Hantavirus; Andes virus; Hantavirus pulmonary syndrome; Infection diseases; culture
isolation; Animal model; Hamster; person-to-person transmission.

30

#### 31 Summary

32 On November 2018, a person-to-person transmission outbreak of Andes virus (ANDV) 33 began in the small town of Epuyen, Argentina. The strain involved demonstrated a high 34 capacity for sustained transmission among the human population requiring the 35 implementation of quarantine measures, rigorous contact tracing, isolation of close 36 contacts, and active clinical monitoring to prevent further spread. In this study, we 37 report the isolation of this strain, which we name the ARG-Epuyen after just three 38 passages in cell culture. Complete sequencing revealed only a single amino acid change 39 post-isolation, revealing that it is a non-adapted, wild-type ANDV strain, and its 40 isolation probably represents a critical step toward the development of medical 41 countermeasures against this emerging pathogen. The pathogenicity and transmissibility 42 potential of ARG-Epuyen were evaluated in hamsters, the only animal model for 43 Hantavirus Pulmonary Syndrome. Additionally, this strain was compared with ARG, an ANDV strain previously isolated from the same geographical area in the Argentinian 44 45 Patagonia, from a rodent specimen. Our findings revealed high infectiousness and 46 efficient hamster-to-hamster transmission through direct contact experiments, although 47 ARG-Epuyen appeared to be less pathogenic than ARG.

48 **1. Introduction** 

Hantaviruses (*Bunyavirales: Hantaviridae: Mammantavirinae*) are enveloped, single
stranded, negative sense RNA viruses with three-segmented genome. The genomic
segments consist of a small segment (S), a medium segment (M), and a large segment
(L), which encode the nucleocapsid (N) protein, a nonstructural protein (NSs) in some

53	species, surface glycoproteins (Gn and Gc), and an RNA-dependent RNA polymerase
54	(RdRp), respectively (1). Hantaviruses are distributed worldwide and are hosted by
55	various vertebrate animal species. Pathogenic hantaviruses are primarily associated with
56	rodents as natural reservoirs and are classified under the genus Orthohantavirus. These
57	viruses establish seemingly asymptomatic and chronic infections in several rodent
58	species. The risks of viral spillover have increased due to new farming practices,
59	climate change, the expansion of rural human settlements, and disruptions to the
60	zoonotic interface. Additionally, rural tourism has led to travel-related cases (2-4).
61	Several species of orthohantaviruses are responsible for Hantavirus Pulmonary
62	Syndrome (HPS) in the Americas and Hemorrhagic Fever with Renal Syndrome
63	(HFRS) in Asia and Europe. HPS, first described in 1993 in the US (5), is caused by at
64	least 24 distinct viruses (6). Humans generally become infected through the inhalation
65	of aerosolized rodent excreta. In Argentina, most HPS cases are caused by seven viruses
66	closely related to Andes virus (ANDV), species Orthohantavirus andesense. ANDV
67	was the first hantavirus characterised in Argentina (7) and it was associated with the
68	long-tailed pygmy rice rat Oligoryzomys longicaudatus in the Patagonian Andean
69	region. The signs and symptoms of the disease can manifest after a long period of up to
70	40 days after infection (8,9). ANDV-HPS is associated with high case-lethality rates
71	ranging from 21–50% (10,11).
72	Before 1996, the route of orthohantavirus transmission was considered strictly zoonotic,
73	resulting in "Dead-End" human infections (7). However, in 1996, an ANDV-caused
74	HPS outbreak began in the small city of El Bolsón and then expanded to distant cities,
75	such as Bariloche (121 km) and Buenos Aires (1700 km), involving 16
76	epidemiologically linked cases. This outbreak became a focal point for orthohantavirus
77	research because molecular and epidemiological evidence suggested person-to-person

78	(PTP) transmission (12,13). A larger PTP transmission outbreak that began in 2018 and
79	involved 34 cases, could be curtailed by the implementation of strict quarantine
80	measures. In this outbreak, several individuals were identified as superspreaders,
81	predicting the high transmission potential of this strain (10).
82	To date, no vaccines or therapeutic treatments are available for any HPS agent,
83	therefore, there is an urgent need for vaccine candidates and/or therapeutics. The
84	paucity of vaccine developments relayed for many years on the lack of animal models,
85	due to their zoonotic origin, and on the difficulty to isolate New World Hantaviruses in
86	cell culture. Only three strains of ANDV had been propagated in cell culture (CH-
87	9717869; CH-7913 and ARG). CHI-7913 was obtained from a serum sample of a
88	Chilean patient before the onset of symptoms (14). CH-9717869 and ARG were isolated
89	from long tailed pygmy rice rats captured in Chile and Argentina respectively (15,16). It
90	was first described that CH-9717869, and later ARG, caused a lethal and very similar
91	disease to HPS in Syrian Golden Hamsters (17,18) and, since then, the model
92	ANDV/hamster became a unique resource for the study of HPS. Most recently, the
93	human CHI-7913 strain resulted in an asymptomatic infection in the same animal model
94	suggesting that the lethal ANDV model of HPS is strain specific, reinforcing the
95	necessity to obtain and characterise new human strains of ANDV to understand their
96	pathogenesis in humans (19). In this work we report the isolation in cell culture of the
97	strain responsible for the largest ANDV PTP-transmission outbreak ever reported,
98	ARG-Epuyen. In addition, we performed a preliminary virological characterization of
99	this strain proving its ability to infect hamsters causing high levels of viremia and to
100	spread efficiently between them through direct contact experiments.
101	2. Materials and methods

102 **2.1. Virus isolation on cell culture.** Biological samples involved in this study were 103 obtained during the Ministry of Health activities for the epidemiological investigation of 104 the PTP outbreak form November 2018 to March 2019. The specimens were originally 105 obtained from living individuals in a form that neither the recipient nor the provider can link the biospecimens directly to identifiable private information of the original source. 106 107 Unidentified remnant biological specimens were utilized for virus isolation. The 108 samples with higher viral load and absence of antibodies were selected. Complete 109 genome sequencing revealed 100% nucleotide identity with cases involved in the PTP 110 transmission outbreak (8). The selected serum samples were inoculated onto Vero E6 111 cell monolayer (CRL-1586; ATCC, Manassas, VA, USA) and incubated for one hour at 112 37 °C in a humidified atmosphere containing 5% CO2. After the incubation, fresh complete medium (MEM, 10% FBS, antibiotics, and antimycotics) was added to each 113 flask, and incubated at 37 °C under the same conditions. After 15 days, the cells were 114 115 trypsinized, washed, and seeded onto a new monolayer, and incubated under identical 116 conditions (first blind passage). For each flask, one-third of the cells were stored at -80 117 °C, another third was tested by indirect immunofluorescence assay (IFA), and the final 118 third was seeded onto a new monolayer. The medium was centrifuged, aliquoted, and 119 stored at -80 °C. Three blind passages were performed in total. Each passage was 120 monitored by real-time RT-PCR for ANDV RNA in the culture media and by IFA for 121 detecting viral antigen in the cells. Mock-infected Vero E6 cells, treated under identical 122 conditions, were used as a negative control. 123 **2.2. Immunofluorescence Assay.** Infected and mock-infected cells were resuspended 124 in 1X phosphate-buffered saline (PBS) and washed three times by centrifugation at 400 125 x g for five minutes at 4 °C. The pellets were then resuspended in 1 ml PBS, and several

126  $10 \,\mu$ l drops of each suspension were spotted onto a slide. The slides were left inside a

127	laminar flow cabinet until completely dried. The slides were then immersed in ice-cold								
128	acetone for 10 minutes at -20 °C, removed from the acetone, allowed to dry, and stored								
129	at -20 $^{\circ}$ C until further processing. The slides were blocked with 3% horse serum in								
130	PBS-Triton for 15 minutes at room temperature and then washed with PBS. The cells								
131	were treated with a 1:500 dilution of rabbit polyclonal serum against ANDV in PBS-								
132	Triton-BSA and incubated for one hour at 37 °C in a humid chamber. After washing,								
133	the slides were incubated with FITC-conjugated anti-rabbit IgG (Kirkegaard & Perry) in								
134	PBS-Triton-BSA under the same conditions. Finally, the cells were incubated with 1								
135	$\mu$ g/ml DAPI in PBS for 15 minutes at room temperature and then washed. The slides								
136	were allowed to drain, mounted, and analyzed under a fluorescent microscope.								
137	2.3. Virus infection in Vero E6 and A549 cell lines. Vero E6 and A549 (human								
138	epithelial lung cell, ATCC CCL-185) cells were maintained in Dulbecco's Modified								
139	Eagle's Medium (DMEM high glucose; Sigma) supplemented with 5% fetal bovine								
140	serum (FBS, Gibco), 10 mM HEPES buffer, and 2 mM L-glutamine. The cells were								
141	infected with ARG and ARG-Epuyen at the indicated multiplicity of infection (MOI)								
142	for 60 minutes at 37 $^{\circ}$ C. After incubation, the monolayers were washed three times with								
143	PBS, and the cells were maintained in complete DMEM (Sigma). Supernatants were								
144	collected at various days post-infection, centrifuged to remove cells, and stored at -80								
145	°C until use. Viral RNA was isolated using the Qiagen QIAamp® Viral RNA kit								
146	according to the manufacturer's protocol. Viral growth kinetics were determined by								
147	quantifying ANDV RNA at different days post-infection using real-time RT-PCR as								
148	described below.								
149	2.4. Evaluation of ARG-Epuyen virulence in the hamster model. To evaluate								

150 whether ANDV could be transmitted between hamsters in a manner similar to human

151 transmission, Syrian Golden Hamsters were infected with either the ARG-Epuyen or

152	ARG strains. Seventeen 9-week-old hamsters were distributed across seven ventilated
153	cages. One hamster per cage was infected via intramuscular injection (rear thigh) with
154	100 $\mu l$ (1 $\times$ 10 $^4$ FFU) of ARG-Epuyen passage No. 4 (two males and four females) or
155	ARG passage No. 19 (one male). The infected hamsters were placed in direct contact
156	with one or two non-infected individuals in the same ventilated cages on the day they
157	were inoculated (day 0). As a control group, four hamsters were inoculated with cell
158	culture supernatant from non-infected Vero E6 cells. All individuals were monitored
159	daily for 30 days for signs of disease, including fatigue, inappetence, lethargy
160	(reluctance to move), and/or dyspnea. Animals with fatal outcomes were necropsied on
161	the day of death to collect lung samples, which were stored at -80 $^\circ$ C until processing.
162	On day 30, all survivors were anesthetized by inhalation of isoflurane, terminally bled
163	by cardiac puncture, and necropsied to obtain lung tissue.

Samples were considered IgG positive if ΔOD values were greater than 0.4. The IgG titre was calculated as the inverse of the highest dilution that

176	2.6. Viral RNA detection and genomic sequencing. Total RNA was extracted from
177	lung samples and from the culture medium of infected cell passages using Trizol
178	(Invitrogen) according to the manufacturer's protocol. RT-qPCR was performed as
179	previously described (20). Briefly, each RNA sample was amplified in duplicate using
180	the One Step RT-qPCR qScript kit (Quanta Biosciences) following the manufacturer's
181	instructions. Each reaction mixture contained 12.5 $\mu l$ of 2X Master Mix, 2 $\mu l$ of an
182	oligonucleotide mix designed to amplify the ANDV S-segment (1 $\mu$ M each), 4.75 $\mu$ l of
183	nuclease-free water, 0.5 µl of the ANDV probe (5 FAM-BHQ-3 ), 0.25 µl of qScript
184	One Step RT, and 5 $\mu l$ of template RNA. Reverse transcription was performed at 50 $^{\circ}\text{C}$
185	for 15 minutes, followed by denaturation at 95 $^{\circ}$ C for 5 minutes, and 40 cycles of
186	amplification at 95 $^{\circ}$ C for 15 seconds and 60 $^{\circ}$ C for 60 seconds in a Real-Time PCR
187	Detection System CFX-96 (Bio-Rad, CA). To obtain complete genomic sequences, an
188	amplicon-based method was selected using a one-step RT-PCR strategy to enrich
189	vRNA, followed by library preparation as previously described (21). The library was
190	sequenced on a MiSeq sequencing platform (Illumina, San Diego, CA) using 2 x 151-bp
191	paired-end sequencing. Bioinformatic analysis was performed as described previously
192	(8).
193	2.7. Biosafety precautions and Ethics statements. The entire procedure of viral
194	isolation, subsequent propagation, and sample analysis before viral inactivation was
195	conducted at the biosafety level 3 facility at the Unidad Operativa Centro de Contención
196	Biológica (UOCCB-ANLIS). All procedures involving human samples for viral
197	isolation used in this study were approved by the Bioethics Committee, Area
198	Programatica Comodoro Rivadavia, Chubut province, to ensure compliance with ethical
199	standards. All procedures involving animal handling were carried out within an animal

200	biosafety level 3 facility at UOCCB-ANLIS and hamsters were housed in ventilated									
201	cage racks. Research was conducted in compliance with institutional guidelines									
202	and the national law no.: 14,346, that regulates experiments involving animals, and									
203	adheres to principles stated in the Guide for the Care and Use of Laboratory Animals,									
204	National Research Council, 2011 (22). An institutional committee for animal use and									
205	care approved the protocols used.									
206	3. Results									
207	3.1. A new strain of Andes virus was isolated in cell culture from a human serum									
208	<b>sample.</b> A human serum sample with a high viral load ( $6.3 \times 10^7$ copies/ml) and no									
209	detectable specific antibodies against ANDV, was selected to infect a Vero E6 cell									
210	monolayer. After three blind passages, viral RNA was detectable in the supernatant of									
211	the infected cell culture ( $2.5 \times 10^8$ copies/ml). Infection was confirmed in the cells by									
212	IFA, showing the presence of viral antigen in approximately 50% of the cells in passage									
213	No. 3 and 80% in passage No. 4 (p4) (Figure 1). A large viral stock was prepared from									
214	the supernatant of passage No. 3, as described above, for use in subsequent experiments.									
215	The infectious titre of the viral stock obtained was $2.1 \times 10^6$ FFU/ml. This new strain									
216	was designated as ARG-Epuyen.									
217	3.2. ARG-Epuyen and ARG showed differential kinetics of replication and									
218	infectivity in cell cultures. The growth kinetics of the ARG and ARG-Epuyen strains									
219	were first assessed in Vero E6 cells using an MOI of 0.002 (Figure 2). Quantification of									
220	viral RNA in the culture supernatants of cells infected with each strain showed that									
221	ARG replicates faster than ARG-Epuyen. Both strains produced high levels of									
222	infectious viral particles, with the maximum level observed for ARG, which reached up									
223	to $2.1 \times 10^7$ FFU/ml, whereas ARG-Epuyen did not exceed $2.1 \times 10^6$ FFU/ml (Figure									
224	2B). The growth kinetics were then compared using the epithelial cell line A549 with a									

225 higher MOI. The results were consistent, showing that ARG replicates faster than ARG-

Epuyen in both Vero E6 and A549 cells (Figure 3).

## 227 **3.3. Both strains of Andes virus are highly transmissible in Hamsters.** Seven Syrian 228 Golden hamsters of different sexes (3 males: MI; 4 females: FI) were inoculated intramuscularly with high doses of ANDV (approximately $1 \times 10^4$ FFU) and placed in 229 230 separate cages with one or two non-inoculated cage-mates (receptors: MR and FR). 231 During the 30 days post-infection (p.i.) period, neither the hamsters inoculated with 232 ARG-Epuyen (n=6) nor the receptors exposed to them (n=9) showed any visible signs 233 of illness. However, infection was confirmed in all of them through seroconversion 234 and/or genomic RNA detection in lung tissues (Table 1). In contrast, the single hamster 235 inoculated with ARG (MI-1) exhibited inappetence and lethargy starting from day five p.i., and dyspnea was evident from day 13 to day 16 p.i. After 11 days of illness, MI-1 236 237 gradually improved and fully recovered by the end of the experiment. However, the two 238 hamsters exposed to MI-1, MR-1 and MR-2, became ill 16 and 22 days after the onset 239 of symptoms in MI-1, respectively, and both rapidly died. After 30 days p.i., all the survivors were sampled and sacrificed. The six index hamsters showed a strong humoral 240 241 response (IgG titers >25,600), while four out of 11 of their cage-mates (receptors) exhibited low to moderate IgG titers. Nevertheless, all of them (n=11) were infected, as 242 evidenced by the detection of viral RNA in blood (up to $1.5 \times 10^7$ RNA copies/ml) 243 244 and/or in lung tissues (up to $1.6 \times 10^8$ copies/100 ng RNA). 245 **3.4. ARG-Epuyen grew in cell culture without need of adaptation.** To analyze 246 potential changes that could lead to viral adaptation for growth in cell culture and 247 replication in hamsters, the complete genomes of the isolated virus (p4) and from the 248 lung of an infected hamster (MI-3) were sequenced and compared with the previously 249 published sequence from the human sample (GenBank MN258238, MN258204,

250	MN258171). The isolated strain ARG-Epuyen p4 showed only one nucleotide change in							
251	the non-coding region of the S segment (position 1522) and one non-synonymous							
252	change, K2116E, in the L segment (A6381G). No changes were observed between the							
253	isolated strain (p4) and the virus recovered from the infected hamster.							
254	To investigate the molecular basis for the observed differences in pathogenicity between							
255	ARG-Epuyen (p4) and ARG (p19) in the hamster model, we compared the complete							
256	sequences of both strains. We identified 25 non-synonymous substitutions: three in the							
257	S segment (one in the N ORF and two in the NSs ORF), 10 in the M segment (six in Gn							
258	and four in Gc), and 12 in the L segment (Table 2).							
259	4. Discussion.							
260	The limited progress in vaccine development and other medical countermeasures							
261	(MCMs) against hantaviruses has been partly due to restricted access to wild-type viral							
262	strains and the lack of appropriate animal models of the disease. Additionally, no							
263	reverse genetic system for hantaviruses has been reported to date. Generally, in vivo and							
264	in vitro studies of hantavirus infections have been conducted using cell-cultured strains							
265	derived from moderate to high passage numbers. The success of MCM development							
266	depends on selecting strains that are actively circulating and have proven pathogenicity							
267	in humans.							
268	Following the COVID-19 pandemic, the National Institute of Allergy and Infectious							
269	Diseases proposed a prototype pathogen approach to develop a generalizable MCM							
270	strategy. This approach can be applied to other viruses within the same viral family,							
271	enabling the rapid development of MCMs and shortening the timeline between							
272	pathogen outbreak and regulatory authorization if a virus with similar properties							
273	emerges. ANDV has been mentioned as a prototype pathogen of the Hantaviridae							
274	family and should be considered for vaccine development and pre-clinical and clinical							

testing (23,24). For these purposes, the availability of well-characterized ANDV strainsis critical.

277	In this work, we described the isolation of the strain responsible for the largest ANDV
278	PTP transmission outbreak, which occurred in the small town of Epuyen and began on 2
279	November 2018. This strain, ARG-Epuyen, exhibited a high capacity for PTP
280	transmission, necessitating the implementation of quarantine measures to curtail further
281	spread (8). The median reproductive number (the mean number of secondary cases
282	caused by an infected person) was 2.12 before control measures were implemented and
283	subsequently dropped to below 1.0 by late January. Early intervention allowed for the
284	collection of samples leading to the isolation of this new ANDV strain from an
285	asymptomatic case. An early passage of this strain was sequenced, revealing only one
286	amino acid difference from the virus recovered from the patient, indicating that it can be
287	considered a wild-type strain. Like the ARG strain, this strain was able to grow in a new
288	host without needing adaptation (25).
289	Two of the three previously isolated ANDV strains in cell culture caused lethal disease
290	in hamsters (17–19,25). Although this animal model has become crucial for studying
291	the pathogenesis of HPS, the spreading capacity and horizontal transmission of ANDV
292	have only been evaluated in one previous study with the CH-9717869 strain (26). In this
293	study, we assessed the pathogenicity and spreading capacity of the strain responsible for
294	sustained PTP transmission in this animal model and compared it with the highly lethal
295	ARG strain in direct exposure experiments. All hamsters-both those directly
296	inoculated and those exposed to infected hamsters-became infected. Our data
297	indicated that ARG-Epuyen was less virulent than ARG, as none of the six index
298	hamsters inoculated with ARG-Epuyen developed severe disease during the 30-day
299	period, despite showing high viral titres in blood and lungs. However, as five hamsters

300	exposed to the index hamsters were sacrificed during the incubation period-when they									
301	had no IgG titres and rising viral RNA loads in blood and lungs-their final outcomes									
302	could not be assessed. We demonstrated that both ARG and ARG-Epuyen were highly									
303	transmissible in direct exposure experiments. Although the mechanism of transmission									
304	remains to be confirmed through indirect exposure experiments, we hypothesize that the									
305	route was likely respiratory or digestive, due to the absence of wounds in the animals.									
306	Further studies are required to assess the pathogenic characteristics of this strain in the									
307	animal model.									
308	Our preliminary data revealed differences in lethality between the two Argentinean									
309	strains. A previous comparative study of two Chilean strains found similar results. The									
310	strain obtained from a human serum sample (CHI-7913) caused an asymptomatic									
311	infection in hamsters, while the strain obtained from a rodent (CHI-9717869) was									
312	highly lethal (19). The molecular basis for the observed differences in pathogenesis									
313	between these strains was evaluated through in silico studies (19,25). However, the									
314	specific differences observed need further investigation through directed mutagenesis									
315	experiments. The N protein plays no role, as both strains share 100% identity. In vitro									
316	studies suggested that ANDV virulence could be determined by its ability to alter									
317	cellular signalling pathways by restricting the early induction of beta interferon (IFNB)									
318	and IFN-stimulated genes (ISGs) (26-28). Additionally, compared with other									
319	pathogenic hantaviruses, ANDV is unique in that three viral proteins-N, NSs, and									
320	Gn/Gc—can block the same signalling pathway at different levels. However, the few									
321	differences found in the Gn/Gc between the strains seem to be located outside									
322	conserved motifs or domains involved in the regulation of the IFNB response. Further									
323	characterization of the NSs and RdRp proteins is needed to evaluate the effects of the									
324	observed changes.									

325	As a result of comparing the complete sequences of both ANDV strains, several amino
326	acid changes were predicted. None of the substitutions represented drastic changes that
327	could affect key motifs already described for the structural conformation and/or
328	function of the N, Gn/Gc, and RdRp proteins. Exceptions included the changes P97S
329	and T641I in the M-segment; the P residue is in the Gn ectodomain and may impact the
330	flexibility of a loop structure, affecting recognition by some immune response
331	components and/or interaction with cell receptors. The T641I change, located in an
332	alpha-helix structure near the WAASA motif, may result in the loss of an oxygen
333	molecule capable of forming a hydrogen bond with the adjacent residue C642.
334	In conclusion, we obtained a low-passaged isolate of a prototype pathogen: ANDV. The
335	new strain, ARG-Epuyen, is a well-characterized isolate due to its known outcome in a
336	recent HPS outbreak and its high PTP transmission potential. Furthermore, the isolation
337	was obtained directly from a clinical sample with a low number of passages (p=4) and
338	only one amino acid change. Therefore, it can be considered an ANDV wild-type strain,
339	representing a critical step toward developing MCMs against this emerging pathogen.
