#### 29 ABSTRACT

30 **Background:** Early gut microbiota disruptions can increase the risk for dysbiosis and 31 predispose to chronic diseases. While chlorinated drinking water is generally considered safe, 32 the antimicrobial effects of chlorine-based disinfectants may negatively impact the 33 developing infant microbiota, which is particularly vulnerable during this critical period. This 34 study investigates the specific effects of chlorinated water on the gut microbiome in infants.

Methods: The waTer qUality and Microbiome Study (TUMS) is a double-blinded, randomized controlled trial (RCT). Six-month old infants (n=197) received either dechlorinated drinking water (via benchtop filtration), or regular tap water for twelve months. Stool samples were collected at six-months (baseline) and at eighteen-months of age. Metagenomic sequencing was used for faecal microbiome analysis. Samples of participant tap water was also collected pre- and post-intervention.

41 Results: Participants were balanced for sex, delivery method, and breast-feeding status at 42 time of recruitment between the control (n=98) and treatment (n=99) groups. We collected a 43 total of 170 baseline stool samples (83 in the control group and 87 in the treatment group), 44 and 130 follow-up stool samples (65 in the control group and 65 in the treatment group). 45 Interindividual variation was higher at six-months compared to eighteen months. No 46 significant differences in overall community structure (beta diversity (p=0.35), richness 47 (p=0.98) or Shannon Index (p=0.45) were found between treatment groups. However, 55 48 genera were differentially abundant at follow-up (adjusted p-value < 0.01), primarily within 49 the Firmicutes phylum. Analysis of metabolic pathways revealed the chlorinated water group 50 showed significantly higher abundance of antibiotic resistance genes mostly attributable to 51 Escherichia and Klebsiella species.

52 **Conclusion:** Water chlorination induces predominantly minor changes in infant gut 53 microbiome composition; but appears to increase the abundance of antibiotic-resistant genes. 54 While water chlorination remains a vital public health tool for ensuring safe drinking water, 55 our findings underscore the need for continued research into the potential for increased 56 antibiotic resistance and suggest there may be value in exploring alternative disinfectant 57 strategies.

#### 66 **INTRODUCTION**

67 The gut microbiota, a complex ecosystem of microorganisms residing in the gastrointestinal 68 (GI) tract, is essential for healthy development and protection against non-communicable 69 disease. In infancy, environmental factors significantly influence the establishment of this microbiota<sup>1</sup>, with long-term consequences for gut health and disease risk. Dysbiosis, a 70 71 disruption of the normal microbial balance, can lead to altered composition, diversity, and function, potentially allowing harmful species to colonize  $^2$ . This early life dysbiosis has been 72 repeatedly linked to an increased risk of chronic diseases in later childhood, including 73 allergies, asthma, atopic dermatitis, diabetes, obesity, cardiovascular diseases, and 74 neurological disorders <sup>3-5</sup>. Given the global rise in chronic non-communicable diseases, 75 76 understanding the factors that contribute to gut dysbiosis is a critical research priority.

77 One understudied environmental factor with the potential to disrupt infant gut microbiota assembly is early-life exposure to chlorinated drinking water <sup>6</sup>. Water chlorination, a widely 78 79 implemented and effective method for controlling microbial contamination, has been 80 instrumental in safeguarding public health from waterborne diseases. Chlorine-based 81 disinfectants effectively inactivate harmful pathogens such as Legionella pneumophila, Salmonella typhi, and Vibrio cholerae, known to cause severe illnesses<sup>7</sup>. To ensure adequate 82 83 disinfection throughout the distribution system, current practices aim to maintain a controlled 84 residual chlorine level, typically below 5 mg/L<sup>8</sup>, as recommended by international standards. 85 This level is considered sufficient for disinfection while minimizing adverse health effects 86 from disinfection by-products, which are formed when chlorine reacts with organic matter. 87 Notably, current infant feeding guidelines in many countries, including Australia, recommend 88 boiling and cooling tap water before giving it to infants under twelve months of age to 89 minimize potential risks <sup>9</sup>.

90 Previous research in animal models has consistently shown that chlorine exposure alters gut microbiome composition, diversity, and function <sup>10-14</sup>. Additionally, observational human 91 92 studies have revealed associations between household water sources and distinct gut microbiota signatures <sup>6,15</sup>. However, only one intervention study to date has directly 93 examined the impact of chlorine on the gastrointestinal microbiota in children <sup>16</sup>. Conducted 94 95 in a low-middle income urban setting in Bangladesh, this study delivered chlorine via a 96 dosing device fitted to communal taps. Using metagenomic sequencing, the authors found 97 small, age-specific effects on the relative abundance of several human enterobacteria, as well as an increased abundance of antibiotic resistance genes (ARGs) in children aged 15-30 98 months <sup>16</sup>. While these findings support the overall safety of chlorine residuals for the GI 99

100 microbiota, they also suggest heightened susceptibility to alterations in microbial 101 composition and ARG enrichment in children, particularly during specific developmental 102 windows. Whether these effects on the gut microbiome are also evident in high-income 103 settings with more advanced water treatment infrastructure and demographically unique 104 microbiota remains an important unanswered question.

105 This study directly investigates the impact of chlorinated drinking water consumption on the 106 developing infant gut microbiome within a high-income setting. We conducted a randomized 107 controlled trial (RCT) in which six-month-old infants were assigned to receive either 108 chlorinated tap water or de-chlorinated water for twelve months. Our primary objective was 109 to compare measures of microbiome community composition, diversity and functional 110 potential between infants exposed to chlorinated or de-chlorinated water, to identify any 111 chlorine-specific alterations. These findings shed light on the impact of early-life chlorine 112 exposure on the developing microbiota and the potential public health implications.

#### 114 METHODS

#### 115 **Ethics approval and consent to participate**

116 The study protocol was approved by the Ramsay Health Care (RHC) WA | SA Human 117 Research Ethics Committee (EC00266; HREC reference number 1911). Mothers provided 118 written informed consent on behalf of their children. All procedures were conducted in 119 accordance with the Declaration of Helsinki.

120

## 121 Study design

122 The Water Quality and the Microbiome Study (TUMS) is a parallel (ratio 1:1), double-123 blinded randomized controlled trial (RCT), nested within the ORIGINS Project birth cohort <sup>17</sup>. The ORIGINS Project is a longitudinal observational study of 10,000 pregnant women and 124 125 their families, recruited from the Joondalup and Wanneroo communities of Western Australia during pregnancy, and followed until their offspring are five years of age <sup>17</sup>. We recruited six-126 127 month-old infants participating in the ORIGINS Project and randomly assigned them to 128 receive either de-chlorinated tap water (intervention group) or regular tap water (control 129 group) for twelve months. De-chlorinated water was provided via a benchtop water filtration 130 device, while the control group received an identical sham filter that did not alter the 131 chemical composition of the water.

Stool samples were collected from participants at study entry (baseline, six months of age) and again after one year (follow-up, eighteen months of age). Metagenomic sequencing was performed on both samples to profile the gut microbiome. Tap water samples were collected at baseline (prior to filter installation) and post-intervention for detailed chemical analysis. Health assessments were conducted on approximately half of the cohort (opt-in) at twelve months of age as part of the standard ORIGINS Project protocol. The study design is presented in Figure 1.

139

#### 140 Eligibility criteria

Inclusion criteria were: living within the Perth metropolitan area (Western Australia), born healthy, at least 37 weeks' gestation, and using tap water connected to the mains water supply to prepare infant drinks. Exclusion criteria were: participating in another diet-based research study, using bottled or filtered water to prepare infant drinks, using childcare facilities for three or more days per week, planning overseas holidays lasting longer than four weeks, having received antibiotics since birth, or being in their seventh month of life.

## 149 Intervention

150 All participants received a benchtop water filter attached to their kitchen faucet. The 151 intervention group's filters contained a Hi-Tech Optimizer carbon filtration block rated to 152 remove >97% of chloramines and >99% of chlorine, while preserving fluoride. The control 153 group received identical filters with a sediment-only filter that did not alter the chemical 154 composition of the water. Participants were encouraged to use the provided filter for all infant 155 drinks, maintain normal drinking habits, and carry study-supplied filtered water when outside 156 the home. Filter cartridges were rated for 5,000 liters or twelve months to last the study 157 duration. Participants were advised to follow Australian Infant Feeding Guidelines, regardless 158 of group assignment. Pure Water Systems (Burleigh Heads, Queensland, Australia) supplied 159 the intervention devices (unbranded) but did not sponsor this study. Both participants and 160 investigators were blinded during the intervention period.

161

#### 162 **Randomization and blinding**

Following enrolment, participants were randomized to either treatment group 'A' or 'B' using minimization (biased coin; 0.7) stratified by sex, breastfeeding status at recruitment, and mode of delivery. Allocation of filters to treatment groups was done by an independent biostatistician, with both participants and investigators blinded throughout the intervention. The allocator labelled filters, removing identifying information, and revealed group assignments only after data collection was complete. Filters were installed by the principal investigator, and unblinding occurred at completion of the intervention.

170

## 171 Data collection

*House visits*: Home visits were conducted at study entry and post-intervention. Baseline data collection included a study entry questionnaire, stool sample collection, tap water sampling, and filter installation. Post-intervention, a water sample was collected from the filter before removal. Participants returned their stool sample kits via a pre-paid envelope.

Water quality testing: A sample of flushed (30 seconds) tap water was analyzed for heavy metals, major ions, nitrates, pH, phosphates, chloramines, and trihalomethanes at baseline before installing the intervention filter, and at follow-up. On-site testing for free/total chlorine and pH was also conducted using a Hach D300 pocket colorimeter. Sample collection bottles were filled to exclude air and kept out of direct sunlight. Water samples were delivered to accredited facility ChemCentre in Bentley, Perth. *Questionnaires*: Participants completed ORIGINS Project questionnaires providing
 information on antenatal characteristics, water use, child health, breastfeeding, demographics,
 medical history, and diet. Additional questionnaires assessed filter usage at nine, twelve, and
 fifteen months. Data was entered into a secure REDCap database.

186 Health assessments: Infant eczema, recurrent wheeze, and allergen sensitization were 187 assessed at twelve months in a subset of participants who opted for pediatrician visits. Medically diagnosed eczema was defined by typical skin lesions <sup>18</sup> clinically observed by a 188 189 medical practitioner. Recurrent wheeze was defined as more than one separate episode of 190 wheeze symptoms clinically observed by a medical practitioner. Infant allergen sensitisation 191 is defined as a positive skin prick test (with mean weal diameter  $\geq 3$  mm above the control 192 weal size) to at least one food and/or environmental allergen at one year of age. The panel of 193 allergens tested included hen's egg, cow's milk, wheat, fish (tuna), peanut, cashew nut, 194 ryegrass pollen, cat and house dust mite, with histamine and control solutions, using 195 commercial extracts, and in accordance with standard clinical methods.

196 Stool sample collection: Mothers collected stool samples at six and eighteen months using 197 provided stool collection kits that utilized a Copan FLOQSwab in an active drying tube 198 (FLOQSwab-ADT, Copan Diagnostics, Murrieta, CA, USA). Samples were shipped directly 199 to Microba Life Sciences Limited (for storage and processing).

200

#### 201 Laboratory processing and bioinformatics profiling

202 Metagenomic sequencing: DNA was extracted from stool samples and subjected to shotgun 203 metagenomic sequencing and microbiome profiling using standard workflows developed by 204 Microba Life Sciences (Brisbane, Queensland, Australia). A more detailed description of the 205 methodology; DNA extraction, library preparation, and sequencing, has been previously published<sup>1</sup>. To summarise, DNA extraction was performed using a modified protocol, 206 207 optimising the mechanical lysis step, and following the manufacturer's instructions for the 208 QIAmp 96 PowerSoil QIAcube HT Kit (Qiagen 47021) on the QIAcube HT automated 209 extraction system. Samples were required to reach a minimum of  $0.2 \text{ ng/}\mu\text{L}$  to pass quality 210 control requirements. Libraries were prepared according to the manufacturer's instructions 211 using the Illumina DNA Prep (M) Tagmentation Kit and indexed with IDT for Illumina 212 Nextera DNA Unique Dual Indexes Set A-D (Illumina 20027213-16) with a modification to 213 volume to accommodate processing in a 384-well plate format. Nextera XT libraries were 214 pooled in equimolar amounts to create a sequencing pool and assessed using QuantIT 215 (Thermo Fisher Q33120) and visualised by capillary gel electrophoresis using a QIAxcel

DNA High Resolution Kit (Qiagen 929002). Sequencing pools were loaded and sequenced
on a NovaSeq6000 (Illumina) according to manufacturer's instructions and sequenced with 2
x 150bp paired-end chemistry in the Microba accredited laboratories.

219 Raw data processing: Data quality control and processing was performed at Microba Life 220 Sciences Limited. Paired-end DNA sequencing data was demultiplexed and adaptor-trimmed 221 using the Illumina BaseSpace Bcl2fastq2 (v2.20), accepting one mismatch in index 222 sequences. Reads were quality trimmed and residual adaptors were removed using the Trimmomatic v0.39<sup>19</sup> software package with the following parameters: -phred33 223 224 LEADING:3 TRAILING:3 SLIDINGWINDOW:4:15 CROP:100000 HEADCROP:0 225 MINLEN:100. Human DNA was identified and removed by aligning reads to the human genome reference assembly 38 (GRCh38.p12, GCF\_000001405) using bwa-mem v0.7.17 <sup>20</sup> 226 227 with default parameters, except that the minimum seed length was set to 31 (-k31). Human genome alignments were filtered using SAMtools v1.7<sup>21</sup>, with flags -ubh-f1-F2304. Any 228 229 read pairs in which at least one read mapped to the human genome with >95% identity and 230 >90% of the read length were flagged as human DNA and removed. All samples were 231 randomly subsampled to a standard depth of seven million read pairs to standardize the 232 number of reads across all samples to ensure they could be statistically compared.

233 Taxonomic and metabolic Profiling: Species-level metagenomes were assembled using the 234 Microba Community Profiler (MCP) v1.0 (www.microba.com) using the Microba Genome 235 Database (MGDB) v1.0.3 as the genome reference database. Reads were assigned to 236 genomes within the MGDB, and the relative cellular abundance of species clusters were 237 estimated and reported. Quantification of gene and pathway abundance in the metagenomic 238 samples were performed using the Microba Gene and Pathway Profiler (MGPP) v1.0 against 239 the Microba Genes (MGENES) database v1.0.3. MGPP is a two-step process. In step one, all open reading frames (ORFs) from all genomes in the MGDB were clustered against 240 UniRef90<sup>22</sup> release 2019/04 using 90% identity over 80% of the read length with MMSeqs2 241 Release 10-6d92c<sup>23</sup>. To determine metabolic pathways encoded by metagenome profiles, we 242 243 used the Enzyme Commission annotations of MetaCyc<sup>24</sup> pathways using the EnrichM tool 244 (https://github.com/geronimp/enrichM), and identified MetaCyc pathways with a minimum 245 completeness  $\geq 80\%$ . In step two, all DNA sequencing read pairs aligned with one or more 246 bases to the gene sequence from any protein within an MGENES protein cluster were 247 summed. The abundance of encoded pathways of species reported as detected by MCP was 248 calculated by averaging the read counts of all genes for each enzyme in that pathway.

## 251 Statistical analyses

All analyses were performed using R version 4.3.1. All boxplots represent the first and third quartiles, with a median as a middle line and whiskers at the last value within a  $1.5 \times IQR$ distance from the upper or lower quartile, where IQR is the interquartile range. An alpha level 0.05 was used to define statistical significance for unadjusted and adjusted p-values as appropriate.

257 *Sample size:* Our sample size was based on a previously published randomized control 258 crossover intervention, which investigated the effects of alkaline and neutral water pH on 259 faecal microbiota in 29 Danish men. The authors noted that their post hoc analysis indicated a 260 sample size of 180 would have 80% power to detect differences alpha diversity at a p-value 261 of  $0.05^{25}$ .

*Study outcomes:* The primary outcome of this study was the difference in infant gut microbiome composition between the intervention and control groups, measured from stool samples collected at six and eighteen months of age. Secondary outcomes included the incidence of allergic sensitization, wheeze, and atopic eczema, as assessed by physician diagnosis at 12 months of age.

*Community comparison:* The overall composition of the gut microbiome was visualized
 using taxonomic bar plots of the average relative abundance of the top eight most abundant
 phyla. Data were stratified by age and intervention group.

Diversity analysis: Diversity measures were calculated using the phyloseq R package
 (version 1.38.0) <sup>26</sup>. The Shannon index and observed richness were used to estimate alpha
 diversity

- and differences between groups was assessed using the Kruskal-Wallis test, followed by
  Dunn's post hoc test with Bonferroni correction for multiple comparisons. Beta diversity was
  calculated using the Bray-Curtis dissimilarity index, and non-metric multidimensional scaling
  (NMDS) was employed to visualize beta diversity. Permutational multivariate analysis of
  variance (PERMANOVA) was used to formally test for differences in beta diversity between
  groups <sup>27</sup>.
- 279 Differential analysis: To identify differentially abundant amplicon sequence variants (ASVs)
- and metabolic pathways between the intervention and control groups at 18 months of age, we
- utilized DESeq2 (version 1.40.2)  $^{28}$ . This approach models count data using a negative
- binomial distribution and applies a Wald test for significance. ASVs present in at least 5% of
- samples (n=9/170) and with a total count exceeding 1000 were considered for analysis, and

taxonomic classification was determined at the species level. P-values were adjusted for
multiple comparisons using the Benjamini-Hochberg false discovery rate (FDR) correction.
Similarly, differentially abundant MetaCyc pathways between groups were identified using
DESeq2. Data visualization was performed using the R packages phyloseq (24), microViz
(version 0.10.0) (27), ggplot2 (version 3.4.0) (28), and ggstatsplot (package version 0.12.2)
(29).

290

SAGER guidelines. Subject sex was recorded in clinical notes as parent-reported male or female. Regression modelling was adjusted for sex such that findings are generalizable to both sexes.

294

**Inclusion and Ethics.** This research was conducted in partnership with local researcher consumers who were involved in the design, data collection, analysis and reporting of the study. The research is locally relevant, and the study protocol was acceptable to parents and local IRB.

#### 300 **RESULTS**

## 301 Study Design and Participant Flow

302 Recruitment occurred between November 2019 and March 2022, enrolling 197 participants 303 randomized to the control (n=98) or treatment (n=99) groups. Baseline characteristics were 304 balanced between groups, including sex, delivery method (assisted vaginal, unassisted 305 vaginal, elective caesarean, or emergency caesarean), and breastfeeding status at recruitment 306 (predominantly formula-fed, predominantly breastfed, or mixed-fed), as shown in Table 1. 307 Further demographic details on the cohort were described previously (ref). During the study, 308 76 adverse events (AEs) were reported, defined as instances where a participant presented to 309 hospital for any reason. These were mostly due to unrelated common childhood infections or 310 injuries. Two participants experienced serious adverse events (SAEs) including anaphylaxis, 311 and septic arthritis which were assessed and deemed unrelated to the intervention.

312 Of the 426 infants assessed for eligibility, 229 were excluded (Figure 2). Reasons for 313 exclusion included: not meeting inclusion criteria (n=190), declining participation (n=36), 314 residing outside the eligible area (n=1), and logistical constraints preventing the initial home 315 visit (n=1). Of the 197 randomized participants, 10 did not receive the intervention (4 316 treatment, 6 control) due to filter incompatibility with their tap fittings. A total of 130 317 participants (66%) completed the study and provided stool samples at 18 months of age.

Among those with 12-month health assessment data available, no significant differences were observed in health outcomes between intervention and control groups, including antibiotic use (Table 1). Due to the logistical disruptions related to the COVID-19 pandemic, the rate of missing data in these health outcomes was high (approximately 50%).

322

## 323 Effectiveness of the Intervention on Water Quality

Participants primarily resided in the northern regions of Perth, Western Australia (Figure 3A). Pre- and post-intervention water samples were collected from 83 and 57 treatment group households, and 82 and 57 control group households, respectively. Pre-intervention total chlorine levels varied across homes (0.3-1.1 mg/L), but all were below the 5 mg/L recommended by the Australian Drinking Water Guidelines (Figure 3A). Disinfection byproducts (bromoform, bromodichloromethane, chloroform, chlorodibromomethane) also varied at baseline but remained below recommended levels (Supplementary Figure 1).

The intervention significantly reduced total chlorine levels in the treatment group from a mean of 0.74 mg/L (SD = 0.2447) pre-intervention to 0.10 mg/L (SD = 0.000) postintervention (paired t-test,  $p = 2.2^{-16}$ ). In contrast, the control group showed no significant change in mean total chlorine levels (0.71 mg/L pre-intervention vs. 0.63 mg/L postintervention, paired t-test, p = 0.06). The intervention also significantly reduced bromoform, bromodichloromethane, and chlorodibromomethane levels, while the control group showed no significant changes in these disinfection by-products (Figures 3C, 3D, and 3E).

338 Participant compliance with the intervention, assessed through three monthly surveys, 339 revealed no significant differences between the treatment and control groups. Survey 340 questions encompassed the daily consumption of filtered water (cups per day) by the infant 341 (mean in control group=3.1, mean in intervention=2.9, P=0.06, Welch t-test), usage of study-342 provided filters outside the home (never, sometimes, always, P=0.574, Chi-Squared test), and 343 the age at which unboiled tap water was introduced (mean in control group=10.71, mean in 344 intervention=10.60, P=0.781, Welch t-test). These findings suggest consistent adherence to 345 the intervention protocol across both groups (Supplementary Figure 2).

- 346
- 347

## 348 Microbial community profiling

We analysed 170 stool samples collected at baseline (six months of age) and 130 samples collected at follow-up (18 months of age), totalling 300 unique faecal metagenomes. Batch effect analysis did not identify any significant differences in microbial community composition between sequencing batches (Supplementary Figure 3).

353 After quality filtering and rarefaction to 7,000,000 read pairs per sample, a total of 354 3,936,112,872 reads were obtained (mean per sample:  $12,990,472 \pm 301,687$  SD). On 355 average, 47,087 human DNA reads per sample (SD  $\pm$  655,372) were removed before 356 analysis. Across all samples, we identified 1,305 bacterial ASVs classified at the species 357 level, belonging to 420 genera, 98 families, 42 orders, 17 classes, and 14 phyla. Additionally, 358 we identified two archaeal ASVs (Methanobrevibacter smithii and Methanobrevibacter 359 smithii\_A) and ten eukaryotic ASVs (various Candida, Clavispora, Geotrichum, 360 Kluyveromyces, Saccharomyces, Wickerhamiella, and Blastocystis species).

361

#### 362 Effect of chlorinated water on microbiota taxonomic structure and diversity

The taxonomic characterization of participants' microbiota aligned with previous reports on young infants, with *Bifidobacterium infantis*, *Bifidobacterium longum*, and *Bifidobacterium breve* as the predominant species at six months of age <sup>29,30</sup>. Interindividual variation in microbiome composition decreased from baseline to follow-up (Supplementary Figure 4). 367 While at each timepoint both groups displayed similar phylum-level structures (Figure 4A),

these structures overall changed significantly from baseline to follow-up.

Beta diversity analysis revealed significant variation associated with age (11.3% of variance explained, PERMANOVA, p = 0.001), but no significant clustering by treatment group (0.6% of variance explained, p = 0.35) in both longitudinal (Figure 4B) and cross-sectional analyses (Supplementary Figure 5). Alpha diversity was not significantly different between treatment groups at either time point (observed richness index p = 0.98, Shannon diversity index p =

- 374 0.45) (Figures 4C & 4D).
- 375

## 376 Water chlorination-induced shifts in taxa abundance

377 Differential abundance analysis using DESeq2 revealed 55 genera across 7 phyla were 378 significantly different in abundance between the intervention (de-chlorinated water) and 379 control (chlorinated water) groups in the 18-month (post-intervention) stool samples 380 (adjusted p-value < 0.01) (Figure 5). These differentially abundant genera were primarily 381 members of the Firmicutes phylum. However, due to high inter-individual variation, most of 382 these taxa were present at low frequencies in both groups, although they were more 383 frequently detected in the intervention group (Supplementary Figure 6). A comprehensive list 384 of all differentially abundant ASVs, along with their statistical significance, is provided in 385 Supplementary Table 1.

386

#### 387 Higher antibiotic resistance gene abundance in children receiving chlorinated water

To assess the impact of water chlorination on gut microbiome function, we analysed the 388 abundance of metabolic pathways annotated in the MetaCyc database  $^{24}$  using DESeq2  $^{28}$ . In 389 390 the 18-month (post-intervention) samples, we identified 901 metabolic pathways belonging to 391 51 major groups. Two of these groups were differentially abundant between the intervention 392 and control groups, with chlorinated water exposure most significantly associated with 393 higher abundance of the 'Antibiotic Resistance' major group, as well as the sundry group 394 'Other' (adjusted p < 0.05) (Figure 6A, Table 2). At the pathway level, 29 metabolic 395 pathways were upregulated in the chlorinated water group (adjusted p < 0.05), including 396 polymyxin resistance which has membership in the Antibiotic Resistance major group 397 (Figure 6B, Table 2). To determine which species contributed to increased expression of 398 antibiotic resistance genes, we examined the species abundance in individual microbiomes 399 that were annotated to the MetaCyc "Antibiotic Resistance" functional pathway. This analysis 400 revealed that antibiotic resistance genes were distributed across multiple species, including

- 401 Escherichia, Klebsiella, Enterobacter, Clostridia, and Citrobacter, among others
- 402 (Supplementary Figure 7).
- 403
- 404

#### 405 **DISCUSSION**

406 In this double-blinded randomized controlled trial conducted in a high-income setting, infants 407 exposed to chlorinated drinking water exhibited no differences in the overall richness and 408 diversity of the microbiota, although subtle shifts in taxonomic abundance were observed. 409 Several species known to be part of a healthy gut microbiome, including *Bacteroides*, 410 *Clostridium*, and *Blautia* showed reductions in taxonomic abundance. While some beneficial 411 bacteria like Faecalibacterium prauznitzii and Bifidobacterium increased in abundance, 412 others Streptococcus, Clostridia and Klebsiella pneumoniae also increased, which could be 413 opportunistic pathogens under certain circumstances. It is important to note that carriage of 414 differentially abundant taxa was generally low across the cohort against a background of 415 strikingly individualized microbiota compositions in this age group. On balance, our data 416 suggest chlorination-induced shifts in the microbiota vary substantially from infant to infant, 417 possibly due to a range of factors including genetics, diet and environmental exposures.

Consistent with the recent study by Nadimpalli<sup>16</sup>, we found that exposure to chlorinated 418 419 drinking water for a 12-month period was associated with a higher carriage of antibiotic 420 resistance genes in stool samples. These ARGs, which encompass genes encoding efflux 421 pumps and antibiotic-degrading enzymes, were detected across diverse bacterial species, 422 including Escherichia, Klebsiella, Enterobacter, Clostridia, and Citrobacter. While not 423 directly indicative of antibiotic-resistant species, this finding aligns with the Bangladeshi trial 424 suggesting chlorinated water may selectively promote the growth of bacteria harbouring these 425 genes. It's noteworthy that the age group in the previous study where chlorination effects 426 were observed (15-30 months) overlaps with the age range of our study participants. This 427 suggests there might be specific developmental windows during which the gut microbiome is 428 particularly susceptible to the influence of chlorinated water. Further investigation is required 429 to ascertain the potential for the development or spread of antibiotic resistance in this 430 population.

431 Our study has limitations, including a relatively small sample size and the inability to draw 432 definitive conclusions about infant health outcomes. Antibiotic use, recorded in 433 approximately one-third of participants equally across both groups, could not be controlled 434 for in a per-protocol analysis due to power limitations. While compliance and water 435 consumption practises were monitored, the potential for unmeasured confounders is 436 acknowledged. Individual exposure patterns likely varied due to the complexities of Perth's 437 water distribution network. Additionally, our findings cannot be solely attributed to chlorine, 438 as the study filters also removed nitrates, heavy metals, and disinfection by-products. The

439 potential for unmeasured confounders related to diet or socioeconomic status is also440 acknowledged.

441

#### 442 CONCLUSION

443 Our study extends previous findings and provides valuable insights into the impact of 444 chlorinated drinking water on the infant gut microbiota. These findings are particularly 445 relevant to the current Australian Infant Feeding Guidelines, which recommend introducing 446 unboiled tap water at twelve months. Considering the high plasticity of the infant gut 447 microbiome until three years of age, our findings raise questions about the potential benefits 448 of continuing to boil or filter tap water to remove chlorine residuals until later ages. Further 449 research is needed to explore the potential for increased antibiotic resistance.

## 451 FUNDING STATEMENT

This work was supported by Telethon Kids Institute Blue Sky award 2018. Individual authors are supported by: DM work was supported by the Western Australian Future Health Research and Innovation Fund, which is an initiative of the WA State Government. VV work was supported by the funding endowed by the Family Larsson-Rosenquist Foundation. DJP was supported by the NHMRC Medical Research Futures Fund (MRFF) Career Development Fellowship ID1144544 (2018-2021) and the Telethon Kids Institute Ascend Fellowship (2022-2026).

459

#### 460 INSTITUTIONAL REVIEW BOARD STATEMENT

The study was conducted in accordance with the Declaration of Helsinki and was completed in accordance with the ethical guidelines of the Ramsay Health Care (RHC) WA | SA HREC (EC00266) and under the approved HREC reference number 1911 (approved 14 June 2019).

465

#### 466 INFORMED CONSENT STATEMENT

467 468

#### 469 DATA AVAILABILITY STATEMENT

470 Raw data supporting the conclusions of the article will be make available by the471 authors upon request.

Informed consent was obtained from all subjects involved in the study.

#### 473 COMPETING INTERESTS STATEMENT

The authors declare that this study received funding from the Water Corporation WA. This funding was used to support the costs associated with home tap water analysis and metagenomic sequencing. The funder had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript. The authors declare no other potential conflicts of interest.

479

#### 480 ACKNOWLEDGEMENTS

The authors gratefully acknowledge the invaluable contributions of the ORIGINS Project families for their ongoing support of The Water Quality and Microbiome Study (TUMS). We extend our sincere thanks to the following teams and individuals who have made The ORIGINS Project possible: The ORIGINS Project team; Joondalup Health Campus (JHC); members of ORIGINS Project Community Reference and Participant Reference Groups; Research Interest Groups and the ORIGINS Project Scientific Committee; Telethon Kids Institute; City of Wanneroo; City of Joondalup; and Fiona Stanley.

488 We are also grateful for the contributions of Richard Theobald (WA Department of 489 Health) for advice on water quality testing and study design considerations; the Telethon 490 Kids Biostatistics team (Ali Hollingsworth, Zac Dempsey) for their assistance with 491 randomisation, blinding and compliance monitoring; Nikki Schultz for her analysis of the 492 compliance data, the Water Corporation WA (Cameron Gordon, Steve Christie, Gabrielle 493 O'Dwyer) for their interest, advice, and engagement with the study. We acknowledge the 494 support of our research partners, Microba Life Sciences, ChemCentre and Pure Water 495 Systems for their additional in-kind support of the project. We would also like to thank Jen 496 Rozier from Telethon Kids Institute for the geospatial mapping analysis, and Cynthia Joll 497 from Curtin University for her expertise and advice on water quality guidelines in Australia.

**Figure 2. CONSORT flow diagram of participant recruitment, enrolment, allocation, follow-up, and analysis.** This diagram illustrates the flow of participants through the different stages of the TUMS randomized controlled trial. It shows the number of infants assessed for eligibility, reasons for exclusion, randomization into the intervention and control groups, loss to follow-up, and the final number of participants included in the analysis.

592

593 Figure 3. Impact of the intervention on water quality in TUMS participant homes. A 594 geospatial heatmap map displaying mean total chlorine levels (mg/mL), grouped by suburb. 595 Total n=197 (A). Boxplot comparison between mean levels of total chlorine (B) and 596 disinfection bromoform (**C**), bromodichloromethane by-products: **(D)**. and 597 chlorodibromomethane (E) between the treatment and control groups. The box indicates the 598 interquartile range (25th to 75th percentile), the horizontal line within the box represents the 599 median, and the whiskers extend to 1.5 times the interquartile range. Outliers are shown as 600 individual points. Total n=140.

601

602 Figure 4. No effect of chlorinated drinking water on the taxonomic structure and 603 diversity of the infant gut microbiome. (A) Average relative abundance of bacterial phyla 604 across all samples, stratified by age (6 and 18 months) and treatment group (chlorinated or 605 de-chlorinated water). (B) Non-metric multidimensional scaling (NMDS) plot visualizing 606 beta diversity (inter-sample dissimilarity) based on Bray-Curtis distances. Each point 607 represents a sample, colored by age and shaped by treatment group. (C) Boxplots comparing 608 observed richness (number of unique genera) between treatment groups at 6 and 18 months of 609 age. (D) Boxplots comparing Shannon diversity indices (a measure of both richness and 610 evenness) between treatment groups at 6 and 18 months of age. The boxes indicate the 611 interquartile range (25th to 75th percentile), the horizontal line within the box represents the 612 median, and the whiskers extend to 1.5 times the interquartile range. Outliers are shown as 613 individual points.

614

Figure 5. Differential abundance of bacterial genera in infant gut microbiota between
 treatment groups. The dot plot displays the log2 fold change in abundance for each bacterial

617 genus identified as significantly different (adjusted p-value < 0.01) between the de-618 chlorinated water (intervention) and chlorinated water (control) groups at 18 months of age. 619 Each dot represents a genus, coloured by phylum. A positive log2 fold change indicates 620 higher abundance in the intervention group, while a negative value indicates higher 621 abundance in the control group. Data are plotted at the genus level for ease of visualisation.

622

623 Figure 6. Impact of water chlorination on infant gut microbiome metabolic pathways. 624 (A) Volcano plot displaying the differential abundance of MetaCyc metabolic groups 625 between the de-chlorinated water (intervention) and chlorinated water (control) groups. Each 626 point represents a metabolic group, with the x-axis showing log2 fold change and the y-axis 627 showing -log10 adjusted p-value. Red points indicate groups with significantly higher 628 abundance in the control group (adjusted p < 0.05). (B) Volcano plot displaying the 629 differential abundance of individual MetaCyc metabolic pathways between the intervention 630 and control groups, following the same format as panel A.

631

Supplementary Figure 1. Geospatial heatmap of disinfection by-products (DBPs).
Visualisation represents DBPs expressed as ug/mL averaged over participant homes and
represented at the suburb level.

635

636 Supplementary Figure 2. Participant compliance with the intervention assessed through 637 three-monthly questionnaires. (A) Frequency of parent-reported consumption of 638 intervention water (n=??). (B) Counts of the frequency that parents report taking intervention 639 water with them when outside the home (n=?). (C) Histogram showing distribution of mean 640 age of introduction of unboiled tap water into the infant diet for intervention and control 641 groups (n=?).

642

643 Supplementary Figure 3. Lack of batch effect on gut microbiota composition. Stool 644 samples were sequenced in two batches. The first batch included all 170 baseline samples and 645 35 follow-up samples. The remaining follow-up samples, along with three follow-up samples 646 re-sequenced from the first batch, were included in the second batch. Non-metric 647 multidimensional scaling (NMDS) ordination demonstrates no significant difference in gut 648 microbial community composition between sequencing batches. Each point represents an 649 individual sample. Red symbols denote three randomly selected samples sequenced in batch 650 1, while blue symbols represent the same three samples re-sequenced in batch 2. The proximity of red and blue symbols for each sample indicates minimal variation introduced bysequencing batch.

653

# 654 Supplementary Figure 4. Inter-individual variation in gut microbiota composition with

age. Taxonomic bar plot illustrating the top twelve most abundant genera at baseline (top)
and at follow-up (bottom), ranked by Bray-Curtis dissimilarity within each time point. Each
bar represents an individual participant, coloured according to the relative abundance of each
genus (x-axis).

659

660 **Supplementary Figure 5. Developmental shifts in gut microbiota composition.** Non-661 metric multidimensional scaling (NMDS) ordination illustrating pairwise genomic distances 662 between samples at (A) six months and (B) eighteen months of age. Each point represents an 663 individual sample. The distinct clustering patterns at different ages suggest significant shifts 664 in gut microbial community structure during early childhood development.

665

666 Supplementary Figure 6. Differentially Abundant Gut Microbiota Associated with 667 Intervention. Box plots display the log-transformed abundance of the top four Amplicon 668 Sequence Variants (ASVs) exhibiting significant differences between the intervention and 669 control groups: (A) *Clostridium MIC*8573, (B) *Bacteroides faecis*, (C) *Bacteroides* 670 *fragilis\_A*, and (D) *TF01-11 sp000436755*.

671

572 Supplementary Figure 7. Antibiotic Resistance Genes in Gut Microbiota Across 573 Treatment Groups. Heatmap depicting the abundance of bacterial species harbouring genes 574 associated with antibiotic resistance (as defined by the MetaCyc database) within the gut 575 microbiome of each infant. Rows represent individual bacterial species, while columns 576 represent treatment groups. Cell color intensity reflects the relative abundance of each species 577 within the respective group, highlighting potential differences in antibiotic resistance profiles 578 among infants receiving different treatments.

## **Most Differentially Abundant Genus**

# Disinfection by-products in Perth suburbs at study intake.

ſ

Chlorodibromomethane

# Parent-reported consumption of study supplied water per day

# NMDS analysis of sequencing batch effect

# Taxa bar plots of baseline samples

Taxa bar plots of 18-month samples

NMDS analysis of treatment main effect

## Log2 Sequencing reads for species annotated to the **Antibiotic Resistance Metacyc pathway**

**Read Counts by Species**
