Abstract:

A typical pattern observed in M/EEG recordings of Mild Cognitive Impairment (MCI) patients progressing to Alzheimer's disease is a continuous slowing of brain oscillatory activity. Definitions of oscillatory slowing are imprecise, as they average across time and frequency bands, masking the finer structure in the signal and potential reliable biomarkers of the disease.

Recent studies show that high averaged band power can result from transient increases in power, termed 'events' or 'bursts'. To better understand MEG oscillatory slowing in AD progression, we analyzed features of high-power oscillatory events and their relationship to cognitive decline. MEG resting-state oscillations were registered in age-matched patients with MCI who later convert (CONV, N=41) or do not convert (NOCONV, N=44) to AD, in a period of 2.5 years. To distinguish future CONV from NOCONV, we characterised the rate, duration, frequency span and power of transient high-power events in the alpha and beta band in anterior cingulate (ACC) and precuneus (PC).

Results revealed event-like patterns in resting-state power in both the alpha and beta-bands, however only beta-band features were predictive of conversion to AD, particularly in PC. Specifically, compared to NOCONV, CONV had a lower number of beta events, along with lower power events and a trend toward shorter duration events in PC ($p < 0.05$). Beta event durations were also significantly shorter in ACC ($p < 0.01$). Further, this reduced expression of beta events in CONV predicted lower values of mean relative beta power, increased probability of AD conversion, and poorer cognitive performance.

Our work paves the way for reinterpreting M/EEG slowing and examining beta event features as a new biomarker along the AD continuum, and a potential link to theories of inhibitory cognitive control in neurodegeneration. These results may bring us closer to understanding the neural mechanisms of the disease that help guide new therapies.

Keywords: transient high-power events, magnetoencephalography, Alzheimer's Disease, computational neuroscience, mild cognitive impairment

1 Introduction

1 According to the World Health Organization 2017 Alzheimer's disease (AD), a leading cause of disability
2 and dependency among older individuals worldwide, is expected to affect 130 million people by 2050.
3 Despite intensive research efforts, disease-modifying human therapies are still lacking, since the link
4 between amyloid-induced cellular damage and cognitive decline is incomplete (Maestú et al., 2021).
5 Magnetoencephalography (MEG) has been an valuable technique to fill this gap, as it can directly capture
6

7 human neuronal processes, associated with the disease and cognition, with high temporal resolution (da
8 Silva, 2013; Maestú et al., 2021).

9 A typical pattern observed in M/EEG recordings of AD patients is a progressive slowing of brain oscillatory
10 activity (Dauwels et al., 2011; Hsiao et al., 2013; Ishii et al., 2017; Jeong, 2004), typically characterised
11 by an increase in low-frequency delta (0.5 – 4 Hz) and theta rhythms (4– 7 Hz), along with a decrease in
12 higher frequency bands, alpha (8–12 Hz) and beta (12–30 Hz) rhythms. This oscillatory slowing initiates
13 in early stages of the disease, such as Mild Cognitive Impairment (MCI) (Babiloni et al., 2004, 2009,
14 2010; Dauwels et al., 2011; Jelic et al., 2000), and may even manifest before, in the subjective cognitive
15 decline stage (Bruña et al., 2023; López-Sanz et al., 2016), progressing from anterior to posterior cortices
16 and particularly in frontal and parietal regions, (Huang et al., 2000; Nakamura et al., 2018), in line with
17 the onset of amyloid accumulation in the fronto-temporal association cortices (Bang et al., 2015; Cho
18 et al., 2016; Wiesman et al., 2022). It has been shown that MCI patients who finally convert to AD
19 exhibit a significant disruption (i.e., decrease in synchronisation (König et al., 2005; López-Sanz et al.,
20 2017; Pusil, Dimitriadis, et al., 2019), as stated in the “X” model) between anterior cingulate cortex
21 (ACC) and precuneus (PC), two regions typically associated with high amyloid deposition (Forsberg
22 et al., 2008). As MEG oscillatory slowing accelerates, cognitive decline worsens producing alterations in
23 memory processes and executive functions (Hoshi et al., 2022; Wiesman et al., 2022).

24 Definitions of oscillatory slowing are imprecise, as they typically rely on methods based on a spectral
25 decomposition followed by averaging across time, frequency bands, and often subjects. Such averaging
26 can mask finer structure in the signal that may provide more reliable biomarkers of the disease and
27 cognitive decline and help connect human biomarkers to the underlying neural mechanisms of the disease
28 including possible connections to hyperexcitability as shown in animal models (Maestú et al., 2021;
29 Stoiljkovic et al., 2018; Zott et al., 2019). In recent years, there has been a shift in spectral M/EEG
30 methods, as many studies have shown that, in non-averaged data, brain oscillations often occur as
31 transient increases in high spectral power, a phenomenon termed oscillatory “bursts” or “events” (Jones,
32 2016; Lundqvist et al., 2024; van Ede et al., 2018). Quantifying transient changes in spectral activity
33 requires new methods that consider temporal characteristics of spectral activity such as event rate,
34 amplitude, duration, or frequency span (Shin et al., 2017). Such event-based methods have recently been
35 applied in a growing body of M/EEG studies on the brain dynamics of cognitive processes (Kavanaugh
36 et al., 2023, 2024; McKeon et al., 2023; Morris et al., 2023; Quinn et al., 2019; Shin et al., 2017), helping
37 to establish neural correlates of cognitive behavior on a single trial level. Variability in oscillatory event
38 parameters may represent a new set of explainable MEG biomarkers for AD, as it can reflect differences
39 in circuit-level origins and provide insights into the underlying activity patterns and functions (Jones,
40 2016; Lundqvist et al., 2024; M. A. Sherman et al., 2016).

41 In this study we applied standard power spectral density (PSD) and event-based analysis methods to
42 resting-state MEG from adults with MCI who later convert (CONV) or do not convert (NOCONV) to AD.
43 Motivated by the findings of the AD continuum model described by (Pusil, López, et al., 2019) (namely
44 the “X” model), we first hypothesized that averaged PSD slowing exhibits divergent effects in features
45 of high-power transient spectral events. Second, we hypothesized that slowing-related effects in spectral
46 event features would be associated to cognitive decline, as measured by a battery of neuropsychological
47 tests in memory and executive functions in the MCI sample. We characterize MEG oscillatory slowing in
48 terms of transient spectral event parameters in a MCI-to-AD longitudinal sample, taking the initial step
49 towards the potential identification of biophysically principled biomarkers.

50 2 Methods

51 2.1 Subject recruitment and neuropsychological assessment

52 Participants were recruited from Hospital Clínico Universitario San Carlos in Madrid, Spain. The study
53 was approved by the Ethics Committee, and all participants provided written informed consent prior to
54 participation. All participants were right-handed native Spanish speakers.

55 The study sample included 85 subjects diagnosed with mild cognitive impairment (MCI). Initially, partic-
56 ipants were screened according to the diagnostic criteria of the National Institute on Aging-Alzheimer’s
57 Association (NIA-AA) (Albert et al., 2013) and underwent a comprehensive neuropsychological assess-
58 ment as previously described (López-Sanz et al., 2016; Pusil, Dimitriadis, et al., 2019), along with a
59 MEG recording. They were cognitively and clinically followed-up in a temporal interval of 2.5 years and
60 then subdivided in two groups considering the criteria for probable Alzheimer’s disease (McKhann et al.,
61 2011): 41 subjects with mild cognitive impairment who converted to AD (CONV), and 44 subjects with
62 mild cognitive impairment (MCI) which did not convert to AD (NOCONV). Subjects in CONV and
63 NOCONV group were matched by age, sex, and education years, as it is reported in reported in Table 1.

64 The neuropsychological assessment included seven tests: four measures of memory recall, *Immediate*
65 *Logic Memory Units*, *Delayed Logic Memory Units*, *Immediate Logic Memory Themes* and *Delayed*
66 *Logic Memory Themes* (Wechsler Memory Scale, WMS-III) (Wechsler, 1955); one measure of working
67 memory, *Inverse Digits* (WMS-III); one measure of cognitive flexibility, *Trail Making Test-B* (TMT-B)
68 (Bowie & Harvey, 2006); two language measures, *Semantic Fluency* (Controlled oral Word Association
69 Test, COWAT) (Benton et al., 1994) and *Boston Naming Test* (BNT) (Kaplan et al., 1983) ; and
70 one global screening measure for cognitive impairment and dementia, the *Clock-Drawing test* (Agrell &

Table 1: Mean \pm SD values of the demographic and neuropsychological characteristics for AD converters (CONV) and NOCONV groups

71 Dehlin, 1998). Table 1 includes paired t-test and previously reported differences across groups (López-
72 Sanz et al., 2016; Pusil, Dimitriadis, et al., 2019) .

73 2.2 Magnetoencephalography data acquisition

74 The dataset was acquired using a 306-channel (102 magnetometers and 204 gradiometers) Vectorview
75 MEG system (Elekta AB, Stockholm, Sweden) placed inside a magnetically shielded room (Vacuum-
76 Schmelze GmbH, Hanau, Germany) located at the Laboratory of Cognitive and Computational Neu-
77 roscience (Madrid, Spain). MEG data consisted of 5 min eyes-closed resting-state recordings in a 60
78 min session, with a sampling rate of 1000 Hz and an online [0.1 - 330] Hz anti-alias band-pass filter.
79 To allow further analysis, including subject-specific source reconstruction, MEG recordings were com-
80 plemented by MRI scans acquired within a month after the MEG session, which were recorded at the
81 Hospital Universitario Clínico San Carlos (Madrid, Spain) using a 1.5 T General Electric MRI scanner
82 with a high-resolution antenna and a homogenization PURE filter (fast spoiled gradient echo sequence,
83 with parameters: repetition time/echo time/inversion time = 11.2/4.2/450 ms; flip angle = 12°; slice
84 thickness = 1 mm; 256 \times 256 matrix; field of view = 256 mm).

85 The MEG recordings were preprocessed offline using a temporal-spatial filtering algorithm (tSSS) (Taulu
86 & Hari, 2009) (Maxfilter Software v2.2, correlation limit of 0.9 and correlation window of 10 s) to

87 eliminate magnetic noises and compensate for head movements during the recording. The continuous
88 MEG data were imported into MATLAB (R2017b, Mathworks, Inc.) for pre-processing steps, carried
89 out using the Fieldtrip Toolbox (Oostenveld et al., 2011) (<https://www.fieldtriptoolbox.org/>). Data
90 were automatically scanned for ocular, muscle and jump artefacts using the Fieldtrip software. Artefacts
91 were then visually confirmed by an MEG expert. The remaining artefact-free data were segmented
92 into 4-s segments (epochs). An independent component analysis-based procedure was used to remove
93 the heart magnetic field artefact. Source reconstruction was performed using minimum norm estimates
94 (Hämäläinen & Ilmoniemi, 1994) with the software Brainstorm (Tadel et al., 2011). Current dipoles
95 were constrained to be perpendicular to the individual's cortical surface, to model the orientation of
96 macro columns of pyramidal neurons (Tadel et al., 2011). Neural time series were finally averaged
97 within regions of interest (ROI) of the Schaefer 100-17 network atlas (Schaefer et al., 2018). Two
98 regions of interest were extracted for subsequent analysis: the anterior cingulate cortex (as the merge
99 of *left ACC* and *right ACC*, corresponding to *SalVentAttnB PFCmp1* area of the mentioned atlas,
100 respectively), and the precuneus (as the merge of *left PC* and *right PC*, corresponding to *ContC pCun 1*
101 and *DefaultApCunPCC 1* area of the mentioned atlas), see Figure 1a. The data was band-pass filtered
102 between 0.5 and 45 Hz (broadband), using FIR filtering.

103 2.3 Power spectral density (PSD)

104 We computed the power spectral density of each of the ROI time series by using the Welch's periodogram
105 method (Welch, 1967), with 1s window length and 50% overlap ratio. For each ROI signal, the normalised
106 power was calculated by averaging the power spectral density obtained by each epoch and then normalising
107 the value associated to each frequency by total power over the [1–30] Hz range (Figure 2).

108 2.4 Time-Frequency Representations (TFRs) & Spectral Events Extraction

109 During resting-state alpha and beta activity, periods of transient high power can be quantified over time
110 in unaveraged data. We use a time-frequency-based algorithm as in Shin et al. (2017) to capture these
111 bursts.

112 Time-Frequency Representations (TFRs) were calculated using the MATLAB SpectralEvents Toolbox
113 (find method = 1, as in Shin et al. (2017)) (<https://github.com/jonescompneurolab/SpectralEvents>).
114 Each artefact-free 4-sec epoch was convolved with a 7-cycle Morlet wavelet. For all epochs, TFR across
115 time and across each patient was calculated and finally averaged to obtain a representative TFR for each

2.4 Time-Frequency Representations (TFRs) & Spectral Events Extraction

7

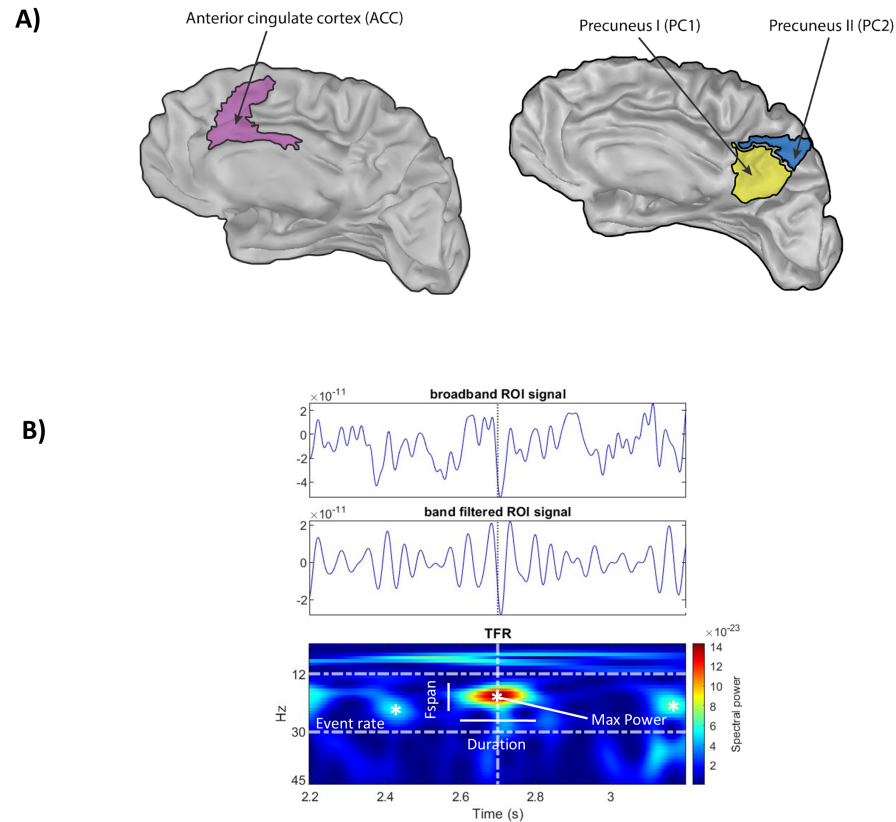

Figure 1: a) Representation of the right side regions of interest using the Schaefer 100-17 network atlas: *SalVentAttnBPFCmp1* (corresponding to ACC), *ContCpCun1* (corresponding to PC) and *DefaultApCunPCC1* (corresponding to PC); b) Example of resting-state beta activity from left-ACC and detection of transient burst of high-power activity (events), using the frequency-based algorithm of Shin et al. (2017). There are several possible features of such events that could contribute to increased power averaged across time and frequency, including event number (rate), event duration, event frequency span and event power

116 ROI (PC or ACC) and group (CONV or NOCONV) in the range [2-30] Hz.

117 The bands of interest reflected the slowing effect typical of MCI (Bruña et al., 2023; Dauwels et al.,
118 2011; López-Sanz et al., 2016) and observed in our sample and were chosen to be [5-10] Hz for alpha
119 and [12-30Hz] for beta. (See also methods section 2.5 *Statistical Analysis*). More specifically, we defined
120 alpha by determining the group averaged peak (GAP) frequency of 8Hz in PC and taking a range of GAP
121 [-3, +2] Hz. This choice provides a more precise capture of alpha oscillations in the ageing population
122 (Tröndle et al., 2023) and reflects the range of significant difference in both PC and ACC across groups
123 in our sample (see results Figure 2 below). The [12-30]Hz beta band, which does not exhibit a clear
124 GAP, was similarly chosen to include the areas of significant difference in our sample.

125 Spectral Events were detected by first retrieving all local maxima in un-normalized TFR using *imregional-*
126 *max*. For each subject and ROI, transient high-power events were defined as local maxima above a 6X
127 factor of the median (FOM) threshold within a frequency band of interest, to be consistent with prior
128 studies (Shin et al., 2017). Additionally, we tested the robustness of our analysis with 4X FOM and 8X
129 FOM thresholds (see Supplementary Figure 2 and Supplementary Table 1 & 2). As reported, we had
130 the most significant results for 6X FOM median threshold. The spectral event method applied (namely,
131 find method=1 in the SpectralEvent Toolbox) allows for multiple, overlapping events to occur in a given
132 suprathreshold region and does not guarantee the presence of within-band, suprathreshold activity in any
133 given trial, see Figure 1b.

134 Importantly, it was noticed that events detected in contralateral medial ROIs (especially in left ACC and
135 right ACC) were in part mirrored across the midline due to the close proximity of neighbouring bilateral
136 dipoles (this effect of spatial smearing in source reconstruction is explained in Supplementary Figure 1).
137 To remove duplicated mirror events when two detected events shared the corresponding contralateral
138 ROI, epoch, time and frequency, we rejected the one with lower amplitude.

139 For each subject and ROI, spectral events were characterised by 4 key features: event number in a fixed
140 time window (i.e. event rate), duration, frequency span (Fspan) and power (Power FOM) (see Figure
141 1b). Event number was calculated by counting the number of events in the 4-second period of each
142 epoch. Event power was calculated as the normalised FOM power value at each event maximum. Event
143 duration and frequency span were calculated from the boundaries of the region containing power values
144 greater than half the local maxima power, as the full-width-at-half-maximum in the time and frequency
145 domain, respectively.

146 2.5 Statistical analysis

147 To determine frequency ranges that represent oscillatory slowing in our cohort, we tested for significant
148 differences in average power spectral density between AD CONV and NOCONV for each selected ROI
149 by performing a non-parametric statistical test (Maris & Oostenveld, 2007) in the frequency domain (see
150 light grey window in Figure 2).

151 In each frequency-band, we examined the relationship between event features and the averaged PSD using
152 a linear regression analysis over all subjects. The regression β coefficients were calculated with a 95%
153 CI and all p-values were corrected for multiple comparisons using the Benjamini–Hochberg (BH) step-up
154 procedure (Benjamini & Hochberg, 1995) with a False Discovery Rate (Q) set at 0.05. Statistically
155 significant p-values after BH correction are reported as $*p < 0.05(Q = 0.05)$.

2.5 Statistical analysis

9

156 We also tested for group differences in spectral event features between CONV and NOCONV groups.
157 High power spectral event features were detected in alpha and beta frequency bands for each resting
158 state segment from four ROI's (left and right ACC and PC, respectively). Event rates were averaged
159 across epochs, and other features (duration, f-span, power) were averaged across all events, and then
160 between hemispheres, within each subject. The final dataset consisted of 16 variables for each subject:
161 four event features (averaged spectral event rate, duration, f-span and power); by two ROI's (ACC,
162 PC); by two frequency bands (alpha and beta). For each variable, t-tests were used to assess group
163 differences in transient event features. The tests were conducted with a left tail for the beta band and a
164 right tail for the alpha band. This approach was consistent with the observation that the average power
165 spectra in the alpha band are higher for CONV compared to NOCONV, while the effect is reversed in the
166 beta band. We hypothesized that differences in event features align with the directional trend observed
167 in the averaged relative spectral power. All reported p-values were corrected for multiple comparisons
168 across the number of tests applied using the Benjamini–Hochberg (BH) step-up procedure (Benjamini
169 & Hochberg, 1995) with a False Discovery Rate (Q) set at 0.05. Statistically significant p-values after
170 BH correction are reported as $* * p < 0.05(Q = 0.05)$. Statistical tendencies are reported as significant
171 if $*p < 0.1$. We computed effect size of the differences between groups with a robust variant of Cohen's
172 d (Algina et al., 2005).

173 For event features where significant difference across groups were found, we examined the relationship
174 between these features and AD conversion and cognitive performance.

175 To assess the relationship with AD conversion, we fit beta event features from ACC and PC to a
176 logistic regression model (`R glm()` function, `family = binomial` argument) in order to predict each
177 patient's conversion label (CONV or NOCONV). The model's output is the probability of the positive
178 class (CONV group). We used a default 0.5 threshold value to transform the probability to a binary
179 class. Thus, a subject is classified as class 1 (CONV) if the predicted probability is greater than or equal
180 to 0.5, and class 0 if the probability is less than 0.5. The odds ratio in logistic regression is calculated
181 by exponentiating the coefficient of the predictor variable. As an example, for predictor variable *Number*
182 *of events*, if the coefficient is $\beta = 0.58$ the odds ratio is given by $OR = e^{0.58} \approx 1.79$. This means that
183 the likelihood of the predicted outcome (AD conversion), is approximately 1.79 times greater than the
184 likelihood of the outcome not occurring (no conversion to AD). Every reduction of 1 unit in *Number of*
185 *events* increases by 79% the odds of AD conversion (CONV group).

186 To assess the relationship with cognitive performance, we calculated a Cognitive Performance Index and
187 applied linear regression. Aiming to account for variability across the nine neuropsychological tests used,
188 the Cognitive Performance Index was calculated by applying Principal Components Analysis (PCA) (R

189 *princomp()* function) to the neuropsychological testing dataset. As a first step, the data from each
190 of the nine tests was z-scored to prevent biases due to different test scales. Additionally, the data
191 were transformed so that for each test higher values correspond to better cognitive performance. Then,
192 we extracted the first principal component, which explained at least 55% of variance. The projection of
193 individual data onto the new axes (principal component) represent the Cognitive Performance Index values
194 for each subject, and this projection is achieved through linear transformation using the eigenvectors of
195 the covariance matrix. All eigenvectors had a positive load in the first component. A subject with higher
196 values of this Cognitive Performance Index correspond to better cognitive performance.

197 3 Results

198 3.1 AD Converters (CONV) exhibit oscillatory slowing in average PSD

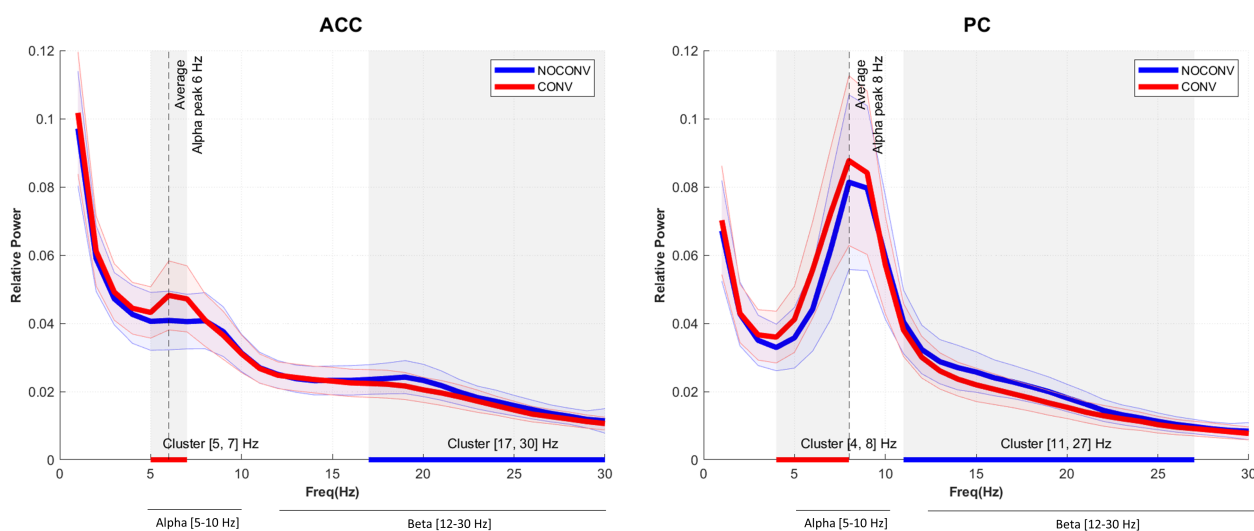

Figure 2: Normalized power spectral density plots (mean \pm SEM) for regions of interest in CONV and NOCONV patients, in the range [2-30] Hz. Shaded grey areas represent statistically significant clusters of differences between CONV and NOCONV groups (non-parametric statistical test).

199 We confirm a slowing effect in power spectral density in CONV subjects for all ROIs of interest in ACC
200 and PC, as observed in prior studies (Pusil, Dimitriadis, et al., 2019). In averaged PSD, the CONV group
201 shows a statistically significant cluster of decreased relative power in beta frequency band compared to

3.2 Resting-state alpha and beta emerge as transient high-power events

11

202 NOCONV (Figure 2, 17-30Hz ACC and 11-27Hz PC, blue underlines) and increased relative power in
203 lower frequency bands (theta, low-alpha) (Figure 2, 5-7Hz ACC and 4-8Hz PC, red underlines). Based
204 on our data, for all subsequent analyses, we utilized a [5-10] Hz alpha bands and [12-30] Hz beta-band
205 (see Methods section 2.4 for further details).

3.2 Resting-state alpha and beta emerge as transient high-power events

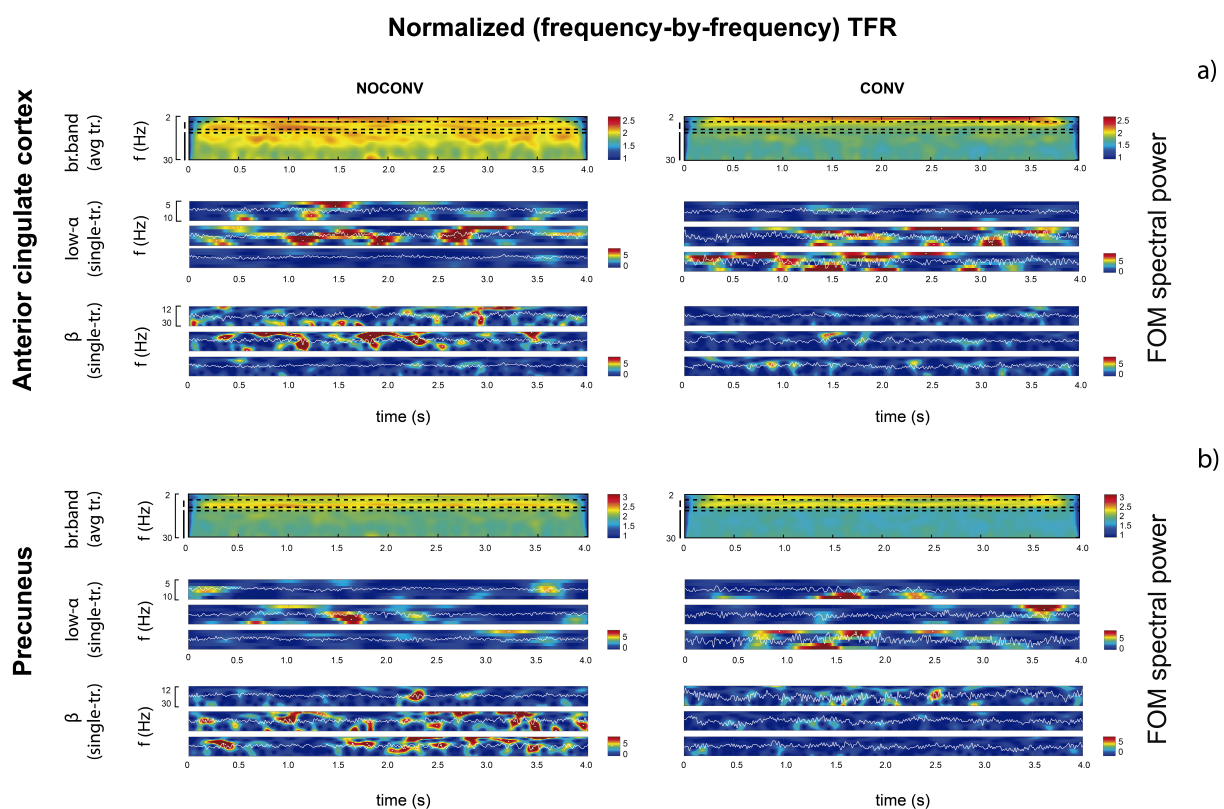

Figure 3: Time-Frequency representations of spectral events in PC (a), and ACC (b) for non-converters (NOCONV, left) and converters (CONV, right) groups. For each case, we show the representative averaged broadband TFR (top), as well as three TFR related to randomly chosen trials for low-alpha (middle), and beta (bottom) band.

207 The PSD plots of Figure 2 rely on Fourier analysis performed on averaged epochs of brain activity from
208 the two different groups. As described previously, differences in averaged power across patient groups
209 could emerge from several features in transient of high-power activity (i.e., *events*) in the unaveraged
210 data.

211 Visual inspection of time-frequency representations in Figure 3 shows that seemingly continuous high
212 average power in the alpha and beta bands (top panels) is the result of the accumulation of transient

213 high power activity ('events') across epochs of the unaveraged resting-state data (Figure 3 middle and
 214 bottom panels) for both groups.

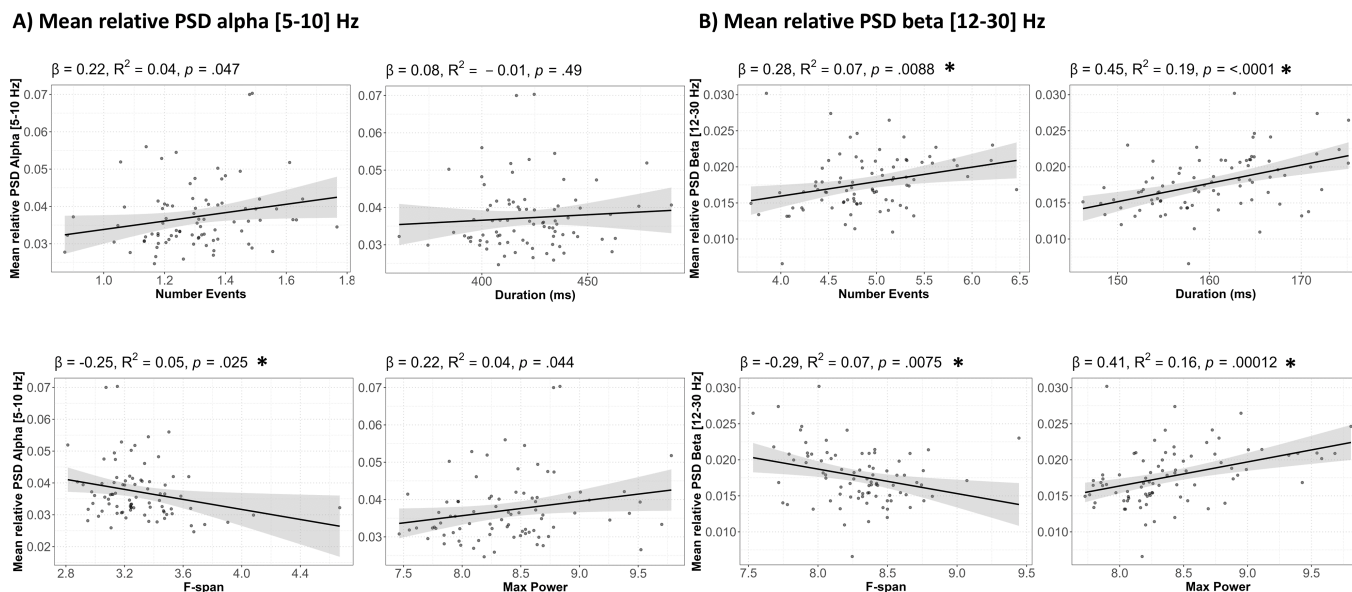

Figure 4: Diminished expression of event features in ACC and PC is associated with reduced mean power spectral density (PSD). A) Regression analysis between alpha [5-10] Hz spectral events and averaged alpha power. B) Regression analysis between beta [12-30] Hz spectral events and averaged beta power. Statistically significant p-values after BH correction are reported as $*p < 0.05 (Q = 0.05)$.

215 As such, higher averaged power could be due to increased expression in several features, including a higher
 216 number of events (rate), longer duration events, increased frequency spans and or increased power of
 217 the event. To assess if these features contributed to averaged power in our sample, we performed a
 218 regression analysis between each feature and averaged alpha and beta power (Figure 4). Our results
 219 show a strong correlation with averaged power and each event features in the beta band (number:
 220 $\beta = .28, R^2 = .069, p - value = .0088$; duration: $\beta = .45, R^2 = .192, p - value < .0001$; max power:
 221 $\beta = .41, R^2 = .156, p - value = .0001$, frequency span: $\beta = -.29, R^2 = .07, p - value = .0075$).
 222 While similar relationships occurred between alpha event features and averaged alpha power, only alpha
 223 event frequency span significantly correlated with averaged alpha power after correction for multiple
 224 comparisons and the effect was weaker than in the beta band (frequency span: $\beta = -.25, R^2 = .05,$
 225 $p - value = .025$).

3.3 Reduced beta event features as predictive biomarkers of AD conversion and cognitive decline 13

Freq.	ROI	Feature	CONV	NOCONV	t Stat	p	Cohen d

Table 2: Statistical comparison of event features averaged for CONV and NOCONV groups in low-alpha [5-10] Hz and beta [12-30] Hz frequency bands and x6 FOM. Significant differences after BH correction ($p < 0.05$) are marked with the asterisk (**). Statistical tendency ($p < 0.1$) are marked with the asterisk (*).

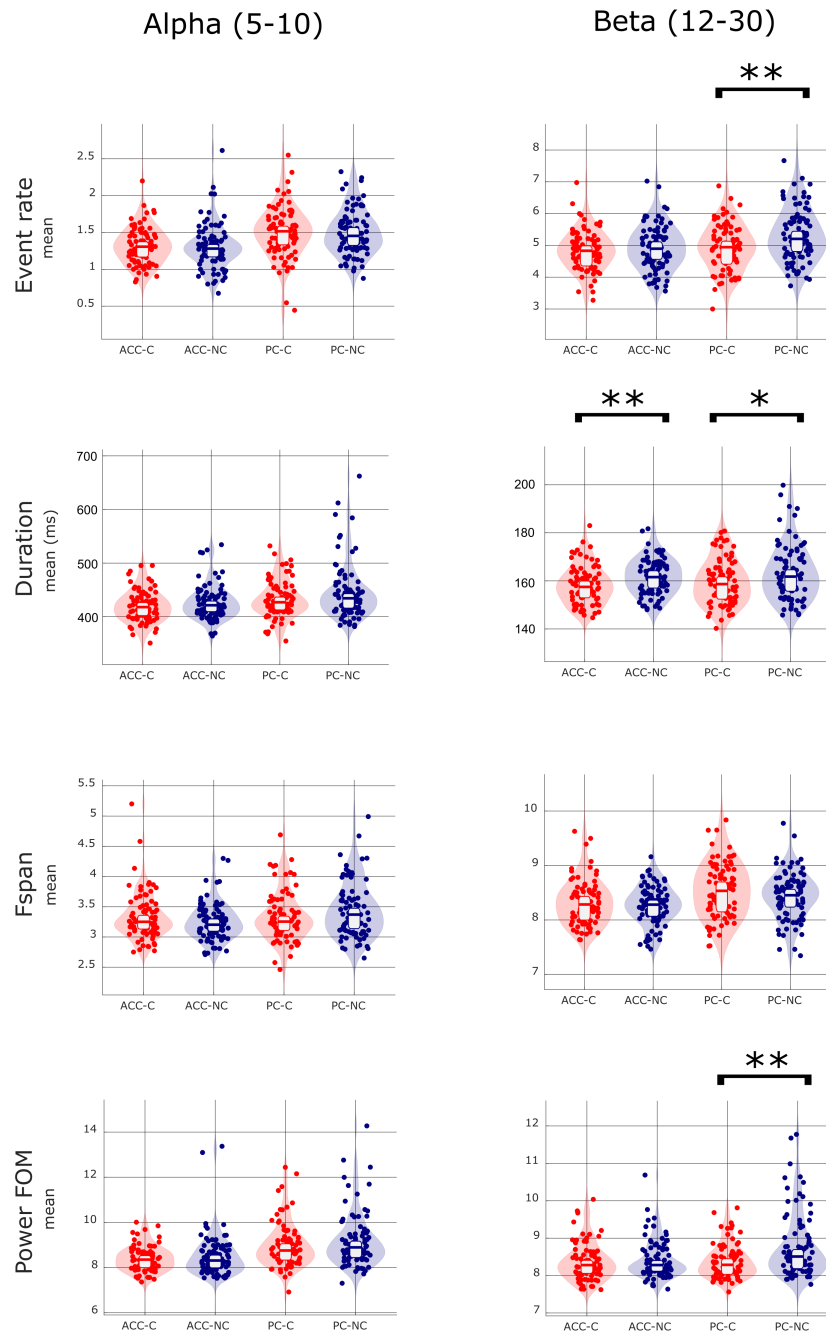

Figure 5: Mean and distribution of event features for AD converters (CN) and non-converters (NC) in alpha [5-10] Hz and beta [12-30] Hz frequency bands. T-test statistically significant p-values ($p < 0.05$) after BH correction are marked with the asterisk (**). Statistical tendency ($p < 0.1$) are marked with the asterisk (*).

3.3 Reduced beta event features as predictive biomarkers of AD conversion and cognitive decline

Given the event like nature of alpha and beta, we next tested the hypothesis that the slowing observed differences across groups in averaged PSD power in Figure 2 was due to across group differences in event features, namely rate, power, duration and/or frequency-span. We found effects only in the beta band that were more prominent in PC, such that CONV had a lower mean rate of beta events, lower power events, and a trend to shorter duration beta events in PC. Shorter duration beta events were also present in ACC in the CONV group (Figure 5 and Table 2; rate in PC $p - value_{BH} = .003$, power in PC $p - value_{BH} = .002$, duration in PC $p - value_{BH} = .051$; duration in ACC $p - value_{BH} = .01$, see also Supplementary Figure 2 and Figure 3 for further summary statistics). Notably, the effect size for differences between CONV and NOCONV in these features are of medium size (*Cohen d* > 0.4), see Table 2).

The fact that our method allows us to explain differences in beta band, but not in alpha band, could reflect the method's sensitivity in the alpha band. Indeed, as shown in Figure 4, in this subject sample, individual alpha event features are not a strong predictor of averaged alpha power (see also Supplementary Tables 1 & 2 for analysis of other power thresholds) and the slowing effects in the alpha band may instead be due to a combination of transient event features and/or more stationary properties of the signal.

To investigate the further predictive potential of resting-state beta event features as a biomarker for conversion from MCI to AD, we examined the association between beta event rate, duration, and maximum power and the probability of AD conversion within a 2.5-year timeframe (See Figure 6A). The probability of conversion was calculated from a logistic regression (see Methods section 2.5). Consistent with the pooled results in Figure 5, lower beta event rates, shorter duration, and reduced event power are linearly associated with an increased probability of conversion. MCI subjects with fewer than 4.92 events in four seconds of resting-state data have 1.79 (95 %CI [1.1, 3.0]) times greater odds of converting to AD ($R^2_{Nag} = .10$, $p - value = .024$). Those with event duration less than 159 ms have 1.06 (95 %CI [1.0, 1.1]) times greater odds of AD conversion ($R^2_{Nag} = .06$, $p - value = .008$), and subjects whose events have maxima power (calculated as factors of median power) less than 8.41 have 2.01 (95 %CI [1.15, 3.76]) times greater odds of AD conversion ($R^2_{Nag} = .05$, $p - value = .019$).

Further examination of the relationship between beta event features and cognitive performance showed that, in the CONV group, a lower rate of beta events and lower power beta events were linearly associated with greater cognitive decline (Figure 6B, lower Cognitive Performance Index values, see Methods section 2.5 *Statistical Analysis*) ($\beta = .26$, $R^2 = .07$, $p - value = .016$ for number of events; $\beta = .31$, $R^2 = .10$,

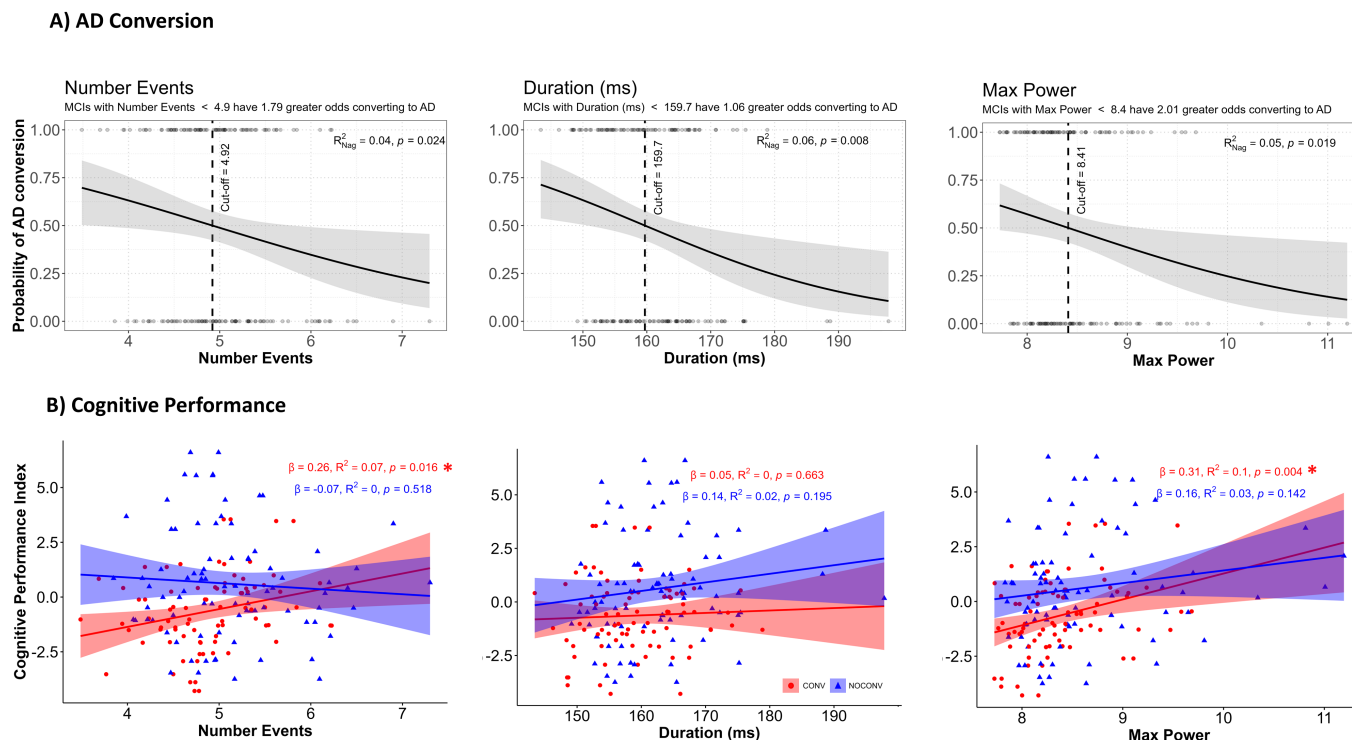

Figure 6: Diminished expression of beta event features in ACC and PC (number of events, duration, maxima power) is associated with greater odds of future AD conversion, and reduced cognitive performance. A) Logistic regression between beta event features and AD conversion within 2.5 years. B) Linear regression between beta event features and Cognitive Performance Index separated by CONV (red) and NOCONV (blue).

258 $p - value = .0041$ for maxima power). These relationships did not emerge for duration, nor appear in
 259 NOCONVs, suggesting beta event features and particularly beta event power ($p - value = 0.0041$) are
 260 predictive of cognitive decline only in MCI patients that will convert to AD within 2.5 years.

261 4 Discussion

262 Resting-state M/EEG signals provide a powerful non-invasive method to examine human brain physiology
 263 associated with AD (Bruña et al., 2023; Hsiao et al., 2013; Ishii et al., 2017; López et al., 2020; López-
 264 Sanz et al., 2016). Oscillatory slowing has been associated with AD conversion based on PSD analysis
 265 that relies on signal averaging. Our study shows for the first time that in non-averaged data, resting
 266 state alpha and beta oscillations from ACC and PC are composed of transient high-power events. To
 267 explore how transient high power events relate to findings of slowing in PSD, we studied their properties
 268 in a sample of individuals diagnosed as MCI and characterized novel features of transient high-power

269 events that distinguish patients who later convert or do not convert to AD (i.e., CONV and NOCONV,
270 respectively). Our analysis reveals a consistent pattern of a lower number of transient 12-30 Hz beta
271 events, duration and power for CONV compared to NOCONV in PC, with the duration effect also
272 occurring in ACC. This diminished beta event expression in ACC and PC was associated with increased
273 odds of future AD conversion and decreased cognitive performance in the CONV group. It is well known
274 that PC and ACC are part of the default mode network, which has decreased metabolism in the early
275 stages of the disease (Greicius et al., 2004) and it is closely involved with episodic memory processing (Liu
276 et al., 2022). Our finding of reduced event-activation in CONV is predominantly found in precuneus, a
277 ROI typically associated with deposition of amyloid- β in the early stages of the AD continuum (Forsberg
278 et al., 2008).

279 Overall, our results lay the foundation for further examination of beta event features as a novel biomarker
280 for early AD diagnosis and a possible neurobiological measures of the effectiveness of preventative in-
281 terventions. The more fine-grained description of slowing in unaveraged MEG data may also bring us
282 closer to understanding the underlying neural mechanisms, and a more direct link to hyperexcitability as
283 observed in animal models (Maestú et al., 2021; Zott et al., 2019), ultimately guiding new therapeutics
284 in humans.

285 **4.1 Consistency with prior studies examining beta, ageing and cognitive con-** 286 **trol**

287 Reductions in beta event expression yielded a lower PSD in the beta band [12-30] Hz averaged across
288 trials, giving further insight into the underpinning of oscillatory slowing in AD (Bruña et al., 2023;
289 Dauwels et al., 2011; Jelic et al., 2000). This trend is also consistent with a critical shift in beta activity
290 at approximately 60 years of age in healthy patients (Brady et al., 2020; Power & Bardouille, 2021).
291 Following this inflection point, resting-state relative source power, as well as beta event characteristics
292 such as event rate, peak frequency, duration, peak power, etc., progressively begin to decline with age
293 (Brady & Bardouille, 2022). Other studies have shown that averaged M/EEG spectral activity in the
294 beta frequency range (13-30) Hz is a more powerful predictor of MCI-to-AD conversion than activity in
295 other frequency bands, including in the slow alpha frequency range ((Gaubert et al., 2024; Poil et al.,
296 2013). Thus, transient beta event features may be key factors in delineating differences and tracking the
297 neurophysiology of healthy and pathological ageing.

298 We found that reductions in beta event features were associated with global cognitive decline, as measured
299 by an index based on a battery of neuropsychological tests. However, this effect is only significant in the

300 CONV group. MCIs who convert to AD 2.5 years later seem to be more reliant on beta event expression
301 for cognitive robustness.

302 Several studies have shown that beta events throughout the cortex are a signature of inhibitory control.
303 In sensory cortex, beta event expression can be manipulated with attention (increasing in non-attentive
304 states), and an increase in beta event rates is associated with a decrease in perceptual salience (Shin
305 et al., 2017), a process predicted to be mediated by an increase in inhibitory neuron activity (Law et al.,
306 2022). In motor cortex, increased beta event expression is associated with inhibited motor control and
307 Parkinson's disease (Yu et al., 2021), and in frontal cortex beta events are a signature of stopping of
308 movement and long-term memory retrieval (Schmidt et al., 2019; Wessel, 2020). Conversely, reduction in
309 beta event rates in frontal cortex has been explicitly linked to encoding and decoding in working memory
310 processes, where they have been suggested as a mechanism for volitional control and memory content
311 reactivation (Lundqvist et al., 2016, 2018; Spitzer & Haegens, 2017). Likewise, decreased posterior
312 parietal beta oscillatory activity predicts episodic memory formation and retrieval (Griffiths, Martín-
313 Buro, Staresina, Hanslmayr, & Staudigl, 2021; Nyhus, 2018), and is correlated with enhanced memory
314 performance (Griffiths, Martín-Buro, Staresina, & Hanslmayr, 2021). Transcranial stimulation of the
315 prefrontal cortex at beta (18 Hz) has been found to induce memory encoding impairments (Hanslmayr
316 et al., 2014), and during posterior parietal cortex stimulation, lower prestimulus beta power predicts
317 higher phosphene ratings, reflecting increased neural excitability (Samaha et al., 2017).

318 The consistent relationship between beta event expression and inhibitory control in these myriad studies
319 (Lundqvist et al., 2024) suggests that the ability to modulate beta events according to task demands is
320 necessary for optimal function, and that the diminished resting state beta event expression and associated
321 cognitive decline observed in the PC in CONV in our study may be directly related to lack of inhibitory
322 cognitive control.

323 **4.2 Why are differences in alpha bursts not present?**

324 Despite the observation of significant across group differences in alpha band in the average PSD (Figure
325 2), we did not find a significant relationship between transient [5-10] Hz alpha event features and averaged
326 power, nor did we find a difference in event features between MCI patients who will convert to AD and
327 those who will not, which is consistent with previous longitudinal studies of AD progression (Gaubert
328 et al., 2024; Poil et al., 2013). This was true for several event detection thresholds (see Supplementary
329 Figure 2 and Supplementary Tables 1 and 2).

330 Since we did not find a relationship between spectral events in the lower 5-10 Hz alpha band and averaged

4.3 *A mechanistic link between reduced beta event expression and hyperexcitability in CONV* 19

331 alpha power in our sample, we did not examine the relationship to cognitive performance. In terms of
332 components of slowing, other studies have found a relationship between bursts of slow activity (1-6 Hz)
333 age and cognition in healthy adults, where older subjects and lower cognitive performance participants
334 exhibited longer and slower events (Power et al., 2024).

335 The lack of alpha event effects in our sample could reflect the sensitivity limitations of the spectral
336 event detection method or indicate that, although the alpha band contains transient components, the
337 differences between the two groups involve a combination of transient feature or more stationary features
338 than transient ones. A slowed occipital alpha rhythm is a common biomarker of several neurological or
339 psychiatric disorders (Hughes & Crunelli, 2005; Samson-Dollfus et al., 1997). According to the “thalamo-
340 cortical (TC) hypothesis” (Klimesch et al., 2007; S. M. Sherman, 2001) slow cortical rhythms could be
341 generated by TC cells in tonic, single spike, firing, or in arrhythmic bursting mode. Hugues (2005) argued
342 that a slowing effect when shifting from alpha to theta waves could arise from the hyperpolarization of
343 the thalamo-cortical neuron population, resulting in a deceleration of high-threshold bursting (HT) in
344 individual cells, which could translate to a shift from bursty alpha to more continuous slower theta range
345 oscillations. Thus, in this cognitively impaired population, while we still detect some alpha bursting,
346 Alzheimer’s disease-related mechanisms may be disrupting thalamo-cortical connections (Eustache et al.,
347 2016) and slowing the thalamic bursting activity, making it more stationary.

348 In the early stages of AD continuum, even before a mild cognitive impairment diagnosis, alpha disruption
349 is a marker of cognitive decline (Babiloni et al., 2010; Bruña et al., 2023; Huang et al., 2000; López et al.,
350 2020; López-Sanz et al., 2016). Still, when patients reach a more advanced stage of the disease, as it is
351 mild cognitive impairment, beta band is more discriminant between AD converters and non-converters
352 (Gaubert et al., 2024; Poil et al., 2013; Pusil, Dimitriadis, et al., 2019). Consequently, when measured
353 in MCIs the spectral events method may not be sensitive to this transient-to-stationary shift in the alpha
354 [5-10] Hz frequency band but can detect differences in the beta [12-30] Hz band.

355 **4.3 A mechanistic link between reduced beta event expression and hyperex-** 356 **citability in CONV**

357 Animal studies have suggested $A\beta$ -induced changes in E/I balance is a mechanism for hyperexcitability
358 and cognitive decline in Alzheimer’s disease (Maestú et al., 2021). This notion has been supported
359 by several computational neural modeling frameworks examining causal links between disease processes
360 and increased neuron firing rates (Alexandersen et al., 2023; Cabral et al., 2014; de Haan et al., 2017;
361 Hutt et al., 2023; Nakagawa et al., 2014; Stefanovski et al., 2019; Zimmermann et al., 2018), albeit

362 without explicit consideration of the biophysical generators of MEG current sources or of beta frequency
363 oscillations.

364 Modeling work by our group specifically designed to interpret the detailed cell and circuit origin of localized
365 MEG (and EEG) current source signals (Neymotin et al., 2020) provides a hypothesized direct mechanistic
366 link between beta event expression and hyperexcitability in CONV. Specifically, our prior modeling and
367 cross-species empirical studies suggested neocortical beta events are generated by bursts of exogenous
368 thalamocortical drive that targets excitatory synapses on the proximal and distal dendrites of pyramidal
369 neurons in deep and superficial neocortical layers, such that the distal drive is stronger and last a beta
370 period (i.e. ≈ 50 ms) (Jones et al., 2009; M. A. Sherman et al., 2016). This thalamic burst drive induces
371 current flow in pyramidal neuron dendrites that generates MEG beta event waveform characteristics
372 consistent with those observed experimentally in sensory, motor and frontal cortices (Bonaiuto et al.,
373 2021; M. A. Sherman et al., 2016), and when occurring rhythmically can produce multiple beta cycles
374 and/or a complex of alpha and beta activity (Jones et al., 2009). Follow-up studies predicted further
375 that the thalamic drive inducing a beta event also activates inhibitory neurons in supragranular layers,
376 providing a causal mechanism for beta-associated inhibitory control (Law et al., 2022; Shin et al., 2017).
377 Together with our current findings that CONV have reduced beta expression (namely lower event rates,
378 power and duration), these prior studies suggest CONV have a reduction in thalamocortical burst drive
379 to cortex, which in turn recruits less cortical inhibitory neuron activity leading to hyperexcitability.

380 Such a decrease in inhibitory activity could contribute to the observation of diminished Gabaergic terminals
381 on cortical neurons near amyloid plaques, in addition to the toxic effects of amyloid oligomers on inhibitory
382 terminals (Alexandersen et al., 2023; Garcia-Marin et al., 2009), particularly in PC which exhibits $A\beta$
383 deposition in the early stages of AD. The predicted reduction in thalamic bursting is also synergistic
384 with studies showing thalamic atrophy and reduced inhibitory thalamic tone (Abuhassan et al., 2014;
385 Forno et al., 2023), as inhibition from the thalamic reticular nucleus is known to be a driver of rebound
386 bursting mechanisms in thalamic relay cells (Destexhe & Sejnowski, 2002). Moreover, decreases in
387 thalamocortical drive are consistent with theories of thalamocortical dysrhythmia (Llinás et al., 1999)
388 and could contribute to loss of cortical signal complexity and biophysical heterogeneity (Szul et al., 2023)
389 occurring with the disease and thought to be an important homeostatic control mechanisms capable of
390 bolstering the network's resilience to perturbations, such as the toxic effects of amyloid (Dauwels et al.,
391 2011; Hutt et al., 2023).

392 Supplementary Material

393 “Mirror” events

394 The MEG activity of medial regions is characterized by the presence of synchronized, contralateral, spu-
395 rious mirror events (see TFRs in Figure S1). This phenomenon is caused by the limited resolution of
396 MEG/volume conduction. When using the MNE dipole-constrained source reconstruction method, these
397 duplicated events are noticeable because they are characterized by a mutual inversion of the time series.
398 We performed a removal step of duplicated mirror events: when two detected events shared the same
399 (but contralateral) ROI, epoch, time and frequency, we discarded the one with lower amplitude.

400

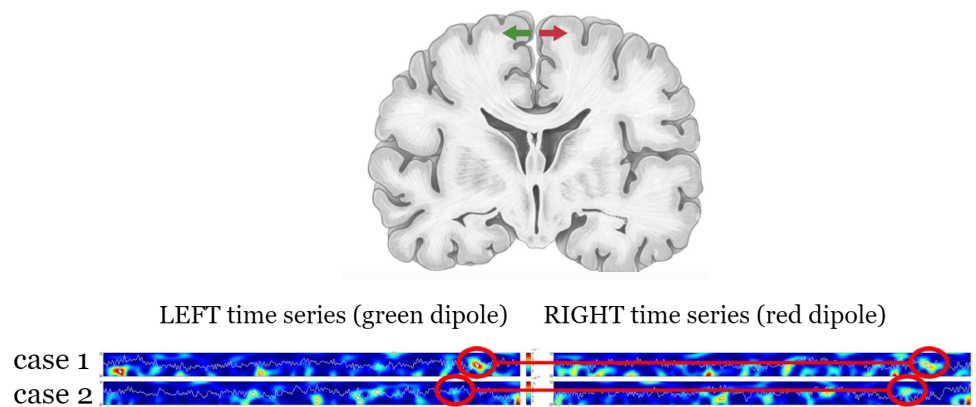

Figure 1: Example of mirror event in left ACC and right ACC due to spatial smearing in source reconstruction. The events considered at the end of the detection process were the left one in the case1, and the right one in the case2, due to their amplitudes.

401 **Event threshold analysis**

- 658 Zimmermann, J., Perry, A., Breakspear, M., Schirner, M., Sachdev, P., Wen, W., Kochan, N. A., Map-
659 stone, M., Ritter, P., McIntosh, A. R., & Solodkin, A. (2018). Differentiation of alzheimer’s
660 disease based on local and global parameters in personalized virtual brain models. *Neuroimage*
661 *Clin*, *19*, 240–251.
- 662 Zott, B., Simon, M. M., Hong, W., Unger, F., Chen-Engerer, H.-J., Frosch, M. P., Sakmann, B., Walsh,
663 D. M., & Konnerth, A. (2019). A vicious cycle of β amyloid–dependent neuronal hyperactivation.
664 *Science*, *365*(6453), 559–565.

665 **Data and Code Availability**

666 Code to perform analyses is available at: <https://github.com/jonescompneurolab/SpectralEvents>

667 Data will be made available on request.

668 **Author Contributions**

669 DSB, GL, RB – methodology, software, analysis, visualization, original draft

670 DZ, JC, BC, EP, ME, RB, FM, SJ – conceptualization, methodology, review and editing.

671 **Funding**

672 This work was supported by funds from NIH and the Collaborative Research in Computational Neu-
673 roscience (CRCNS) under the project " *Interpreting MEG Biomarkers of Alzheimer's Progression with*
674 *Human Neocortical Neurosolver*". UCM-Santander grants for PhD students, provided additional eco-
675 nomical support to main author.

676 **Declaration of Competing Interests**

677 The authors declare no competing financial interests
