Abstract

As observed in the case of COVID-19, effective vaccines for an emerging pandemic tend to be in limited supply initially and must be allocated strategically. The allocation of vaccines can be modeled as a discrete optimization problem that prior research has shown to be computationally difficult (i.e., NP-hard) to solve even approximately. Using a combination of theoretical and experimental results, we show that this hardness result may be circumvented. We present our results in the context of a metapopulation model, which views a population as composed of geographically dispersed heterogeneous subpopulations, with arbitrary travel patterns between them. In this setting, vaccine bundles are allocated at a subpopulation level, and so the vaccine allocation problem can be formulated as a problem of maximizing an integer lattice function $g: \mathbb{Z}_+^K \to \mathbb{R}$ subject to a budget constraint $||\mathbf{x}||_1 \leq D$. We consider a variety of simple, well-known greedy algorithms for this problem and show the effectiveness of these algorithms for three problem instances at different scales: New Hampshire (10 counties, population 1.4 million), Iowa (99 counties, population 3.2 million), and Texas (254 counties, population 30.03 million). We provide a theoretical explanation for this effectiveness by showing

> that the approximation factor of these algorithms depends on the submodularity ratio of objective function g , a measure of how distant g is from being submodular.

Author summary

Strategic and timely allocation of vaccines is crucial in combating epidemic outbreaks. Developing strategies to allocate vaccines over sub-populations rather than to individuals leads to policy recommendations that are more feasible in practice. Despite this, vaccine allocation over sub-populations has only received limited research interest, and the associated computational challenges are relatively unknown. To address this gap, we study vaccine allocation problems over geographically distinct subpopulations in this paper. We formulate our problems to reduce either i) the total infections or ii) the sum of peak infections over meta-population disease models. We first demonstrate that these problems are computationally challenging even to approximate and then show that a family of simple, well-known greedy algorithms exhibit provable guarantees. We conduct realistic experiments on state-level mobility networks derived from real-world data in three states of distinct population levels: New Hampshire, Iowa, and Texas. Our results show that the greedy algorithms we consider are i) scalable and ii) outperform both state-of-the-art and natural baselines in a majority of settings.

Introduction

In the early stages of a pandemic like COVID-19, the demand for vaccinations far exceeds supply $[1, 2]$ $[1, 2]$ and it is critical to strategically allocate vaccines $[3, 4]$ $[3, 4]$. The vaccine allocation problem can be modeled in a variety of ways, including as discrete ⁴ optimization problems $[5-9]$ $[5-9]$. However, all of these problems are computationally hard, even to solve approximately (see $[10]$, for a specific example). Despite these obstacles, we need to be able to solve vaccine allocation problems at scale and have confidence that the obtained solutions are close to being optimal. In this paper, we take steps ⁸ towards this goal.

We consider the metapopulation-network model for disease-spread $[11, 12]$ $[11, 12]$, which $\frac{10}{2}$ allows for heterogeneity among geographically distinct subpopulations and arbitrary 11

> travel patterns between them. Vaccine allocation within this model consists of 12 allocating some number of bundles of vaccines to each subpopulation while satisfying an 13 overall budget constraint. The resulting family of problems, which we call the ¹⁴ *Metapopulation Vaccine Allocation (MVA)* problems, can be formalized as maximizing $_{15}$ an objective function (e.g., number of cases averted) defined over an integer lattice $\frac{1}{16}$ domain subject to a budget constraint. Not surprisingly, we show specific problems 17 obtained via realistic instantiations of the metapopulation-network model and objective ¹⁸ function in MVA are not just NP-hard, but even hard to approximate. We show these ¹⁹ hardness results for two instantiations, which we call MAXCASESAVERTED and 20 $\text{MaxPEAKSREDUCED},$ of MVA over SEIR (Susceptible-Exposed-Infected-Recovered) $_{21}$ metapopulation models $[11, 12]$ $[11, 12]$.

> These hardness of approximation results imply that worst-case approximation ²³ guarantees are not attainable for natural instantiations of MVA. However, for a family $_{24}$ of simple, well-known greedy algorithms, we show positive theoretical and experimental ²⁵ results for both MAXCASESAVERTED and MAXPEAKSREDUCED. These simple and natural greedy algorithms lend themselves to the machinery from submodular function $\frac{27}{27}$ optimization for in-depth analysis. There is a rich literature of methods for submodular ²⁸ set function optimization $[13-18]$ $[13-18]$ that has subsequently been extended to submodular $\frac{29}{29}$ optimization over the integer lattice $[19–22]$ $[19–22]$. Furthermore, in the last few years, researchers have attempted to extend some of the aforementioned results for $\frac{31}{31}$ submodular set and lattice function optimization to functions that are not submodular, $\frac{32}{2}$ by using the notion of *submodularity ratio* of a function, which is a measure of how ³³ distant that function is from being submodular $[23-25]$ $[23-25]$. All of this literature is $\frac{34}{4}$ foundational to our approach to analyzing vaccine allocation algorithms in a ³⁵ metapopulation model setting $[11, 12]$ $[11, 12]$.

> In our main theoretical result, we show that simple greedy algorithms provide $\frac{37}{20}$ worst-case approximation guarantees for MAXCASESAVERTED and 38 MAXPEAKSREDUCED that become better as the *submodularity ratio* of their objective ³⁹ functions approaches 1. The submodularity ratio $[23-26]$ $[23-26]$ of a set or lattice function is a measure (between 0 and 1) of how close the function is to being submodular, with $\frac{41}{100}$ values closer to 1 corresponding to functions that are closer to being submodular. We $_{42}$ complement this theoretical result with experimental results indicating that the ⁴³

> objective functions for MAXCASESAVERTED and MAXPEAKSREDUCED might have relatively high submodularity ratios.

> We then experimentally evaluate the performance of greedy vaccine allocation algorithms at three scales; we use New Hampshire (10 counties, population 1.4 million) $_{47}$ for our small scale experiments, Iowa (99 counties, population 3.2 million) for our ⁴⁸ medium scale experiments, and Texas (254 counties, population 30.03 million) for our large scale experiments. We compare the performance of the greedy methods with a set \sim of trivial baselines, such as allocating vaccines according to population sizes. We also ⁵¹ compare against a randomized algorithm called Pareto Optimization for Subset $\frac{52}{2}$ Selection (POMS) [\[24\]](#page-33-4). POMS works by expanding a random pareto-optimal frontier, $\frac{53}{12}$ and was designed to compete against greedy algorithms for small scale problems. We $\frac{54}{54}$ show the greedy algorithms we consider outperform POMS for our experimental $\frac{55}{55}$ settings, while scaling more readily. Our experiments demonstrate that \mathbf{i}) simple greedy $\frac{1}{56}$ vaccine allocation algorithms outperform the natural baseline algorithms substantially $\frac{57}{2}$ (up to 9M more individuals saved than the worst-performing baseline in some settings), ii) for both MAXCASESAVERTED and MAXPEAKSREDUCED, greedy algorithms perform 59 near-optimally for most problem instances we evaluate for New Hampshire (and recover 60 similar approximation guarantees to those of submodular functions for experiments in ϵ Iowa and Texas), and iii) the fastest of our greedy algorithms are feasible even for large ϵ_{2} scale instances such as the state of Texas. 63

$\rm{Background}$ $\rm{5.5}$ $\rm{5.5}$ $\rm{6.5}$ \rm

Notation. We use \mathbb{Z}_+ to denote the set of non-negative integers and for any positive integer *n*, we use [*n*] to denote the set $\{1, 2, \ldots, n\}$.

Metapopulation disease-spread models A metapopulation disease-spread 68 model $[11]$ generalizes the classic homogeneous-mixing compartmental models $[27]$, by allowing geographically-diverse subpopulations. Let $K \in \mathbb{Z}_+$ denote the number of \overline{a} subpopulations in the metapopulation model. For each subpopulation $i \in [K]$, let n_i denote the size of the subpopulation and let **n** denote the vector (n_1, n_2, \ldots, n_K) of \ldots

71

> subpopulation sizes. For each pair $(i, j) \in [K] \times [K]$, let $w_{ij} \in \mathbb{Z}_+$ denote the number of 73 individuals moving from subpopulation i to subpopulation j daily. Thus, each w_{ij} is a 74 static (i.e., time independent) quantity. Let **W** denote the $K \times K$ mobility matrix induced by the w_{ij} values.

> Our goal is to decrease the spread of disease by allocating a total of $D \in \mathbb{Z}_+$ bundles π of vaccines to individuals over all subpopulations; here D is the vaccine budget. A $\overline{}$ bundle can be viewed as the smallest "shipment" of vaccines that can be allocated to a $\frac{79}{2}$ subpopulation and we assume that each bundle consists of an integer $\Delta > 0$ number of ϵ individual vaccines. Let $\mathbf{x} = (v_1, ..., v_K) \in \mathbb{Z}_+^K$ denote a vaccine allocation, where v_i is sum the number of bundles of vaccines allocated to subpopulation i . For simplicity, we $\frac{1}{2}$ assume that vaccination is preemptive, i.e., occurs at time 1, with knowledge of initial $\frac{1}{83}$ infected, but before the disease has started to spread. It is straightforward to generalize this to a setting in which vaccine allocation occurs later in the progression of the disease. ⁸⁵ Let $I = (I_1^0, I_2^0, \ldots, I_K^0) \in \mathbb{Z}_+^K$, where $0 \leq I_i^0 \leq n_i$, denote the number of initial so infections in subpopulation i. Let $f(x | \mathcal{M}, I)$ denote some measure of disease-spread according to the metapopulation model $\mathcal M$ starting with initial infection vector **I**, expressed as a function of the vaccine allocation vector **x**. For example, $f(\mathbf{x} \mid \mathcal{M}, \mathbf{I})$ could denote the total number of infected individuals over some time window. Let $\frac{90}{90}$ $g(\mathbf{x} \mid \mathcal{M}, \mathbf{I})$ denote $f(\mathbf{0} \mid \mathcal{M}, \mathbf{I}) - f(\mathbf{x} \mid \mathcal{M}, \mathbf{I})$, representing the reduction in disease-spread due to vaccine allocation $\mathbf{x} \in \mathbb{Z}_+^K$, relative to the no-vaccine setting. Note 92 that both f and g are defined over the integer lattice \mathbb{Z}_+^K and our goal is to maximize s the integer lattice function $g(x | \mathcal{M}, I)$ subject to the cardinality constraint $||x||_1 \leq D$. **Submodularity of lattice functions** For $K \in \mathbb{Z}_+$, let $g: \mathbb{Z}_+^K \to \mathbb{R}$ be a function defined on an integer lattice domain. The function g is said to be *submodular* if for all $\mathbf{x},\mathbf{y}\in\mathbb{Z}_{+}$ 97

$$
g(\mathbf{x}) + g(\mathbf{y}) \ge g(\mathbf{x} \vee \mathbf{y}) + g(\mathbf{x} \wedge \mathbf{y})
$$
\n(1)

Here $(\mathbf{x} \vee \mathbf{y})_i = \max\{\mathbf{x}_i, \mathbf{y}_i\}$ and $(\mathbf{x} \wedge \mathbf{y})_i = \min\{\mathbf{x}_i, \mathbf{y}_i\}.$

Below we provide an alternate "diminishing returns" notion of submodularity that is 99 easier to work with. Here \mathbf{e}_i denotes the unit vector with 1 in coordinate i.

Definition 1. [\[21\]](#page-33-5) **(DR-Submodularity)** A function $g : \mathbb{Z}_{+}^{K} \to \mathbb{R}$ is said to be $diminishing$ returns submodular (DR-submodular, in short) if $_{102}$

$$
g(\mathbf{x} + \mathbf{e}_i) - g(\mathbf{x}) \ge g(\mathbf{y} + \mathbf{e}_i) - g(\mathbf{y})
$$
 for all $i \in [K]$ and $\mathbf{x}, \mathbf{y} \in \mathbb{Z}_+^K$, where $\mathbf{x} \le \mathbf{y}$.

For set functions, submodularity and DR-submodularity are equivalent. However, it $_{104}$ is known [\[20\]](#page-33-6) that if a lattice function is DR-submodular then it is submodular, but the ¹⁰⁵ converse is false. Thus, DR-submodularity is a stronger notion compared to ¹⁰⁶ submodularity. However, [\[24\]](#page-33-4) presents a DR-type characterization of submodular lattice $_{107}$ functions that is quite useful for our analysis. 108

Lemma 2. [\[24\]](#page-33-4) A function $g: \mathbb{Z}_+^K \to \mathbb{R}$ is submodular if and only if for any $\mathbf{x}, \mathbf{y} \in \mathbb{Z}_+^K$, we $\mathbf{x} \leq \mathbf{y}$ and $i \in [K]$ with $\mathbf{x}_i = \mathbf{y}_i$, $g(\mathbf{x} + \mathbf{e}_i) - g(\mathbf{x}) \geq g(\mathbf{y} + \mathbf{e}_i) - g(\mathbf{y})$.

Note that according to this lemma, for submodular lattice functions, the DR 111 property is only required to hold at identical coordinates of x and y .

The computational complexity of maximizing a submodular lattice function 113 $g: \mathbb{Z}_+^K \to \mathbb{R}$ subject to a cardinality constraint, namely $\max_{\|\mathbf{x}\|_1 \leq D} g(\mathbf{x})$, is well $\lim_{\theta \to 0} g(\mathbf{x})$ understood. [\[20\]](#page-33-6) extend the result for set functions from [\[28\]](#page-34-3) to lattice functions and 115 show that greedy approaches yield a $(1 - \frac{1}{e})$ -approximation for this problem for both 116 submodular and DR-submodular lattice functions. These approximation guarantees are $\frac{117}{200}$ optimal due to the inapproximability result of [\[29\]](#page-34-4). ¹¹⁸

The SEIR Metapopulation model 119

The SEIR equations are governed by parameters λ , η , and δ , where λ is the *infectivity*, 120 $1/\eta$ is the *latency period*, and $1/\delta$ is the *infectious period*. Let r_i denote a multiplier 121 that scales λ to allow for county differences in contact rates. Let T be a positive integer 122 denoting the size of the time window under consideration. For $t \in [T] \cup \{0\}$, each 123 subpopulation is split into compartments S_i^t , E_i^t , I_i^t , and R_i^t representing the number of 124 susceptible, exposed, infected, and recovered individuals within subpopulation i at time $\frac{1}{25}$ t. We assume the initial conditions $E_i^0 = R_i^0 = 0$, I_i^0 is an arbitrary non-negative 126 number satisfying $I_i^0 \leq n_i$, and $S_i^0 = n_i - I_i^0$. The evolution of S_i^t , E_i^t , I_i^t , and R_i^t over 127 time t is respectively governed by equations [\(2\)](#page-6-0)-[\(5\)](#page-6-1). The term q_i^t that appears in these 128 equations is called the *force of infection*. When $q_i^t = \lambda r_i \frac{I_i^t}{n_i}$, equations [\(2\)](#page-6-0)-[\(5\)](#page-6-1) represent 129

the spread of disease in a single subpopulation i with a homogeneous mixing assumption. $_{130}$

$$
S_i^{t+1} = S_i^t - q_i^t S_i^t \tag{2}
$$

$$
E_i^{t+1} = E_i^t + q_i^t S_i^t - \eta E_i^t \tag{3}
$$

$$
I_i^{t+1} = I_i^t + \eta E_i^t - \delta I_i^t \tag{4}
$$

$$
R_i^{t+1} = R_i^t + \delta I_i^t \tag{5}
$$

We use the following expression for the force of infection term q_i^t that takes the 131 infection incidence within subpopulation i along with flows of individuals into and out 132 of subpopulation *i*. The derivation of q_i^t is inspired by a similar derivation in [\[5,](#page-32-0)12] and 133 is included in the Supplementary Information. 134

$$
q_i^t = \lambda \left[r_i \left(1 - \sum_j \frac{w_{ij}}{n_i} \right) \frac{\hat{I}_i^t}{\hat{n}_i} + \sum_j \frac{w_{ij} r_j}{n_i} \frac{\hat{I}_j^t}{\hat{n}_j} \right]
$$
(6)

 \hat{n}_i denotes the *effective* population of subpopulation i at time t, describing the number 135 of individuals present in subpopulation i after a daily commute has occurred, and \hat{I}_i^t 136 denotes the effective number of infected individuals in subpopulation i after a commute. $_{137}$ The first term in the right hand side of Eqn (6) is the proportion of individuals leaving $\frac{138}{2}$ subpopulation i for their commute, and the second term is the proportion of individuals $\frac{139}{139}$ arriving. The contract of the

The SEIR metapopulation model $\mathcal M$ described above is completely specified by the $_{141}$ vector $(\mathbf{n}, \mathbf{r}, \mathbf{W}, T, \lambda, \eta, \delta)$. In our experiments, each subpopulation represents a county 142 within a state (e.g., $K = 99$ for Iowa) and the mobility matrix **W** is obtained from two $\frac{143}{143}$ independent sources, FRED [\[30\]](#page-34-5) and SafeGraph [\[31\]](#page-34-6). By instantiating a specific ¹⁴⁴ disease-spread model for each subpopulation and describing its interaction with mobility ¹⁴⁵ matrix W , we can obtain a completely specified metapopulation model.

Table [1](#page-7-0) summarizes the notation introduced in this section.

MVA

Given a metapopulation model M, initial infected vector $\mathbf{I} = (I_1^0, I_2^0, \dots, I_K^0) \in \mathbb{Z}_+^K$, where $0 \leq I_i^0 \leq n_i$, and a vaccine budget $D \in \mathbb{Z}_+$, find a vaccine allocation $\mathbf{x} \in \mathbb{Z}_+^K$, satisfying $||\mathbf{x}||_1 \leq D$ such that $g(\mathbf{x} \mid \mathcal{M}, \mathbf{I}) := f(\mathbf{0} \mid \mathcal{M}, \mathbf{I}) - f(\mathbf{x} \mid \mathcal{M}, \mathbf{I})$ is maximized.

SEIR Metapopulation Vaccine Allocation Problems For illustrative purposes, we 152 instantiate the general metapopulation model $\mathcal M$ with an SEIR model for disease $\frac{153}{153}$ spread within each subpopulation. Our framework is general and the SEIR model that 154 we use within subpopulations can be replaced by any other homogeneous-mixing disease 155 $\mathop{\mathrm{spread}}$ model. \blacksquare

Using the SEIR metapopulation model described above, we obtain specific instances 157 of the MVA problem. But before we can describe these specific instances, we need to ¹⁵⁸ describe how vaccination affects disease spread in the SEIR metapopulation model. For 159 simplicity, we assume that vaccine uptake and vaccine effectiveness are both perfect, 160 and thus allocating a vaccine bundle $\mathbf{x} = (v_1, \dots, v_K)$ implies that $\Delta \cdot v_i$ individuals in 161 subpopulation *i* are vaccinated and removed from S_i^0 . Thus the vaccine allocation 162 $\mathbf{x} = (v_1, \dots, v_K)$ updates the initial susceptible to $S_i^0 = \max(0, n_i - I_i^0 - \Delta \cdot v_i)$ for all 163 $i \in [K]$. The assumptions of perfect uptake and effectiveness are easily relaxed; lowering 164 the vaccine uptake or effectiveness is equivalent to allocating fewer vaccines.

We now present two illustrative problems that maximize the impact of vaccines according to different disease spread metrics. In the problem MAXCASESAVERTED, the metric is the total number of infections averted across all subpopulations, and in the problem MAXPEAKSREDUCED, the metric is the decrease in the sum of all infection peaks across all subpopulations (both taken over the entire simulation time). More

151

> precisely, given an SEIR metapopulation model $\mathcal{M} = (\mathbf{n}, \mathbf{r}, \mathbf{W}, T, \lambda, \eta, \delta)$, initial infected vector $\mathbf{I} = (I_1^0, I_2^0, \dots, I_K^0) \in \mathbb{Z}_+^K$, where $0 \leq I_i^0 \leq n_i$, and a vaccine allocation $\mathbf{x} = (v_1, \dots, v_K) \in \mathbb{Z}_+^K$, we define the metric

$$
\text{totBurchen}(\mathbf{x} \mid \mathcal{M}, \mathbf{I}) := \sum_{k \in [K]} (R_k^T + I_k^T),
$$

which is simply the total number of individuals who became infected in the time window $[0, T]$. Another natural disease spread metric for the SEIR metapopulation model is

$$
\mathrm{MAXBURDEN}(\mathbf{x} \mid \mathcal{M}, \mathbf{I}) := \sum_{k \in [K]} \max_{0 \leq t \leq T} I_k^t,
$$

which is the total number of individuals infected during "peak" infection time over all $_{166}$ the subpopulations. This metric is motivated by the fact that even small peaks are $_{167}$ challenging in low-resource counties (typically in low-population counties), because 168 healthcare infrastructure is often limited in such counties. So even a small spike in the 169 number of infected individuals can quickly overwhelm local resources. Thus we seek to $\frac{170}{170}$ reduce the likelihood that local healthcare systems will be overwhelmed with the $_{171}$ MAXBURDEN metric. Given metapopulation model \mathcal{M} , initial infection vector **I**, and $_{172}$ budget D , we define the following discrete optimization problems: 173

MaxCasesAverted

Find a vaccine allocation $\mathbf{x} \in \mathbb{Z}_+^K$, satisfying $\|\mathbf{x}\|_1 \leq D$ such that the following is maximized.

$$
\text{totBurden}(\mathbf{0} \mid \mathcal{M}, \mathbf{I}) - \text{totBurden}(\mathbf{x} \mid \mathcal{M}, \mathbf{I})
$$

MaxPeaksReduced

Find a vaccine allocation $\mathbf{x} \in \mathbb{Z}_+^K$, satisfying $\|\mathbf{x}\|_1 \leq D$ such that the following is maximized.

175

174

 $\text{MAXBURDEN}(\mathbf{0} \mid \mathcal{M}, \mathbf{I}) - \text{MAXBURDEN}(\mathbf{x} \mid \mathcal{M}, \mathbf{I})$

Hardness of MaxCasesAverted and MaxPeaksReduced ¹⁷⁶

As with many resource allocation problems, both MAXCASESAVERTED and 177 MAXPEAKSREDUCED are not only NP-hard, but even hard to efficiently approximate. 178 We show this by a reduction from the *Maximum k-Subset Intersection* (MAXKSI) $_{179}$ problem [\[32\]](#page-34-7). The input to MAX k-SI consists of a collection $\mathcal{C} = \{S_1, S_2, \ldots, S_m\}$ of 180 sets, where each set S_i is a subset of a universe $\mathcal{U} = \{e_1, e_2, \ldots, e_n\}$, and a positive 181 integer k. The problem seeks to find k subsets $S_{j_1}, S_{j_2}, \ldots, S_{j_k}$ from C, whose intersection has maximum size. The following theorem from [\[32\]](#page-34-7) shows that MAX k -SI 183 is highly unlikely to have an efficient approximation algorithm, even with an inverse $_{184}$ polynomial approximation factor.

Theorem 3. [\[32\]](#page-34-7) Let $\epsilon > 0$ be an arbitrarily small constant. Assume that 186 $SATISFIABILITY$ does not have a probabilistic algorithm that decides whether a given 187 instance of size n is satisfiable in time 2^{n^e} . Then there is no polynomial time algorithm use for MAX k-SI that achieves an approximation ratio of $1/N^{\epsilon'}$, where N is the size of the 189 given instance of MAX k-SI and ϵ' only depends only on ϵ .

We now show a reduction from MAX k -SI to both MAXCASESAVERTED and $_{191}$ $\text{MAXPEAKSREDUCED},$ thereby establishing the inapproximability of both of these $\frac{192}{192}$ problems. The contract of the

Theorem 4. Let $\epsilon > 0$ be an arbitrarily small constant. Assume that 194 SATISFIABILITY does not have a probabilistic algorithm that decides whether a given 195 instance of size n is satisfiable in time 2^{n^e} . Then there is no polynomial time algorithm 196 for MAXCASESAVERTED or for MAXPEAKSREDUCED that achieves an approximation 197 ratio of $1/N^{\epsilon'}$, where N is the size of the given instance of MAXCASESAVERTED or 198 MAXPEAKSREDUCED and ϵ' only depends only on ϵ .

Proof: To prove the portion of this theorem pertaining to MAXCASESAVERTED, we show the following lemma. 201

Lemma 5. Suppose there is a polynomial-time algorithm A that yields an α -approximation for MAXCASESAVERTED. Then there is a polynomial-time α ²⁰³ $\alpha/2$ -approximation algorithm \mathcal{A}' for MAX k-SI.

> **Proof of Lemma [5.](#page-9-0)** Given an instance (C, \mathcal{U}, k) of MAX k-SI, we construct the graph $_{205}$ G with $m + n + 1$ nodes. For each subset $S_i \in \mathcal{C}$ and each $e_i \in \mathcal{U}$, there is a node in G , 206 for a total of $m + n$ nodes. There is an extra node I that is connected to every S_i -node. 207 There are edges between the S_i -nodes and the e_i -nodes connecting an S_i -node to an e_i -node iff $e_i \notin S_j$.

> To each node v in G, we assign a population n_v as follows: $n_I = m$, $n_{S_i} = 2n$ for all 210 $j \in [n]$, and $n_{e_i} = M$ for all $i \in [n]$, where M is a large integer whose value will be 211 specified later. We then interpret each undirected edge in G as a pair of directed edges $_{212}$ pointing in opposite directions and assign a flow to each directed edge. We assign flow 1 $_{213}$ to each edge from I to S_j and to each edge from S_j to e_i . To all other edges, i.e., the 214 edges pointing "backwards", we assign flow 0. This construction is illustrated in Fig [1.](#page-10-0) ²¹⁵ This specifies the vectors **n** and **w** of the instance of MAXCASESAVERTED.

Fig 1. The instance of MAXCASESAVERTED and MAXPEAKSREDUCED is a graph G constructed from the given instance $(C = (S_1, S_2, \ldots, S_m), \mathcal{U} = (e_1, e_2, \ldots, e_n), k)$ of Max k-SI. Each node represents a subpopulation, with the size of the subpopulation shown in square brackets next to it. The directed edges permit 1 unit flow. The unit flows from nodes S_j to e_i encode non-membership. For example, the flow from S_1 to e_2 implies that $e_2 \notin S_1$.

We set the contact rate r_v and infectivity λ such that the force of infection q_v^t is 217 always at least 1. This corresponds to "perfect infectivity", meaning that if a ²¹⁸ subpopulation contains some infected and some susceptible individuals at a time step, ²¹⁹ then all the susceptible individuals in the subpopulation will transition to the exposed $_{220}$ state at the next time step. We then set $\eta = \delta = 1$ so that the latency period and 221 recovery period are both 1. With this setting of the parameters, the infection will 222 completely die out in 5 time steps, i.e., every individual will either be susceptible or \qquad 223

216

> recovered. So we set the size of the time window $T = 5$. Finally, we set the vaccination $_{224}$ budget $D = (m - k) \cdot 2n$ and initialize the entire population of m individuals at node I 225 to be infected and all other individuals to be susceptible. This completes the $_{226}$ specification of the problem instance \mathcal{I} of MAXCASESAVERTED. 227

> We now make 2 simple observations that follow from the construction of $\mathcal I$ and 228 depend on the notion of being "unprotected" with respect to a vaccine allocation. Let \mathbf{x} 229 be an arbitrary, feasible allocation for \mathcal{I} . A subpopulation S_i is called unprotected for **x** 230 if $\mathbf{x}_{S_j} < 2n$; otherwise, S_j is called protected for **x**. A subpopulation e_i is called 231 unprotected for **x** if $\mathbf{x}_{e_i} < M$ and for some subpopulation S_i that is unprotected for **x**, 232 the edge $\{S_j, e_i\}$ is in G; otherwise, e_i is called protected for **x**.

> **Observation 1:** In every unprotected subpopulation S_j , $j \in [m]$, $2n - \mathbf{x}_{S_j}$ individuals 234 will become exposed in time step 1 and infected in time step 2. 235

> **Observation 2:** In every unprotected subpopulation e_i , $i \in [n]$, $M - \mathbf{x}_{e_i}$ individuals 236 will become exposed in time step 3 and infected in time step 4. 237

These 2 observations immediately lead to the following 3 claims.

Claim i) Consider a vaccine allocation $\mathbf{x} \in \mathbb{Z}_{+}^{m+n+1}$ that is feasible for \mathcal{I} and satisfies $\mathbf{x}_{e_i} > 0$. Let $\mathbf{x}' \in \mathbb{Z}_+^{m+n+1}$ be an allocation obtained from x by reallocating all vaccines from the subpopulation e_i to subpopulations S_j , $j \in [m]$. Then **x'** is feasible for \mathcal{I} and

TOTBURDEN($\mathbf{x}' | \mathcal{M}, \mathbf{I}$) \leq TOTBURDEN($\mathbf{x} | \mathcal{M}, \mathbf{I}$).

Claim ii) Consider a vaccine allocation $\mathbf{x} \in \mathbb{Z}_{+}^{m+n+1}$ that is feasible for \mathcal{I} and satisfies $0 < \mathbf{x}_{S_j}, \mathbf{x}_{S_{j'}} < 2n$ for two subpopulations $S_j, S_{j'}, j \neq j'$. Let $\mathbf{x}' \in \mathbb{Z}_{+}^{m+n+1}$ be an allocation obtained from x by reallocating as many vaccines as possible from the subpopulation $S_{j'}$ to the subpopulation S_j , until $\mathbf{x}_{S_j} = 2n$ or $\mathbf{x}_{S_{j'}} = 0$ (or both). Then \mathbf{x}' is feasible for $\mathcal I$ and

TOTBURDEN($\mathbf{x}' | \mathcal{M}, \mathbf{I}$) \leq TOTBURDEN($\mathbf{x} | \mathcal{M}, \mathbf{I}$).

Claim iii) Consider a vaccine allocation $\mathbf{x} \in \mathbb{Z}_{+}^{m+n+1}$ that is feasible for \mathcal{I} and satisfies $||x||_1 = D = (m - k) \cdot 2n$. Then using the reallocations from Claims (i) and (ii), it is possible to transform **x** into $\mathbf{x}' \in \mathbb{Z}_{+}^{m+n+1}$ in polynomial time such that **x'** is feasible for

> $\mathcal{I}, \mathbf{x}'_{S_j} = 2n$ for exactly $(m - k)$ subpopulations S_j, \mathbf{x}' is 0 for all other subpopulations, and

$$
\text{totBurden}(\mathbf{x}' \mid \mathcal{M}, \mathbf{I}) \leq \text{totBurden}(\mathbf{x} \mid \mathcal{M}, \mathbf{I}).
$$

Claim (iii) allows us to assume that any α -approximation algorithm $\mathcal A$ for 239 MAXCASESAVERTED returns an allocation x' for the problem instance \mathcal{I} , that picks 240 exactly $(m - k)$ subpopulations S_j and vaccinates these subpopulations entirely, while 241 allocating no vaccines to any of the remaining subpopulations. Similarly, Claim (iii) ²⁴² implies that there is an optimal allocation \mathbf{x}^* for $\mathcal I$ that picks exactly $(m - k)$ subpopulations S_j and vaccinates these subpopulations entirely, while allocating no $\frac{244}{2}$ vaccines to any of the remaining subpopulations.

Let $\mathcal{S}(\mathbf{x}')$ be the set of subpopulations S_j unprotected for \mathbf{x}' . Similarly, define $\mathcal{S}(\mathbf{x}^*)$. 246 Note that $|\mathcal{S}(\mathbf{x}')| = |\mathcal{S}(\mathbf{x}^*)| = k$. Let $\mathcal{E}(\mathbf{x}')$ be the set of subpopulations e_i that are 247 protected for **x'**. Similarly, define $\mathcal{E}(\mathbf{x}^*)$. By the construction of edges from 248 subpopulations S_j to subpopulations e_i in \mathcal{I} , it follows that $\mathcal{E}(\mathbf{x}') = \bigcap_{S_j \in \mathcal{S}(\mathbf{x}')} S_j$. Similarly, $\mathcal{E}(\mathbf{x}^*) = \bigcap_{S_j \in \mathcal{S}(\mathbf{x}^*)} S_j$ 250

The objective function value of MAXCASESAVERTED for the optimal allocation \mathbf{x}^* , ²⁵¹ which is TOTBURDEN($\mathbf{0} | \mathcal{M}, \mathbf{I}$) – TOTBURDEN($\mathbf{x}^* | \mathcal{M}, \mathbf{I}$), can be simplified to 252

$$
(2n \cdot m + n \cdot M) - \text{TOTBURDEN}(\mathbf{x}^* \mid \mathcal{M}, \mathbf{I})
$$

=
$$
(2n \cdot m + n \cdot M) - (k \cdot 2n + M(n - |\mathcal{E}(\mathbf{x}^*)|))
$$

=
$$
2n(m - k) + M \cdot |\mathcal{E}(\mathbf{x}^*)|
$$

=
$$
2n(m - k) + M \cdot |\bigcap_{S_j \in \mathcal{S}(\mathbf{x}^*)} S_j|
$$
(7)

Similarly, the objective function value of MAXCASESAVERTED for the α -approximate allocation **x'** is $2n(m-k) + M \cdot \log_{j \in S(\mathbf{x}')} S_j$. Since **x**^{*} maximizes the objective function value of MAXCASESAVERTED, Equation [\(7\)](#page-12-0) implies that $|\bigcap_{S_i\in\mathcal{S}(\mathbf{x}^*)}S_j|$ has largest possible cardinality. Since $|\mathcal{S}(x^*)|=k$, this implies that $\mathcal{S}(x^*)$ is an optimal solution to the MAX k-SI problem. Using $OPT_{\text{MAX }k\text{-SI}}$ to denote the optimal objective function value of MAX k -SI, we can rewrite the expression (7) as $2n(m-k) + M \cdot OPT_{\text{MAX } k\text{-SI}}$. Since **x'** is an α -approximate solution to

MaxCasesAverted,

$$
2n(m-k) + M \cdot |\bigcap_{S_j \in \mathcal{S}(\mathbf{x}')} S_j| \ge \alpha (2n(m-k) + M \cdot OPT_{\text{MAX } k\text{-SI}}).
$$

Rearranging terms we get 253

$$
|\bigcap_{S_j \in \mathcal{S}(\mathbf{x}')} S_j| \geq \alpha \cdot OPT_{\text{MAX } k\text{-SI}} - \frac{(1-\alpha) \cdot 2n(m-k)}{M}
$$

$$
|\bigcap_{S_j \in \mathcal{S}(\mathbf{x}')} S_j| \geq \alpha \cdot OPT_{\text{MAX } k\text{-SI}} - \frac{2nm}{M}
$$
 (8)

Picking M large enough so that $\frac{2nm}{M} \leq \frac{\alpha}{2}$ and using $OPT_{\text{MAX }k\text{-SI}} \geq 1$, we obtain

$$
|\bigcap_{S_j \in \mathcal{S}(\mathbf{x}')} S_j| \geq \frac{\alpha}{2} \cdot OPT_{\text{MAX } k\text{-SI}}.
$$

This implies that the allocation x' can be used to obtain an $\alpha/2$ -approximation to MAX 254 $k\text{-SI}$.

We now prove a similar lemma for the MAXPEAKSREDUCED problem. 256

Lemma 6. Suppose there is a polynomial-time algorithm $\mathcal A$ that yields an 257 α -approximation for MAXPEAKSREDUCED. Then there is a polynomial-time α α -approximation algorithm \mathcal{A}' for MAX k-SI.

Proof of Lemma [6.](#page-13-0) This uses the same argument as the lemma above. Claims (i) and (ii) hold for MAXBURDEN($\mathbf{x} \mid \mathcal{M}, \mathbf{I}$) as well and from these two claims, Claim (iii) follows. Furthermore,

$$
\text{maxBurdon}(0 \mid \mathcal{M}, I) - \text{maxBurdm}(\mathbf{x}^* \mid \mathcal{M}, I)
$$

simplifies exactly to expression (7) , from which inequality (8) follows. From this, the $_{260}$ lemma immediately follows, as shown above. \Box 261

Algorithmic approach and analysis 262

We consider a variety of greedy algorithms for MVA. These algorithms and their 263 accompanying analyses also apply to the general budget-constrained maximization ²⁶⁴ problem on an integer lattice: $\max_{\|\mathbf{x}\|_1 \leq D} g(\mathbf{x})$, where $g: \mathbb{Z}_+^K \to \mathbb{R}$ is an arbitrary,

Greedy algorithm descriptions 277

LatticeGreedySubroutine Description As shown in the Algorithm [1](#page-15-0) pseudocode, $_{278}$ LATTICEGREEDYSUBROUTINE selects a (k^*, s^*) pair that maximizes the marginal gain $_{279}$ of $g(\cdot)$ in each iteration, where $k^* \in [K]$ is a subpopulation and $s^* \in \mathbb{Z}_+$ is the number 280 of bundles to allocate to subpopulation k^* . To compute the highest marginal gain among all possible $(k, s) \in [K] \times \mathbb{Z}_+$ pairs in each iteration of the algorithm, we assume 282 that the algorithm has access to a "value oracle" that returns the value of the objective 283 function $g(\cdot)$ at any point in its domain. It is possible that the selected pair (k^*, s^*) is 284 not feasible because adding it to the solution causes the budget constraint to be violated. Such an iteration is said to have *failed*, and we remove the (k^*, s^*) pair from 286 the search space Q. Otherwise, the iteration is *successful* and the (k^*, s^*) pair is used to 287 update the allocation. It is useful for our analysis to state the algorithm in this manner, ²⁸⁸ allowing for failed iterations. However, to obtain an efficient implementation we can, in ²⁸⁹ Line 4, prune the search space Q so as to guarantee that the condition in Line 5 is $\frac{290}{2}$ always satisfied. Such an implementation runs in $O(K \cdot D^2 \cdot T_g)$ time in the worst case, 291 where T_g is the worst case running time of the value oracle. However, the at most $K \cdot D$ 292 pairs in Q can all be evaluated in parallel, and assuming full parallelism with no 293 overhead, the running time of LATTICEGREEDYSUBROUTINE can also be reduced to $_{294}$ $O(D \cdot T_g \cdot \log(K \cdot D))$ in the PRAM model (even with exclusive read and exclusive 295

> write). We note that LATTICEGREEDYSUBROUTINE and the algorithms based on it $_{296}$ ϵ come from [\[20\]](#page-33-6).

> We further allow LATTICEGREEDYSUBROUTINE to start with an arbitrary initial 298 allocation $\hat{\mathbf{x}}_0$, and not just **0** (see Line 1). This is so that we can use LATTICEGREEDYSUBROUTINE as the completion step for an algorithm that enumerates $\frac{300}{200}$ solutions of bounded size. Specifically, let $\ell \geq 1$ be a fixed integer and let S be the set $\frac{301}{201}$ of all feasible solutions of size ℓ or less. Thus each element in S is a subset of at most ℓ 302 subpopulations, each allocated some number of vaccine bundles so that the overall $\frac{303}{203}$ allocation is of size at most D. Note that $|\mathcal{S}| = O(K^{\ell} \cdot D^{\ell})$. We then iterate over all some elements of S and call LATTICEGREEDYSUBROUTINE with $\hat{\mathbf{x}}_0$ set to each element in S. 305 We call this entire algorithm ℓ -ENUMGREEDY. Later in this section, we analyze $3-ENUMGREEDY.$

> While 3-ENUMGREEDY runs in polynomial time (specifically, $O(K^4 \cdot D^5 \cdot T_g)$ time), some it is expensive and not practical for large instances. A cheaper algorithm based on $\frac{309}{200}$ LATTICEGREEDYSUBROUTINE computes one solution by starting 310 LATTICEGREEDYSUBROUTINE with **0** as the initial allocation and then computes K_{311} additional "singleton" solutions by allocating the entire budget to each of the K_{312} subpopulations. The final solution returned is the best of these $K + 1$ solutions. We call this the SINGLETONGREEDY algorithm. Note that the running time of $_{314}$ SINGLETONGREEDY is dominated by LATTICEGREEDYSUBROUTINE. 315

1: $\hat{\mathbf{x}} \leftarrow \hat{\mathbf{x}}_0$ 2: $Q := \{(k, s) : k \in [K], 1 \le s \le \lceil \frac{n_k}{\Delta} \rceil - \hat{x}_{\mathbf{k}}\}$ 3: while $\|\hat{\mathbf{x}}\|_1 < D$ and $Q \neq \emptyset$ do 4: $k^*, s^* \leftarrow \underset{(k, k) \in \mathbb{C}}{\operatorname{argmax}} \frac{g(\hat{\mathbf{x}}+s\cdot\mathbf{e}_k|\mathcal{M}, \mathbf{I})-g(\hat{\mathbf{x}}|\mathcal{M}, \mathbf{I})}{s}$ $(k,s) \in Q$ 5: if $\|\hat{\mathbf{x}} + s^* \cdot \mathbf{e}_{k^*}\|_1 \leq D$ then 6: $\hat{\mathbf{x}} \leftarrow \hat{\mathbf{x}} + s^* \cdot \mathbf{e}_{\mathbf{k}^*}$ 7: $Q \leftarrow Q \setminus \{(k, s) : s + \hat{\mathbf{x}}_k > \lceil \frac{n_k}{\Delta} \rceil\}$ 8: else 9: Remove (k^*, s^*) from Q 10: end if 11: end while 12: 13: return $\hat{\mathbf{x}}$

FastGreedy Description FASTGREEDY [\[25\]](#page-34-0) is a relaxation of 316

LATTICEGREEDYSUBROUTINE that sets an initial threshold and adds the (k, s) pair $\overline{317}$ that provides the maximum benefit for each $k \in [K]$ if that benefit exceeds the ³¹⁸ threshold τ_f of that iteration. In each iteration, the threshold is relaxed for the next τ_3 round of allocations. κ_f determines the rate at which the threshold τ_f decreases, and τ_f β_f approaches the FASTGREEDY DR-submodularity ratio β_f^* [\[25\]](#page-34-0), which upper-bounds 321 the DR-submodularity ratio. The rate at which β_f approaches β_f^* is governed by the 322 parameter δ_f . ε_f establishes a lower bound on how small the marginal gain in each $\frac{323}{2}$ iteration can be before the algorithm exits. $\frac{324}{2}$

FASTGREEDY is a relaxation of LATTICEGREEDYSUBROUTINE in two ways: i) in 325 each iteration, FASTGREEDY allows allocation to multiple $k \in [K]$, as long as their $\qquad \qquad \text{as}$ benefit exceeds an iteration dependent threshold, and **ii**) determines the number of $\frac{327}{2}$ bundles s through a binary search subroutine, where $LATTICEGREEDYSUBROUTINE$ 328 exhaustively searches through each (k, s) pair. 329

UnitGreedy Description On the problem instances we consider, in practice, $\frac{330}{330}$ 3-ENUMGREEDY, and SINGLETONGREEDY elect to allocate one bundle at a time for a 331 majority of iterations. With this in mind, we consider another more efficient algorithm, $\frac{332}{200}$ UNITGREEDY. As shown in the Algorithm [3](#page-17-0) pseudocode, UNITGREEDY allocates one $\frac{333}{2}$ vaccine bundle to a subpopulation $k \in [K]$, each time selecting a subpopulation that \qquad 334 yields the highest marginal gain in the objective function - this is equivalent to $\frac{335}{335}$

> converting the lattice into a multiset and running a set greedy algorithm on it (such as $\frac{336}{4}$ the one in [\[26\]](#page-34-1)). The algorithm continues until the vaccine budget D is met. The $\frac{337}{2}$ running time of this algorithm is $O(K \cdot D \cdot T_g)$. Note that the marginal gains for the 338 various bundles can be computed (Line 3 in Algorithm [3\)](#page-17-0) in parallel in a $\frac{339}{3}$ straightforward manner, and if we ignore overhead for parallelization, the running time ³⁴⁰ reduces to $O(D \cdot T_q)$.

Algorithm 3 UNITGREEDY (M, I)

1: $\hat{\mathbf{x}} \leftarrow \mathbf{0}$ 2: while $\|\hat{\mathbf{x}}\|_1 < D$ do 3: $k^* \leftarrow \text{argmax } g(\hat{\mathbf{x}} + \mathbf{e_k} \mid \mathcal{M}, \mathbf{I}) - g(\hat{\mathbf{x}} \mid \mathcal{M}, \mathbf{I})$ $k{\in}[K]$ 4: $\hat{\mathbf{x}} \leftarrow \hat{\mathbf{x}} + \mathbf{e}_{\mathbf{k}^*}$ 5: end while 6: 7: return $\hat{\mathbf{x}}$

Δ pproximation guarantees $\frac{342}{2}$

Lattice function submodularity ratios To analyze the greedy algorithms described $\frac{343}{2}$ above, we utilize the notion of *submodularity ratio* defined in [\[24\]](#page-33-4). The submodularity $\frac{344}{2}$ ratio of a function g is a quantity between 0 and 1 that is a measure of g's "distance" to $\frac{3}{45}$ submodularity. Since there are two distinct notions of submodularity for lattice $\frac{346}{2}$ functions, as defined in the Background section, there are two associated notions of $\frac{347}{2}$ submodularity ratios, which we now present. To simplify notation, we drop $\mathcal M$ and $\mathbf I$ 348 and simply use $g(\mathbf{x})$ for our objective function. $\frac{349}{2}$

Definition 7. DR-Submodularity Ratio. [\[24\]](#page-33-4) The DR-submodularity ratio of a $\overline{}$ 350 function $g: \mathbb{Z}_+^K \to \mathbb{R}$ is defined as 351

$$
\beta(g) = \min_{\mathbf{y} \le \mathbf{x}, k \in [K]} \frac{g(\mathbf{y} + \mathbf{e}_{\mathbf{k}}) - g(\mathbf{y})}{g(\mathbf{x} + \mathbf{e}_{\mathbf{k}}) - g(\mathbf{x})}
$$
(9)

In this definition (and in the next definition below) we designate $\frac{0}{0}$ to be 1 and $\frac{n}{0}$ to ss2 be ∞ for any positive integer n. From this definition it is clear that $\beta(g) \leq 1$ because 353 $x = y$ is included in the space that is being minimized over. Furthermore, this definition 354 along with the definition of DR-submodularity (Definition [1\)](#page-4-0) implies that $\beta(q) = 1$ iff g 355 is DR-submodular. Thus, the "distance" $1 - \beta(g)$ indicates how far the function g is 356

> from being DR-submodular. Below we present a similar definition that captures the ³⁵⁷ notion of "distance" of a function g from being submodular.

> **Definition 8. Submodularity Ratio.** [\[24\]](#page-33-4) The submodularity ratio of a function $\overline{}$ ³⁵⁹ $g: \mathbb{Z}_+^K \to \mathbb{R}$ is defined as 360

$$
\alpha(g) = \min_{\mathbf{y} \le \mathbf{x}, k \in [K]: \mathbf{x}_k = \mathbf{y}_k} \frac{g(\mathbf{y} + \mathbf{e}_\mathbf{k}) - g(\mathbf{y})}{g(\mathbf{x} + \mathbf{e}_\mathbf{k}) - g(\mathbf{x})}
$$
(10)

Like $\beta(g)$, the submodularity ratio $\alpha(g)$ also satisfies $\alpha(g) \leq 1$ and $1 - \alpha(g)$ indicates ³⁶¹ how far the function g is from being submodular. Since submodularity is a weaker $\frac{362}{2}$ notion than DR-submodularity, an arbitrary lattice function will be "closer" to $\frac{363}{100}$ submodularity than DR-submodularity. Correspondingly, $\alpha(g) \geq \beta(g)$.

We now present approximation guarantees for 3-ENUMGREEDY (Theorem [9a](#page-18-0)), $_{365}$ SINGLETONGREEDY (Theorem [9b](#page-18-0)), and UNITGREEDY (Theorem [10\)](#page-19-0). The $_{366}$ approximation guarantee associated with FASTGREEDY can be found in $[25]$. Guarantees for 3-EnumGreedy and SingletonGreedy Theorem [9](#page-18-0) provides a 368 guarantee for 3-ENUMGREEDY and SINGLETONGREEDY. Previously, [\[20\]](#page-33-6) established approximation guarantees for these algorithms over submodular objective functions, ³⁷⁰ whereas we establish them for more general objective functions. 371

Theorem 9. Let $g: \mathbb{Z}_+^K \to \mathbb{R}$ be an arbitrary monotone function. Let OPT denote the \mathbb{R}^3 optimal solution to the problem $\max_{\|\mathbf{x}\|_1\leq D} g(\mathbf{x})$.

(a) If $\hat{\mathbf{x}}$ is the solution returned by 3-ENUMGREEDY then

 $g(\hat{\mathbf{x}}) \geq (1 - e^{-\alpha(g)}) \cdot OPT$

(b) If $\hat{\mathbf{x}}$ is the solution returned by SINGLETONGREEDY then

$$
g(\hat{\mathbf{x}}) \ge \frac{\alpha(g)}{2} \cdot (1 - e^{-\alpha(g)}) \cdot OPT
$$

The proof is included in the Supplementary Information. 374 Guarantee for UnitGreedy Here, we provide a version of the approximation $\frac{375}{275}$ guarantee found in [\[26\]](#page-34-1), which is dependent on the submodularity ratio for set $\frac{376}{376}$ functions [\[23\]](#page-33-3) and generalized curvature [\[26\]](#page-34-1). Their guarantee is applicable to $\frac{377}{27}$

UNITGREEDY when we consider the lattice over which we allocate to be a multiset. $\frac{378}{276}$

Theorem 10. Let $g: \mathbb{Z}_+^K \to \mathbb{R}$ be an arbitrary monotone function. Let OPT denote the optimal solution to the problem $\max_{\|\mathbf{x}\|_1 \leq D} g(\mathbf{x})$. If $\hat{\mathbf{x}}$ is the solution returned by UNITGREEDY then

$$
g(\hat{\mathbf{x}}) \ge (1 - e^{-\beta(g)}) \cdot OPT
$$

The above results show that the approximation guarantees shown in the $\frac{379}{2}$ literature [\[20,](#page-33-6) [28\]](#page-34-3) for greedy algorithms when q is a submodular function (on sets or $\frac{380}{200}$ lattices) are more general and apply to arbitrary monotone integer lattice functions. Note that the theorems above also provide a trade-off between approximation-factor $\frac{382}{8}$ and running time. UNITGREEDY is the fastest algorithm, but this provides an $\frac{383}{2}$ $(1 - e^{-\beta(g)})$ -approximation, which is no better than the $(1 - e^{-\alpha(g)})$ -approximation 384 provided by the more expensive algorithm 3-ENUMGREEDY.

We remark that ℓ -ENUMGREEDY, SINGLETONGREEDY, FASTGREEDY, and 386 UNITGREEDY are well known algorithms for maximizing a submodular function over ³⁸⁷ sets or lattices subject to a cardinality constraint $(e.g., [19, 20, 25, 26])$ $(e.g., [19, 20, 25, 26])$. Our main contribution here is to show that 3-ENUMGREEDY and SINGLETONGREEDY provide $\frac{389}{389}$ approximation guarantees even when the objective function is not submodular and ³⁹⁰ these guarantees degrade gracefully as the objective function becomes less submodular, $\frac{391}{2}$ as measured by the submodularity ratio. We also derive a lattice function based ³⁹² approximation guarantee for UNITGREEDY, extending from the set function guarantee ³⁹³ provided in $[26]$.

Finally, we note that the POMS algorithm in $[24]$ achieves a $\frac{395}{2}$ $\max((1-e^{-\beta(g)}), \alpha(g)/2 \cdot (1-e^{-\alpha(g)}))$ -approximation. Our results show that simple, 396 well-known, and faster greedy algorithms achieve these same approximation factors. ³⁹⁷

$\textbf{Experiments}$

Next, we present a variety of experiments that collectively show that \mathbf{i}) greedy methods $\frac{399}{2}$ outperform various baseline vaccine allocation algorithms for both MAXCASESAVERTED $_{400}$ and MAXPEAKSREDUCED objectives, \mathbf{ii}) greedy methods are very close to optimal for $\frac{401}{201}$ all instances for which this comparison was feasible, and \mathbf{iii}) the greedy methods are $\frac{402}{402}$

Table 2. Summary of greedy algorithms presented in this section. Details of approximation factors for FastGreedy and UnitGreedy may be found in [\[26\]](#page-34-1) and [\[25\]](#page-34-0), respectively.

considerably faster than POMS $[24]$ (when requiring all algorithms to run until their $\frac{403}{403}$ approximation factors can be guaranteed). We run our experiments at 3 different scales: ⁴⁰⁴ (i) small-scale experiments: New Hampshire $(10 \text{~counties}, \text{~population } 1.4 \text{~million}), (ii)$ medium-scale experiments: Iowa (99 counties, population 3.2 million), and (iii) ⁴⁰⁶ large-scale experiments: Texas (254 counties, population 30.03 million). Our code and 407 processed data are part of the Supplementary Information. Experiments were run on ⁴⁰⁸ AMD EPYC 7763 CPUs with 2 TB RAM.

Baselines. Our baselines include natural vaccine allocation strategies such as ⁴¹⁰ POPULATION, OUT-MOBILITY, IN-MOBILITY, and RANDOM, which assign vaccines to $_{411}$ each county proportional to the population, the total mobility originating in the county, $\frac{412}{2}$ the total mobility terminating in the county, and uniformly at random respectively. We $_{413}$ also compare our approaches against POMS [\[24\]](#page-33-4), which works by expanding a random ⁴¹⁴ pareto-optimal frontier. $\frac{415}{415}$

Data. Our experimental test-beds consist of simulated outbreaks over inter-county ⁴¹⁶ mobility graphs for New Hampshire, Iowa and Texas constructed from two separate $\frac{417}{410}$ sources: (i) FRED [\[30\]](#page-34-5) (open source) is a census-based synthetic population contact $\frac{418}{418}$ network, which includes high-resolution social, familial, demographic, and behavioral ⁴¹⁹ details, and (ii) SafeGraph [\[31\]](#page-34-6) (open source for academics) provides aggregated and $\frac{420}{420}$ anonymized mobility data from mobile device GPS signals, which provides inferred 421

> 'home' locations and visits to places of interest (POIs). We derive state-level directed ⁴²² mobility graphs from both data sources, where nodes correspond to counties and $\frac{423}{423}$ directed weighted edges correspond to movement from the source county to the target 424 county. $\qquad \qquad \text{425}$

> The mobility graphs constructed using FRED and SafeGraph are similar for New ⁴²⁶ Hampshire and Iowa, except that the SafeGraph mobility graphs have a slightly higher $_{427}$ density. For Texas, the density of the FRED mobility graph is an order of magnitude 428 lower than that of SafeGraph. A description of the mobility graph construction and a $_{429}$ table of their properties can be found in the Supplementary Information.

> **Parameters** We select values of λ (infectivity) at approximately 0.347 and 0.535 to μ ₃₃₁ result in 20% and 70% of each population becoming infected without vaccination, ⁴³² respectively. We conducted experiments with a wider range of λ values (in general, we λ observed that problem instances with lower values of λ are more easily solved by more λ vaccine allocation methods) and chose two values that represent significantly different $\frac{435}{435}$ levels of infectivity. We performed experiments for New Hampshire, Iowa, and Texas, ⁴³⁶ with a vaccine budget of 10% through 60% of each state's total population in 10% increments. The parameters k, n_i , and w_{ij} are instantiated according to the data when 438 we constructed the mobility graphs. The parameters r_i scale the infectivity parameter λ 439 for each county, and is set in proportion to the population density of each county. We set the initially infected vector I_0 to be 1 for each county. The choice in I_0 does not $\frac{441}{400}$ make a difference in our setting due to the deterministic nature of our model and the $\frac{442}{4}$ small diameter of our mobility graphs (at most 4). η and δ are set according to [\[34\]](#page-34-9). For ϵ FASTGREEDY in New Hampshire and Iowa, we set $\kappa_f = \delta_f = 0.96$, and in Texas, we set ϵ_{444} $\kappa_f = \delta_f = 0.93$. For all FASTGREEDY experiments, we set $\varepsilon_f = 0$. We run each 445 simulation for at least 200 timesteps and terminate the simulation when the disease dies $\frac{446}{460}$ \overline{a} and \overline{a} and

Performance of greedy methods compared to baselines

In our first experiment, we compare the performance of greedy vaccine allocation ⁴⁴⁹ algorithms to baseline algorithms using both the FRED and SafeGraph mobility graphs, ⁴⁵⁰ for both the MAXCASESAVERTED and MAXPEAKSREDUCED problems. For our 451

> small-scale experiment (New Hampshire), we run all four greedy algorithms. For our $\frac{452}{452}$ medium-scale experiment (Iowa), we drop our slowest greedy algorithm $\frac{453}{453}$ 3-ENUMGREEDY. For our large-scale experiment (Texas), we drop our slowest two $_{454}$ greedy algorithms 3-ENUMGREEDY and SINGLETONGREEDY. For this comparison, we 455 always run POMS for the same amount of time as UNITGREEDY. We seek to 456 demonstrate how close the performance of POMS gets to that of UNITGREEDY in a $_{457}$ simple wall clock time based comparison. We repeat these experiments for six different $\frac{458}{458}$ budgets (expressed as a percentage of the population of the state) for two different $\frac{459}{459}$ values of λ . The results for a high infectivity value of λ are summarized in Fig [2,](#page-22-0) [3,](#page-23-0) and ϵ_{460} [4.](#page-24-0) The same experiments for lower infectivity parameter values can be found in the $\frac{461}{461}$ Supplementary Information. 462

Fig 2. Percentage TOTBURDEN and percentage MAXBURDEN reduced by all approaches for $\lambda = 0.5345$ in New Hampshire for FRED (first column) and SafeGraph (second column).

Fig [2](#page-22-0) shows that, for our small-scale experiments, the baselines never outperform the $\frac{463}{100}$ greedy methods. POPULATION and POMS perform on-par with the greedy methods in $_{464}$ some instances, particularly in MAXPEAKSREDUCED. We see the performance of $\qquad 465$ baselines relative to the greedy methods decline as the scale of our experiments become ⁴⁶⁶

Fig 3. Percentage TOTBURDEN and percentage MAXBURDEN reduced by UNITGREEDY, SINGLETONGREEDY, FASTGREEDY and baselines for $\lambda = 0.535$ in Iowa for FRED (first column) and SafeGraph (second column).

larger. As observed in Fig [3,](#page-23-0) even for our medium-scale experiments, the greedy algorithms outperform each baseline in several settings, while no baseline outperforms the greedy methods. Fig [4](#page-24-0) demonstrates that, for our large-scale experiment, UNITGREEDY and FASTGREEDY outperform the baselines by a wider margin than our 470 small and medium-scale experiments over the FRED dataset. This margin is more 471 narrow (with UNITGREEDY and FASTGREEDY still in the lead) over the SafeGraph 472 mobility graph. For SafeGraph, UNITGREEDY and FASTGREEDY perform on-par with 473 the same methods over the FRED data - the difference is primarily in the increased 474 performance of the baselines over SafeGraph. Similar results hold for a lower value of λ , $_{475}$ which we include in the Supplementary Information. UNITGREEDY performs at least 476 on-per with the other greedy methods, all of which employ larger search spaces. In all $\frac{477}{477}$ experiments, after the greedy methods, the POPULATION heuristic performs well, $\frac{478}{478}$ followed by POMS, other baselines, and finally RANDOM. The relatively poor $\frac{479}{479}$ performance of POMS could be attributed to the fact that it requires a long running ⁴⁸⁰ time to achieve its theoretical guarantee (see Performance-Time Trade-off). The $\frac{481}{481}$

Fig 4. Percentage TOTBURDEN and percentage MAXBURDEN reduced by UNITGREEDY, FASTGREEDY and baselines for $\lambda = 0.525$ in Texas for FRED (first column) and SafeGraph (second column).

surprisingly good performance of the POPULATION heuristic suggests that it might be a $_{482}$ good on-the-field strategy in the absence of mobility data for small problem instances. ⁴⁸³ UNITGREEDY substantially outperforms POPULATION and FASTGREEDY for our large-scale experiment on Texas over FRED data, with T OTBURDEN reduced by up to $\frac{485}{100}$ 8% of the population, which translates to almost 2 million additional cases avoided. ⁴⁸⁶

$\textbf{Near-optimality of greedy algorithms}$

In this section, we demonstrate that in practice, the greedy algorithms we evaluate return allocations whose objective function value is close to optimal for both $\frac{489}{489}$ MAXCASESAVERTED and MAXPEAKSREDUCED. Focusing on our small-scale 490 experiment (New Hampshire) using mobility derived from FRED data, we consider 4 $_{491}$ problem instances for each of MAXCASESAVERTED and MAXPEAKSREDUCED, obtained 492 by setting λ to 0.347 and 0.5345 and the budget D to 2 values (10% and 40% of the $\frac{493}{4}$ population). For these problem instances we compute an optimal solution by exhaustive ⁴⁹⁴ search and compare the results to that of 3-ENUMGREEDY, SINGLETONGREEDY, $\frac{495}{495}$

UNITGREEDY, and FASTGREEDY.

For each problem and problem instance, let OPT denote the objective function value $_{497}$ of an optimal solution. Table [3](#page-25-0) shows the performance relative to OPT of problem ⁴⁹⁸ instances for 10% and 40% budgets, high and low infectivity, and both objective functions for each greedy method.

NH (FRED)		Cases Averted	Peaks Reduced	
10% Budget	$\lambda = 0.3475$	$\lambda = 0.5355$	$\lambda = 0.3475$	$\lambda = 0.5355$
3-ENUMGREEDY	99.84%	98.53%	99.71%	96.33%
SINGLETONGREEDY	79.02%	99.04%	99.71%	99.33%
FASTGREEDY	79.02%	95.29%	92.29%	95.21\%
UNITGREEDY	79.02%	99.04%	99.71%	96.33%
NH (FRED)	Cases Averted		Peaks Reduced	
40% Budget	$\lambda = 0.3475$	$\lambda = 0.5355$	$\lambda = 0.3475$	$\lambda = 0.5355$
3-ENUMGREEDY	100%	99.86\%	100%	99.97%
SINGLETONGREEDY	100%	99.86%	100%	99.97%
FASTGREEDY	100%	99.26%	100%	99.97%

Table 3. Approximation factors for each problem instance

Problem instances for the state of Iowa are much larger and it is not feasible to $\frac{501}{501}$ compute OPT to make a direct comparison. To circumvent this problem, we first note $_{502}$ that it is possible to obtain improved versions of Theorems $9(a)$, $9(b)$, and 10 by $\qquad \qquad$ 503 defining "per instance" versions of the DR-submodularity ratio and submodularity ratio. ⁵⁰⁴ To be specific, let $\hat{\mathbf{x}}_i$ denote the allocation after iteration i of UNITGREEDY, let \mathbf{x}^* be sos an optimal solution, and let $y^* = 0 \vee (x^* - \hat{x}_i)$. Define

$$
\beta(g, \hat{\mathbf{x}}_i) := \frac{\sum_{j=1}^K g(\mathbf{y}_j^* \mathbf{e}_j + \hat{\mathbf{x}}_i) - g(\hat{\mathbf{x}}_i)}{g(\mathbf{y}^* + \hat{\mathbf{x}}_i) - g(\hat{\mathbf{x}}_i)}
$$
(11)

The numerator is the total marginal gain of independently increasing each individual $_{507}$ subpopulation's allocation to the optimal allocation. The denominator is the marginal $\frac{508}{200}$ gain of increasing $\hat{\mathbf{x}}_i$ to the optimal solution all at once. If g were submodular, it would $\frac{1}{509}$ follow that $\beta(g, \hat{\mathbf{x}}_i) \geq 1$, but this guarantee does not hold for an arbitrary $g(\cdot)$. It is 510 possible to show that the bound stated in Theorem [10](#page-19-0) holds for $\beta(g, \hat{\mathbf{x}})$, i.e., $\qquad \qquad$ 511 $g(\hat{\mathbf{x}}) \geq (1 - e^{-\beta(g, \hat{\mathbf{x}})}) \cdot OPT$ (more on this may be found in the Supplementary 512) Information). 513

> Since we cannot calculate the optimal solution \mathbf{x}^* directly (and $\beta(g, \hat{\mathbf{x}}_i)$ depends on \mathbf{s}_i (\mathbf{x}^*) we cannot calculate $\beta(g, \hat{\mathbf{x}}_i)$ directly either. Instead, we use a sampling method 515 (described in the Supplementary Information) to find an estimate of $\beta(g, \hat{\mathbf{x}}_i)$, which we 516 denote as $\hat{\beta}(g, \hat{\mathbf{x}}_i)$. We calculate $\hat{\beta}(g, \hat{\mathbf{x}}_i)$ 5000 times for each experiment to estimate 517 $\beta(g, \hat{\mathbf{x}}_i)$.Our key finding is that $\hat{\beta}(g, \hat{\mathbf{x}})$ is very close to (or even larger than) 1 for most 518 of our experimental instances, implying that g might be close to being submodular in $\frac{519}{200}$ practice. This suggests that the allocation $g(\hat{\mathbf{x}}) \ge (1 - 1/e) \cdot OPT \approx 0.63 \cdot OPT$.

NH (FRED)		Cases Averted	Peaks Reduced	
60% Budget	$\lambda = 0.3475$	$\lambda = 0.5355$	$\lambda = 0.3475$	$\lambda = 0.5355$

UNITGREEDY	1.02	1.02	1.06	1.03

Table 4. Estimates of $\beta(g, \hat{\mathbf{x}})$ for each problem instance

Estimates for $\beta(g, \hat{\mathbf{x}})$ can be found in Table [4.](#page-26-0) These values indicate worst-case β_{21} approximation factors for performance on-par (and some exceeding) that of submodular $\frac{522}{2}$ functions for our problem formulations and experimental settings.

$\text{Performance and running-time trade-offs}$

Here, we compare the performance and running time trade-offs for 3-ENUMGREEDY, $_{525}$ SINGLETONGREEDY, FASTGREEDY, UNITGREEDY and POMS. Let $_{526}$ $c_{\text{max}} = \max\{n_i \mid i \in [K]\}.$ The approximation guarantee for POMS requires s_{27} $T = 2e_{\text{max}}D^2K$ queries [\[24\]](#page-33-4); this makes POMS significantly more expensive to run $=$ 528 compared to the greedy methods. The term "query" refers to an evaluation of the $\frac{529}{20}$ objective function $g(\cdot)$; here, that evaluation entails running a disease simulation \sim

NH (FRED)	Queries Required		Wall Clock Time		
20% Budget	$\lambda = 0.3475$	$\lambda = 0.5355$	$\lambda = 0.3475$	$\lambda = 0.5355$	
FASTGREEDY	1567	70	3.9 Minutes	7.4 Seconds	
UNITGREEDY	$6.67 \cdot 10^{3}$	$6.67 \cdot 10^{3}$	16.7 Minutes	7.6 Minutes	
SINGLETONGREEDY	$6.43 \cdot 10^{5}$	$7.57 \cdot 10^5$	1 Hour	37.1 Minutes	
3-ENUMGREEDY	$6.53 \cdot 10^{5}$	$7.58 \cdot 10^{5}$	1 Hour	37.6 Minutes	
POMS	$3.63 \cdot 10^{15}$	$3.63 \cdot 10^{15}$	$\sim 1.5\cdot 10^8$ Years	$\sim 1.2 \cdot 10^8$ Years	
NH (FRED)		Queries Required		Wall Clock Time	
60% Budget	$\lambda = 0.3475$	$\lambda = 0.5355$	$\lambda = 0.3475$	$\lambda = 0.5355$	
FASTGREEDY	4761	2025	7.7 Minutes	3.3 Minutes	
UNITGREEDY	$2\cdot 10^4$	$2 \cdot 10^4$	33.2 Minutes	30 Minutes	
SINGLETONGREEDY	$3.54 \cdot 10^6$	$2.7 \cdot 10^6$	3.9 Hours	3.4 Hours	
3-ENUMGREEDY	$3.55 \cdot 10^6$	$2.66 \cdot 10^6$	5.1 Hours	1.5 Hours	

Table 5. FastGreedy, UnitGreedy, SingletonGreedy, 3-EnumGreedy, and POMS comparison with respect to practical running time (estimated for POMS) to achieve approximation guarantee for New Hampshire with 20% and 60% budgets.

conditioned on a vaccine allocation. Compared to POMS, UNITGREEDY requires $\frac{531}{531}$ relatively fewer $T = K \cdot D$ queries. In addition, UNITGREEDY is much faster in practice $\frac{532}{2}$ (by Wall Clock Time) than POMS since UNITGREEDY is embarrassingly parallel, $\frac{533}{2}$ whereas POMS is much more inherently sequential. These comparisons are presented in $_{534}$ Table [5,](#page-27-0) where we list required iterations and practical run time (extrapolated from 12 535 hours for POMS).

FASTGREEDY introduces an approximation guarantee parameterized by a value $\frac{537}{37}$ which upper bounds the DR-submodularity ratio. Their input parameters can be $\frac{538}{538}$ adjusted to determine the quality required of potential allocation in each iteration, ⁵³⁹ effectively trading performance for speed. When the input parameters to $FASTGREEDY$ $₅₄₀$ </sub> are set so that the performance is maximized, the resulting approximation guarantee is $_{541}$ similar to that of UNITGREEDY, 3-ENUMGREEDY, and SINGLETONGREEDY.

Discussion 543

Through a combination of theoretical and experimental results, we have shown that ⁵⁴⁴ even though metapopulation model vaccine allocation problems are inapproximable in ⁵⁴⁵ the worst case, simple greedy algorithms can be both effective and scalable for these $\frac{546}{546}$ problems. 547

> We provide a possible theoretical explanation for the effectiveness of these greedy $\frac{548}{548}$ algorithms by establishing worst case approximation guarantees in terms of the ⁵⁴⁹ submodularity ratios of the objective functions of these problems. Specifically, we extend worst case approximation guarantees from the literature for lattice greedy $\frac{551}{551}$ algorithms $[20, 25, 26]$ $[20, 25, 26]$ $[20, 25, 26]$ to the non-submodular objective function setting. Our analysis $\frac{552}{2}$ builds upon prior work on submodular set and lattice function 553 maximization $[5, 10, 19, 20, 28, 33]$ $[5, 10, 19, 20, 28, 33]$ $[5, 10, 19, 20, 28, 33]$ $[5, 10, 19, 20, 28, 33]$ $[5, 10, 19, 20, 28, 33]$ $[5, 10, 19, 20, 28, 33]$. For specific instantiations of the metapopulation $\frac{554}{2}$ model vaccine allocation problems (e.g., MAXCASESAVERTED, MAXPEAKSREDUCED) 555 we provide some empirical evidence that the submodularity ratio of the objective $\frac{556}{556}$ functions is high enough (i.e., close enough to 1) to imply that greedy algorithms yield $\frac{557}{157}$ near-optimal solutions to these problems. $\frac{558}{200}$

> The effectiveness of the greedy algorithms we evaluate is maintained across small $\frac{559}{559}$ (New Hampshire), medium (Iowa), and large (Texas) problem scales over two mobility ⁵⁶⁰ graphs constructed from FRED [\[30\]](#page-34-5) and SafeGraph [\[35\]](#page-34-10) data sources. In all problem ⁵⁶¹ instances of MVA we evaluate, the greedy methods outperform the baselines, sometimes by quite a significant margin. This difference in performance is typically greatest for a $_{563}$ high λ (infectivity) value, vaccinating 30% to 50% of the total state's population for each problem scale. We also demonstrate that the greedy algorithms achieve an $_{565}$ approximation factor of over 0.79 for a 10% budget, and an approximation factor of over $\frac{566}{2}$ 0.99 with a 40% budget for both $MAXCASEAVERTED$ and $MAXPEAKSREDUCED$ 567 problem instances over New Hampshire. Our submodularity ratio estimates for each ⁵⁶⁸ problem scale approximation guarantees at least match those of submodular objective ⁵⁶⁹ function maximization. $\frac{570}{200}$

> We observe the performance of the greedy methods are on-par with each other for $\frac{571}{200}$ the Texas FRED and SafeGraph mobility graphs, but the performance of the baselines $\frac{572}{572}$ over the FRED mobility graph are much lower. Because of this, we conjecture that the $\frac{573}{200}$ MVA problem over sparse mobility graphs is harder to solve and we cannot depend on 574 the baselines. Across all experiments, we observe that the MVA problem instances with 575 a lower infectivity value λ - infecting approximately 20% of the population - are $\frac{576}{576}$ generally easier to achieve good performance on for all methods. $\frac{577}{200}$

> Moreover, we have parallelized our algorithms to enhance scalability, making the $\frac{578}{20}$ fastest of them take hours to run for the state of Texas. The ability to parallelize the ⁵⁷⁹

> computation allows us to manage the computational demands of large states, ensuring $\frac{580}{20}$ that our methods remain feasible even in high-dimensional datasets. The query $\frac{581}{581}$ complexities for each greedy algorithm (shown in Table [2\)](#page-20-0) further contributes to the feasibility and speed of the fastest two greedy algorithms we present, UNITGREEDY and $\frac{583}{2}$ FASTGREEDY. In addition, it is quite natural to speed up greedy methods by not $_{584}$ looking for a locally optimal update in each iteration, but an approximately optimal sss update, which is a main principle behind the threshold approach of $FASTGREEDY$. These features of the greedy methods present a computational advantage with respect $\frac{587}{587}$ to scalability over algorithms such as $POMS$, introduced in [\[24\]](#page-33-4).

> Despite these contributions, several limitations remain. Our current model is $_{589}$ relatively simple and deterministic, assuming homogeneous mixing within populations, $\frac{590}{2}$ which may not capture the complexities of real-world disease spread. Future work could $_{591}$ incorporate more sophisticated models, such as agent-based simulations within ⁵⁹² subpopulations, to better reflect heterogeneous contact patterns. Additionally, the inferred mobility data we use is based on limited sources and does not fully reflect ⁵⁹⁴ real-world movement patterns, particularly in rural or less structured areas. Expanding 595 to include more comprehensive mobility data, such as transportation networks, would improve accuracy. We also assume preemptive vaccine allocation, which may not be $\frac{597}{2}$ practical in many real-world settings. Addressing non-preemptive vaccine allocation and ⁵⁹⁸ exploring faster, more scalable algorithms, such as sketch-based methods [\[25,](#page-34-0) [36\]](#page-35-1), are ⁵⁹⁹ promising directions for future research. For this paper, we ran experiments on 600 individual states in isolation without taking physical border effects into account, where $\frac{601}{601}$ in real-world settings, the influence of areas (especially urban) across a state border 602 could have significant impact on vaccine allocation decisions. Additionally, deriving $\qquad \qquad \text{603}$ confidence bounds for the estimated submodularity ratios would enhance the robustness 604 of our theoretical guarantees. $\qquad \qquad \text{605}$
