additionally, concerns were raised about the off-label use of
359 medication. Unlike in controlled clinical trials, the treatment paths of patients are quite
360 heterogeneous due to the decisions of the clinician or the different specializations of the
361 hospitals.

362 [Treatment Comparison](#)

363 Confounding remained a particular area of concern, specifically in achieving balance between
364 the groups. Kim et al. [49] reported persistent imbalance in variables even after applying
365 matching techniques. However, they addressed this issue by adjusting for these variables in
366 further analyses. Likewise, Xie et al. [50] stated that individuals treated with the study
367 medication had a higher baseline health burden, potentially leading to underestimated findings
368 due to residual confounding. Only two studies explicitly report missing risk factors that could
369 subsequently not be used for balancing [51,52]. Wang et al. [8] highlighted that claims data
370 had not recorded medication use in hospital, therefore, they needed to use alternative index
371 date and follow-up definition. Similar to the *Safety and Risk Group Analysis*, most potential
372 information biases were a type of misclassification [50,53–56]. Rentsch et al. [52] reported that
373 the identification of outcome events was not provided by a validated algorithm, which could
374 also potentially lead to information bias. Same holds true for Wong et al. [57] as they did not
375 distinguish the reason for deaths. Kim et al. [49] emphasized the general issues of immortal

376 time and time lag biases in the discussion section, but elaborated on the methods used to
377 address and avoid these biases. One study noted the concern of potential upcoding, i.e. the
378 intentional use of ICD-10 and OPS (Operation and Procedure Classification System) codes
379 with the greatest reimbursement rather than those with the greatest clinical relevance, resulting
380 in overstating the patient's severity of disease [58]. Xie et al. [55] highlighted that the
381 effectiveness of the investigated drug could be overestimated in individuals with poor health
382 characteristics who opt not to receive treatment, while those with better health characteristics
383 who decide not to be treated could lead to underestimation. The studies predominantly stated
384 their open limitations including those that persisted despite implementing causal inference
385 methods or conducting sensitivity analyses aimed at addressing them [50,52,53,55]. Beyond
386 that, Kim et al. [49] detailed how they mitigated their limitations.

387 The focus group discussion resulted in the following additions. First, data availability with
388 regard to the transferability within different health care sectors, e.g., ambulatory and stationary
389 sector, was added as challenge, especially for Germany [59]. Second, the timing of an
390 intervention is also critical to assess its effectiveness accurately, understand its impact on
391 patient outcomes, and make informed clinical decisions. In EHR or administrative databases,
392 the timing may not be explicitly recorded or may be subject to errors or omissions. Third, the
393 difficulty in defining control groups for comparison was highlighted as well as the verifiability of
394 the inclusion or exclusion criteria [9,60]. Fourth, similar to the *Safety and Risk Group Analysis*
395 scenario, follow-up duration is critical. However, in the context of treatment comparison, the
396 criticality arises also from the possibility that drugs can have a longer delay in efficacy.

397 Compared to the previous scenarios the ratings of the *Treatment Comparison* category were
398 more widely distributed, with votes spread across numerous limitations. This distribution
399 highlighted the wide range of challenges to consider. Residual confounding and immortal time
400 bias received the majority of votes. Not only the data availability of different data sectors, but
401 also the availability of variables was considered important which is connected to residual
402 confounding, e.g. absence of known confounders.

403 General limitations and challenges

404 The focus group viewed the linkage of records, the validation of data and the selection of
405 measurements as critical to conduct routine care data analysis. If there are multiple
406 measurements, it can be challenging to specify which measurement is considered as the
407 relevant one. In connection with record-linkage, both with other hospitals and other data
408 sources, the cases and patient data may overlap between hospitals and other data sources.
409 In addition, the challenges with the definition of estimands and estimators was highlighted
410 [14,61,62].

411 Discussion

412 *Major findings of this work briefly summarized*

413 This review aimed to present a comprehensive overview of the limitations and biases inherent
414 in the analysis of routine clinical care data. Additionally, we pinpointed the challenges with the
415 greatest potential to influence the results of the analysis emphasizing thorough consideration
416 and discussion for the derivation of meaningful inference. We have intentionally provided a
417 comprehensive overview of the study's features to serve as a guide, categorically organized
418 into different scenarios.

419 *Strength and limitations of this work*

420 Particular strengths of this work are, first, the inclusion of high impact journals in the review to
421 focus on the databases with highest potential for routine data analyses and use of a broad
422 search strategy to cover the work analyzing data routinely collected within the healthcare
423 system. Second, we extracted and categorized the limitations and potential biases identified
424 in the publications. In addition, our two-step procedure, which included a subsequent focus
425 group evaluation, resulted in a more comprehensive overview of potential challenges. Finally,
426 this review only included studies that were successfully published. Therefore, we could not
427 identify challenges that prevented successful data analyses and publication.

428 Naturally, this study is also subject to further limitations. Firstly, by restricting our search
429 strategy to high-impact publications for the sake of recency and relevance, there is a possibility
430 that we overlooked certain publications and their associated limitations. However, the
431 incorporation of expert experiences and knowledge helped to cover any missed challenge.
432 Second, given that our panel consisted solely of German experts in the field of statistics and
433 clinical epidemiology, the added limitations might be influenced by local challenges specific to
434 this context and might miss the important aspects such as the international or the clinical
435 perspective.

436 Our study assessed various limitations faced across different study scenarios of interest,
437 resulting in a ranked list of potentially relevant challenges. While our focus was specifically on
438 limitations stated in the discussion section of publications, we did not provide explicit methods
439 to address these limitations. However, this has already been partially discussed in other works
440 [10,63]. The choice of the applied methods of causal inferences, such as propensity score
441 techniques or the method of target trial emulation for established treatments, serves to reduce
442 potential biases and preventing fundamental errors in the study design. In the next step, we
443 aim to explore the requirements and concerns of various stakeholders regarding the use of
444 routine clinical data to achieve different objectives, particularly in therapeutic evaluations. This
445 will involve understanding the diverse expectations, needs, and potential challenges faced by
446 stakeholders in leveraging routine clinical data for meaningful and accurate therapeutic
447 assessments.

448 Conclusion

449 This review provides a comprehensive examination of potential limitations and biases in
450 analyses of routine clinical care data reported in recent high-impact journals. We highlighted
451 challenges that could significantly influence analysis results, stressing the necessity for
452 thorough consideration and discussion to derive meaningful conclusions.

463 Funding

464 This work was funded by the Federal Ministry of Education and Research (BMBF) in Germany
465 in the framework of the EVA4MII project (FKZ 01ZZ2308A, 01ZZ2308B, 01ZZ2308C). The
466 funding agency had no role in the design, data collection, analyses, interpretation, and
467 reporting of the study. The work of HB, MB, and NB has also been funded by the Deutsche
468 Forschungsgemeinschaft (DFG, German Research Foundation) – Project-ID 499552394 –
469 SFB 1597.

470 Authors' contributions

471 MP, DZ, HB and NB developed the study conception and design. MP, MB, KU and KG were
472 involved in the systematic search process. MP extracted the data from the publications. KU
473 and KG critically reviewed the extraction. MP wrote the first draft of the manuscript; NB
474 supervised this process. MB, DZ, HB, VR, JRP, PH, MK, FR and AS provided additional
475 intellectual content to the manuscript. All authors critically reviewed and approved the final
476 version.

477 Acknowledgments

478 We would like to thank the participants of the focus group workshop for the joint discussion.

702 [Supplementary S2](#)

703 Table S3 provides a comprehensive overview of the extracted studies, including their
704 characteristics and limitations described in their respective discussion section. Note, that for
705 some publications (indicated with an asterisk) the category could not be clearly assigned,
706 especially in the case of *Treatment Comparison* and *Safety and Risk Group Analysis*. These
707 publications did not only compare the effectiveness of treatments but specifically compared
708 the risk of adverse events between two or more treatments [34,37,40–42,45,47].

709 All studies categorized into the Burden of Disease scenario were cohort studies except for
710 three studies [22,25,28] that were developing or validating a machine learning model to predict
711 certain endpoints using EHR data. Three studies [26,29,64] examined time-to-event outcomes
712 using Cox regression as well as Kaplan-Meier estimator partly with inverse propensity weights.
713 Prevalence and incidences were analyzed in four studies [23,24,27,30]. The studies that were
714 assigned to the category Safety and Risk Group Analysis were mostly cohort studies, in
715 addition to two case-control studies and one cross-sectional cohort study [32,33]. Similar to
716 the category Burden of Disease, predominantly time-to-event outcomes were evaluated using
717 Kaplan-Meier estimation or Cox (proportional hazards) regression models [34,37,38,40–
718 42,44–46]. In contrast, many studies have used propensity score methods such as matching
719 and weighting [32,34,37,40–42,45,46] or applied the concept of target trial emulation
720 [32,37,45]. Similar to the category Safety and Risk Group Analysis, most studies in the
721 Treatment Comparison scenario examined time-to-event outcomes. They employed
722 propensity score methods such as matching and weighting or applied the concept of target
723 trial emulation. In addition to that, two studies used the clone method, a special form of
724 emulating a target trial where each individual is cloned into both treatment groups, censored
725 patients according to their designated treatment strategy and weighted the uncensored to
726 avoid selection bias [9,50,55].

Author	Study Design	Aim of Study	Outcome	Methods	Scope	Countries	Limitations								
							Main Bias Categories				Additional Bias Category				
Burden of disease							Confounding	Selection bias	Information bias	Reporting bias	Follow-up Challenges	Missing Data	Coding Challenges	Validation & Data quality	Operationalization or availability of variables
