Abstract

The performance of Oracol collection device (Oracol) for oral fluid sampling for SARS-CoV-2 molecular detection was compared to nasopharyngeal swabs (NPS). Samples (n = 128) were collected from symptomatic and asymptomatic adults after PCR confirmed COVID-19 on NPS. All samples were tested by 3 real-time PCR's (RT-qPCR) for E, N and RdPR genes. Accuracy of Oracol compared to NPS was 38.28 % for E-gene, 47.66 % for RdRp-gene and 83.59 % for N-gene. A clear correlation between the N-gene Ct values on NPS and on Oracols was observed ($p < 0.001$). The sensitivity of the Oracol compared to the NPS increased in participants with an N-gene Ct value <30 on NPS (89.08%,) reaching 93.2 % with a N-gene Ct value <25 . Oracol can be considered an alternative to NPS to detect SARS-CoV-2, especially in populations where NPS is not well tolerated.

Background

At the end of 2019, a new human coronavirus, now known as severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2), was first reported and is a cause of a currently ongoing pandemic of coronavirus disease 2019 (COVID-19) with the clinical presentations ranging from no to limited symptoms to patients with severe potentially life-threatening pneumonia requiring hospitalization [1].

At the time of writing, the WHO reported more than 440 million infections and a death toll of more than 5.5 million since the start of the pandemic. The rise of the virus and the economic and social impact on the whole world caused a surge of research and the rapid development of several effective vaccines. To date more than 10 billion vaccine doses have been administered worldwide, helping in quenching the impact of the pandemic.

Hygienic measures across the world rely heavily on effective testing. Testing is first performed to confirm an infection in a symptomatic patient to decide on the therapeutic path. Second, testing might be performed to identify infectious individuals in a population, who are then isolated to prevent further spread. Ending the pandemic involves the accurate application of diagnostic testing in high volumes and the rapid use of the results to help implement the appropriate therapy and prevent further spread.

In January 2020 the genome of the virus was published, and within two weeks the first diagnostic PCR tests were available [2]. A PCR for RdRp, E, N or S genes was recommended and is performed on nasopharyngeal swabs [3]. Based on established diagnostics for other respiratory infections, the nasopharyngeal swab was initially adopted as the preferred sampling technique. However, numerous reports have shown that saliva can serve as an alternative upper respiratory tract specimen type for SARS-COV-2 detection [4-8].

Nasopharyngeal sampling requires a swab being inserted into the back of the nose, which can cause irritation that could promote sneezing and coughing. Thus, the non-invasive collection of saliva would be safer, as it protects healthcare workers from being inadvertently exposed to potentially infectious aerosols. This less irritating way of sampling is also especially interesting for people that require frequent testing or for children.

In this study, we evaluated the performance of sampling by Oracol collection device (Malvern Medical Development, UK) (Oracol) compared to nasopharyngeal sampling (NPS) to detect SARS-CoV-2 virus for the COVID-19 diagnosis by PCR. Oracol sampling has been routinely used for diagnostic purposes for the detection of measles and mumps viruses by RT-PCR, as well as for the detection of antibodies against measles, mumps, rubella viruses [9]. Oracol collection device was specifically developed for the collection of oral fluid enriched in gingival crevicular fluid and thus differs from pure saliva obtained from spitting and from saliva mixed with sputum [10]. It is a painless, non-invasive sampling procedure and could thus represent an interesting alternative to nasopharyngeal swab that causes more discomfort, especially for children. Both NPS and Oracol samples were tested with a PCR for the SARS-CoV-2 E-gene, N-gene and the RdRp-gene.

Methods

Samples and participants

Study samples were collected from the participants of the simultaneously ongoing CAMOSTAT study [11] which included repetitive visits on day 5 and day 10 after initial diagnosis of COVID-19 infection by a polymerase chain reaction (PCR) on a nasopharyngeal swab (NPS). The Oracol

study participants were asked if they could provide, in addition to the NPS already included in the CAMOSTAT study, a saliva sample collected by ORACOL – Saliva Collection System® during the same visit. Ethical approval from all of the appropriate institutional review boards was obtained. The ethics review committee of Ghent University Hospital Belgium, approved the study with a reference number B670202000996.

NPS samples were collected by a nurse using eSwab Mini Tip FloQ swab®, Copan (Brescia, Italy), according to the manufacturer’s instructions by gently inserting the swab into the nostril and pushing it deeper into the pharynx with the patient’s head slightly tilted backwards.

Saliva samples were collected by the patient himself using ORACOL – Saliva Collection System® (Malvern Medical Developments, Worcester, United Kingdom) by placing the collection device into the mouth with consequent continuous rotation between cheek and upper teeth during minimal 1, maximal 2 minute(s).

After collection, the swabs were placed in the provided plastic tubes and transported to the Laboratory of Medical Microbiology, Ghent University Hospital, where the saliva samples were processed by centrifugation at 3000 g for 10 minutes in order to collect the patient’s saliva absorbed by the sponge swab . All samples were stored at -80°C temperature prior to dry-ice transport to Sciensano for molecular testing.

Molecular assays

All collected NPS and saliva samples were tested at Sciensano by 3 real-time PCR methods accordingly to previously published procedures targeting separately the E-gene, N-gene (US CDC N1 protocol) and RdRp-gene (Institut Pasteur protocol) of SARS-CoV-2 [3]. PCR’s were

performed after nucleic acid extraction using Nuclisens® easymag® reagents on an EMAG® instrument (Biomérieux).

Evaluation of results

Data processing and statistical analysis was performed in R program version 4.1.1 and graphs were created using GraphPad Prism version 9.0.0.

Results

During the course of the CAMOSTAT study, 134 participants were enrolled in this sub-study to evaluate the performance of Oracol sampling to detect SARS-CoV-2 virus in oral fluid samples. Participants for the Oracol sub-study were enrolled among the CAMOSTAT outpatients (not hospitalized) who tested positive for SARS-CoV-2 and who received the placebo treatment. They were then contacted to take part in the Oracol sub-study. At enrollment in the sub-study, a nasopharyngeal swab and an Oracol swab were collected by and under the supervision of a nurse, respectively.

All samples were tested with three RT-qPCRs targeting different genes of the virus. Among these 134 participants, only 128 tested positive by RT-qPCR for SARS-CoV-2 (whatever the target) in the nasopharyngeal swab taken on the same day as the Oracol and were thus retained in the analysis to evaluate the performance of Oracol compared to nasopharyngeal swab.

The sub-study population was equally distributed between males and females (64 participants in each group, Table 1). Female participants were on average younger than males (Wilcoxon signed-rank test, $p = 0.007$), with a clear over representation of females aged below 30 (Fisher exact test, $p = 0.013$). There was suggestive evidence of a difference between gender in the

proportion of symptomatic patients (Fisher exact test, $p = 0.054$), but not in the number of days after symptom onset. There was strong evidence that a sore throat was more often reported by females (Fisher exact test, $p = 0.002$) and suggestive evidence for sneezing and headache (Table 1). There was no difference between age groups in the proportion of symptomatic patients or in the number of days after symptom onset, but there was strong evidence that younger age groups seemed to report sneezing, headache and a sore throat more often than older ones, and that older age groups seemed to report fever more often than younger ones (Table 2).

All 128 nasopharyngeal swabs were found positive by N-gene RT-qPCR (100 %, CI = 97.09 – 100.00). Only 118 were detected by the E-gene RT-qPCR (sensitivity compared to N-gene = 92.19 %, CI = 86.22 – 95.70) and 121 by the RdRp-gene RT-qPCR (sensitivity compared to N-gene = 95.31 %, CI = 90.15 – 97.83).

When comparing Oracols to nasopharyngeal swabs, the E-gene and RdRp-gene RT-qPCRs showed low accuracy even for samples with a low Ct value (i.e. high viral load) in the nasopharyngeal swab (Figure 1). Accuracy of Oracols compared to nasopharyngeal swabs was only 38.28 % (CI = 29.83 – 47.28) if using the E-gene RT-qPCR, and reached nearly 50 % (47.66 %, CI = 38.76 – 56.66) if using the RdRp-gene RT-qPCR. Using the N-gene RT-PCR, more than three quarters of the participants were correctly identified in the Oracol sample (sensitivity compared to nasopharyngeal swab = 83.59 %, CI = 76.22 – 89.01). There was even strong evidence of correlation between the N-gene Ct values obtained for the nasopharyngeal and the Oracol samples (Spearman rank test, $\rho(126) = 0.625$, $p < 0.001$). The sensitivity of the Oracol compared to the nasopharyngeal swab was increased when considering only

participants with an N-gene Ct value <30 in the nasopharyngeal swab (89.08%, CI: 82.2 – 93.5, n = 119) and even reached 93.2 % (CI: 86.63 – 96.67) when considering only participants with an N-gene Ct value <25 (n = 103).

The association of the N-gene result in Oracol with several univariate explanatory variables was then evaluated (Table 3, Figure 2). The proportion of positivity in Oracol did not significantly differ by gender (chi-square test, $\chi^2(1, N=128) = 1.42$, $p = 0.233$) – although a Wilcoxon signed-rank test revealed some evidence of a difference between males and females in Ct value obtained ($p = 0.040$) – nor with age group (chi-square for trend, $\chi^2(1, N=128) = 1.54$, $p = 0.215$). There was suggestive evidence that the proportion of positivity in Oracol was higher in the group of symptomatic patients compared to the asymptomatic ones (chi-square test, $\chi^2(1, N=128) = 3.50$, $p = 0.062$). When considering only these symptomatic patients, there was a strong evidence that the proportion of positivity in Oracol differed between symptom-onset groups defined as sampling taking place less than 3 days, between 3 and 5 days, or more than 5 days after onset (chi-square for trend, $\chi^2(1, N=117) = 9.53$, $p = 0.002$). When considering each symptom separately, there was strong evidence that the proportion of N-gene Oracol positivity was lower in the groups presenting dyspnea (Fisher's exact test, $p = 0.031$) or dysgeusia (chi-square test, $\chi^2(1, N=117) = 6.30$, $p = 0.012$).

Multivariate logistic regression analyses were then used to identify potential predictors of positivity by N-gene RT-PCR in Oracol samples, taking into account cofounder effects (Table 4, Figure 3). The results of the analysis for the whole study population (N = 128) indicated that, all else being equal, participants with a Ct value below 25 or 30 in the nasopharyngeal swab had higher odds of being detected positive in the Oracol sample than participants with a Ct

value equal or above 25 or 30 in the nasopharyngeal swab (adjusted OR (aOR) = 19.77, CI = 6.36 – 70.75, $p < 0.001$ and aOR = 74.08, CI = 10.85 – 1584.96, $p < 0.001$, respectively). Among symptomatic participants (N = 117), all else being equal, there was strong evidence that participants with dysgeusia or being sampled more than 5 days after symptom onset had lower odds of being detected positive in the Oracol sample (aOR = 0.24, CI = 0.07 – 0.77, $p = 0.019$ and aOR = 0.22, CI = 0.06 – 0.69, $p = 0.011$, respectively), and suggestive evidence for participants with dyspnea (OR = 0.26, CI = 0.06 – 1.14, $p = 0.065$).

Discussion

Since the purpose of the study was to evaluate the performance of the Oracol saliva sampling device to detect SARS-CoV-2 when the corresponding nasopharyngeal swab is positive, only 128 participants were included in the analysis out of the initial 134. A short delay might have occurred between the first test used to define enrollment in the CAMOSTAT study and the samples (nasopharyngeal swab and Oracol) taken for the Oracol study, which could explain the discrepancy for the remaining six that were found negative in their second nasopharyngeal swab.

The differences between the three RT-qPCR targets for nasopharyngeal swabs and especially the lower sensitivity of the E-gene and RdRp-gene RT-PCRs cannot be explained by the quality of the samples (results for housekeeping gene not shown) since all were performed on the same RNA extract. The different assays were validated in nasopharyngeal swabs and oral fluids spiked with a serial dilution of SARS-CoV-2 virus and both sample types showed similar limits of detection (data not shown). Differences observed for clinical samples might be due to differences in the actual copy numbers of targets present in the sample, since viral RNA

molecules other than the genomic RNA might be present, such as mRNAs and subgenomic RNAs. In particular, it was shown that subgenomic RNA molecules of the SARS-CoV-2 N gene are the most abundantly produced during viral replication [12]. These results nonetheless demonstrated the importance of selecting the right target for a given sample type. While the E-gene and RdRp-gene RT-qPCR showed sufficient clinical sensitivity for nasopharyngeal swabs, they were clearly not suitable for Oracol saliva samples. However, using the three assays together or the three genes within a single assay could be envisioned to increase the clinical sensitivity of Oracol [13].

Our logistic regression analysis on the whole study population showed that Oracol saliva samples could be a suitable alternative to nasopharyngeal swab to identify people susceptible to be shedding infectious virus, as defined by having a N-gene RT-qPCR Ct value below 30 in the nasopharyngeal swab [14-18]. Similarly, when considering only the symptomatic patients, our results showed that oral fluid collected with Oracol might be a suitable alternative to nasopharyngeal swabs for symptomatic patients sampled less than 5 days after onset of symptoms, or for those not presenting dysgeusia or dyspnea.

Oracol saliva sampling for the detection of SARS-Cov-2 has not yet been used in many studies. Interestingly, although Defeche et al. [19] found that detection of SARS-CoV-2 in Oracol samples was lower than in nasopharyngeal swab in general, it was performing better for patients presenting with fever. On the other hand, Johnson et al. [20] did not find any association between symptom type and positivity in a saliva sample, but their study included a more limited number of participants. Manabe et al. [21] also found that Oracol sampling performs best in the first five days after symptom onset, but they also suggested that the

moment of sampling in the day and the addition of sputum in the sample might be worth investigating to increase the sensitivity of oral fluid samples. Our results are difficult to compare with other studies that used other devices to collect saliva or oral fluid [22]. Nonetheless, Congrave-Wilson et al. [23] also found that saliva sample was sensitive for SARS-CoV-2 detection in symptomatic patients within the first days after symptom onset and with a high viral load as estimated by RT-qPCR in the paired nasopharyngeal swab.

Our study has some limitations. First, the performance of Oracol was evaluated only in comparison of nasopharyngeal swab. Oracol was not evaluated on its own for its clinical sensitivity to detect SARS-CoV-2 infected people [6, 24]. Then, the participants to the study were mainly symptomatic patients and the observed performance might differ for asymptomatic infections [25, 26]. In addition, the samples were taken while the alpha variant was circulating in Belgium, so before the circulation of the delta and omicron variants. The performance of Oracol would need to be evaluated for these variants, especially with recent reports suggesting that the omicron variant would be detected more easily in saliva samples than nasopharyngeal swabs [27]. Finally, samples were taken before vaccination was introduced. It remains to be checked with infected, vaccinated people whether or not vaccination affects the capacity to detect SARS-CoV-2 in an Oracol sample following, for example, reduction of the viral load during infection [28-30].

In conclusion, Oracol device represents an interesting alternative to nasopharyngeal swab to detect SARS-CoV-2-infected people at a moment when they might be contagious, and should be considered as an interesting tool in the sampling strategy implemented by the health

authorities to control the pandemic, especially when nasopharyngeal swabbing is not well tolerated.

^a Model 1 for the whole study population (N = 128): dependent variable =N-gene RT-PCR positivity status in Oracol sample; explanatory variables = age (continuous variable), gender (binary), symptomatic status (binary), N-gene RT-PCR Ct-value in nasopharyngeal swab (binary, “low”/”high” using a Ct threshold of 30).

^b Model 2 for symptomatic participants (N = 117): dependent variable =N-gene RT-PCR positivity status in Oracol sample; explanatory variables = age (continuous variable), gender (binary), symptom onset status (binary, sampling less or more than 5 days after beginning of symptoms), dysgeusia (binary), dyspnea (binary).
