Abstract

Background: Vestibular schwannoma (VS) often results in persistent dizziness that negatively impacts quality of life (QoL). While physical effects are well-documented, the influence of psychological factors on dizziness severity is less studied. This study investigates how psychological characteristics affect dizziness in VS patients.

Methods: In this cross-sectional study, 93 VS patients were analyzed, with 77 (82.8%) reporting postoperative dizziness. Psychological factors, including premorbid disorders, personality traits, somatization, and current depression and anxiety levels, were assessed using self-report questionnaires. Correlations between these factors and dizziness severity, measured by the Dizziness Handicap Inventory (DHI), were examined.

Results: Patients with postoperative dizziness had higher depression levels and a greater prevalence of preoperative dizziness compared to those without postoperative dizziness. Significant correlations were found between dizziness severity and psychological factors: conscientiousness (r = .30, p = .03), social support (r = .32, p = .03), and the HADS total score (r = .36, p = .01). Emotional aspects of dizziness (DHI-E) were correlated with somatization (r = .27, p = .04) and anxiety (r = .40, p = .01). Functional aspects (DHI-F) were linked to conscientiousness (r = .31, p = .03) and depression (r = .26, p = .06).

Conclusion: Psychological factors significantly impact dizziness severity in VS patients. Incorporating psychological assessments and interventions, such as cognitive-behavioral therapy and combined vestibular and psychological rehabilitation, may improve treatment outcomes and QoL. Further research is needed to assess the effectiveness of these approaches and their impact on the relationship between psychological factors and dizziness.

Introduction 1

2 A vestibular schwannoma (VS), also referred to as an acoustic neuroma, is a benign neoplasm 3 that arises from the Schwann cells of the vestibulocochlear nerve. While the primary consequence of this condition is often auditory, many patients also present with dizziness and 4 vertigo, which may persist after or be induced by microsurgery or radiation treatment (1-3). 5 Conservative VS management ("wait-and-scan") seems to have no impact on the prevalence of 6 7 these symptoms, as well as postural sway and canal paresis (4). The severity of these vestibular 8 symptoms is variable, but they frequently have a long-lasting impact on patients' quality of life 9 (QoL) across multiple domains (2,3,5).

10 As identified by Carlson et al. (5), the strongest predictors of long-term QoL reduction in patients with sporadic VS are ongoing dizziness and headache. In comparison, the impact of 11 12 hearing loss, facial nerve function, and tinnitus was shown to be less significant (5). Dizziness is significantly correlated with challenges in performing routine tasks, which can lead to a 13 deterioration in physical well-being, an increased reliance on external assistance, and 14 occupational limitations (6). It has been demonstrated that dizziness is linked to elevated levels 15 16 of anxiety, depression, and diminished cognitive function, which serves to further exacerbate the decline in QoL (6,7). Furthermore, balance disorders were found to be associated with 17 anxiety and depression, as well as with greater daily consequences and a denial coping response 18 19 (8). In an experimental setting, the presence of anxiety symptoms during a vestibular stimulus may contribute to a priming effect that could explain the observed worsening of balance 20 function (9). 21

In addition to the dizziness associated with VS, it has also been shown that somatoform 22 23 complaints in individuals experiencing dizziness are highly prevalent. The presence of certain 24 factors, such as personality characteristics or accompanying psychopathology, has been 25 identified as influencing the prevalence of these complaints (10). Research on chronic subjective dizziness (11) and persistent postural-perceptual dizziness (PPPD) (12) has revealed 26 27 that anxiety, neuroticism, and somatic symptom burden are markedly elevated in individuals 28 with these conditions. Patients with PPPD also exhibited diminished levels of conscientiousness 29 in comparison to the control group (12). In the aftermath of acute vestibular events, psychological and behavioral responses, along with brain maladaptation, were shown to be the 30 31 most probable predictors of PPPD (13). Furthermore, a correlation was identified between benign paroxysmal positional vertigo and the presence of comorbid major depressive disorder, 32

33 generalized anxiety disorder, and obsessive-compulsive personality disorders when compared34 to the findings in a control group (14).

35 Given the lack of comprehensive examination of psychological factors in this area, the objective 36 of this study was to evaluate the differential impact of these factors on dizziness and to ascertain 37 the potential interplay between psychological characteristics and the severity of dizziness handicap. Specifically, the present study aimed to: 1) elucidate the distinctions between VS 38 39 patients with and without postoperative dizziness. Accordingly, our investigation concentrated 40 on the incidence of premorbid psychological disorders and ailments, personality traits, somatization tendencies, and the current levels of depression and anxiety. And, 2) examine the 41 relationships between the intensity of dizziness handicap and these psychological variables as 42 well as sociodemographic variables (age, gender) and tumor size within the group of individuals 43 44 affected by dizziness.

45 Materials and Methods

This cross-sectional, single-center investigation was conducted at University Hospital Halle 46 (Saale), Germany, as part of a broader study that also explored psychological factors and their 47 48 associations with postoperative headache and tinnitus in patients with VS patients (15). The 49 inclusion criteria were as follows: individuals with a confirmed diagnosis of vestibular schwannoma (VS), aged 18 or above at the time of diagnosis, undergoing retrosigmoid surgery, 50 and possessing proficiency in the German language. Patients were excluded if they had 51 52 undergone prior surgical procedures or radiation therapy, if they had a history of recurrent VS, if they had been diagnosed with additional oncological conditions, or if they had been diagnosed 53 54 with neurofibromatosis type 2. The advent of the SARS-CoV-2 pandemic precipitated a postponement in the recruitment of subjects, with recruitment commencing on 01/05/2020, and 55 56 concluding on 31/08/2020. The initial stage of participant engagement was conducted through direct approaches during resident consultations at University Hospital Halle, and an online 57 survey (SoSciSurvey) comprising identical questions was administered by Vereinigung 58 Akustikus Neurinom e.V. (a non-profit patient self-help organization). Prior to participation, all 59 subjects provided written informed consent. The study was approved by the Ethics Committee 60 61 of University Hospital Halle (No. 2020-008).

62 *Measures*

A self-administered survey was employed to collect data pertaining to demographic
characteristics (e.g., age and gender), psychological aspects (including premorbid

65 psychological diagnoses such as anxiety disorders or other mental conditions such as sleep 66 disturbances), and treatment details (e.g., surgical approach, craniotomy vs. craniectomy). The 67 survey consisted of binary questions (yes/no), with the option of providing additional details 68 when necessary (e.g., "Specify the diagnosed psychological disorder"). Tumor size was 69 evaluated according to the Koos grading system, which ranges from 1 to 4 (16).

70 The German version of the Dizziness Handicap Inventory, known as DHI-G (17), was 71 employed for the purpose of evaluating the extent of disability associated with dizziness. The 72 scale comprises 25 items, with a score of 4 allocated to affirmative responses, 2 to "sometimes" responses, and 0 to negative responses. The total score ranges from 0, indicating no disability, 73 to 100, reflecting severe disability. The questionnaire is comprised of three subscales: a seven-74 item physical subscale, a nine-item emotional subscale, and a nine-item functional subscale. 75 76 The DHI-G has been demonstrated to perform reliably, and it is therefore recommended as a suitable assessment tool for gauging disability in individuals experiencing dizziness and 77 78 unsteadiness.

79 The Glasgow Benefit Inventory (GBI) is a validated questionnaire comprising 18 items that is 80 utilized to assess patients' perceived health benefits (PHB) post-intervention, such as surgery. GBI scores range from -100 to +100, with a score of 0 indicating no perceived benefit, +100 81 82 signifying the highest level of benefit, and negative scores suggesting a decline in health. Principal component analysis revealed that the Glasgow Benefit Inventory items consistently 83 84 fell into three distinct subscales. The first subscale, labeled "General," comprised twelve questions related to overall health changes, both general and psychosocial. The second subscale, 85 86 labeled "Social," included three questions addressing the necessary social support for the specific condition at hand. The final subscale, labeled "Physical," included three questions 87 focusing on changes in physical health status, including medication requirements and doctor 88 89 visits (18).

In order to assess the Big Five personality traits in accordance with the framework established 90 by McCrae and Costa (19), the German version of the Ten Item Personality Inventory (TIPI-91 92 G) (20) was utilized. This inventory captures the five fundamental dimensions of the personality 93 model, namely emotional stability (the opposite of neuroticism), extraversion, agreeableness, 94 openness, and conscientiousness. The TIPI-G, which was designed as a concise version of the 95 questionnaire, is particularly beneficial in situations with time constraints, as it provides a reliable estimate of the comprehensive measurements associated with the five-factor model of 96 97 personality, such as those provided by the NEO-PI-R (21). The respondents employ a 7-point

98 Likert scale (ranging from 1 for "strongly disagree" to 7 for "strongly agree") to evaluate ten
99 pairs of adjectives. The resulting scale score is the mean of two items, including one negatively
100 worded item.

101 Pre-morbid somatization tendencies were assessed using the Screening for Somatoform 102 Disorders (SOMS-2), a validated instrument commonly used in patient populations with 103 psychosomatic disorders (22). In the first part of the questionnaire, participants were asked to 104 report physical symptoms that were intermittent or persistent in the two years prior to the 105 diagnosis of VS. These symptoms should have significantly interfered with their well-being or 106 personal lifestyle, without a clearly identified cause as determined by medical professionals. The questionnaire presented a list of 53 somatoform symptoms, 5 specific to women and 1 107 108 specific to men, based on criteria from the Diagnostic and Statistical Manual of Mental 109 Disorders (DSM-IV-TR) and the International Classification of Diseases (ICD-10). The second section consisted of 15 questions designed to assess disability, frequency of medical 110 111 consultations due to symptoms, and inclusion/exclusion criteria for all somatoform disorders.

We used the Hospital Anxiety and Depression Scale (HADS-D) to assess current symptoms of anxiety and depression (23). This questionnaire consists of two scales, one for anxiety and the other for depression, each ranging from 0 to 21. A total score, ranging from 0 to 42, was calculated based on symptoms experienced in the week prior to the assessment. Elevated scores indicated increased levels of anxiety, depression, or general psychological distress. The HADS-D serves as a screening tool, with scores greater than 8 warranting additional assessment for an affective disorder.

119 The statistical analysis was conducted using the statistical software package SPSS (24), with a significance level set at $\alpha = 0.05$. The normality of the dataset was evaluated through the 120 121 application of the Shapiro-Wilk test, which indicated a non-normal distribution. As the objective of this explorative study was to gain a more comprehensive understanding of the 122 123 relationships and differences among psychological factors and postoperative dizziness, we 124 combined Chi-square tests, Mann-Whitney U-tests and correlation analyses. Chi-square tests were employed to ascertain discrepancies between the dizziness and non-dizziness groups with 125 126 respect to dichotomous variables, including the presence of premorbid psychological disorders. 127 Mann-Whitney U-tests provide insights into the differences between patient groups with and 128 without dizziness, allowing us to identify significant disparities. In contrast, the use of 129 Spearman correlation analysis (r_s) within the dizziness group facilitates a more comprehensive 130 examination of the precise dynamic relationships between these variables, thereby providing

insight into how they interact and potentially influence the severity or nature of dizziness. This
dual approach enables a more nuanced interpretation of our findings, capturing both intergroup
differences and intragroup associations. To address multiple testing, false discovery rate
correction (25) was applied.

135 Results

136 Sample characteristics

137 A total of 93 participants were included in the final analysis, following the exclusion of eight 138 individuals whose questionnaires were incomplete or lacked data regarding tumor size. Of the evaluated participants, 77 (82.8%) reported experiencing postoperative dizziness. It is 139 140 noteworthy that over half of the patients surveyed indicated that they had also experienced 141 dizziness prior to surgery. The participants' ages ranged from 23 to 85 years, with a mean age of 55.4 years (SD = 11.9). The mean age of the participants at the time of surgery was 46.7 142 years (SD = 10.2), and the mean duration since treatment was 7.6 years (SD = 7.8). The 143 144 preoperative dizziness severity scores, as measured by the Numerical Analog Scale (NAS), ranged from 1 to 10, with a mean score of 4.6 (SD = 2.7). Similarly, postoperative dizziness 145 146 severity scores ranged from 1 to 10, with a mean score of 4.8 (SD = 2.7). A total of 18.2% of participants reported experiencing a severe degree of dizziness-related handicap. All patients 147 148 who reported preoperative dizziness also experienced postoperative dizziness, and 29 patients 149 (37.6%) reported that dizziness began to occur after surgery. Table 1 presents the descriptive 150 statistics for the additional demographic variables and questionnaire scales. The descriptive 151 data for the administered questionnaires are presented in Table 2.

161

162

163 Differences between patients with and without postoperative dizziness

164 A comparison of patients with and without postoperative dizziness revealed that those 165 experiencing dizziness following surgery exhibited a higher mean symptom count score (M =

9.4, SD = 7.3 vs. M = 5.4, SD = 4.7, p < .05) and higher levels of depression (M = 7.3, SD = 166 3.8 vs. M = 5.1, SD = 3.8, p < .05). No significant differences were identified with regard to 167 personality traits or perceived health benefits. Patients who experienced postoperative dizziness 168 exhibited a significantly higher prevalence of preoperative dizziness (n = 46 vs. 2, p = .001) 169 and preoperative headaches (n = 28 vs. 1, p < .05) compared to those who did not. 170

171

172 Associations between postoperative dizziness handicap and psychological factors

173 After correcting for multiple comparisons, the analysis yielded several noteworthy correlations 174 (see Table 3). With regard to the physical aspects of dizziness (DHI-P), the following significant correlations were identified: Conscientiousness demonstrated a positive correlation 175 176 (r = .30, corrected p = .03), as did social support (r = .32, corrected p = .02). With regard to the emotional aspects of dizziness (DHI-E), the following significant correlations were identified: 177 178 The Somatization Index DSM-IV demonstrated a correlation of r = .27 (corrected p = .04), while the HADS Depression and HADS Anxiety exhibited correlations of r = .31 (corrected p 179 180 = .03) and r = .40 (corrected p = .01), respectively. For the functional aspects of dizziness (DHI-F), significant correlations were observed with conscientiousness (r = .31, corrected p = .03), 181 182 and the somatization index DSM-IV (r = .30, corrected p = .03). The overall dizziness handicap (DHI total score) demonstrated significant correlations with conscientiousness (r = .30, 183 corrected p = .03), social support (r = .32, corrected p = .03), and the HADS total score (r = .36, 184 corrected p = .01). 185

Discussion 186

To the best of our knowledge, this is the first study to examine the associations between long-187 188 term dizziness and psychological factors, such as personality and somatization, in VS patients 189 who underwent retrosigmoid microsurgery. An understanding of these relationships is essential 190 for the development of more effective treatment strategies that address both the physical and 191 psychological dimensions of dizziness in this patient population.

192 The observation that a significant proportion of patients experienced dizziness both pre- and 193 postoperatively is consistent with previous research indicating that pre-existing vestibular 194 symptoms are a strong predictor of postoperative dizziness (1-3). The elevated mean symptom count score and levels of depression in patients with postoperative dizziness serve to underscore 195 196 the lasting impact of these symptoms on patients' well-being. This finding supports the 197 assertion of Carlson et al. that persistent dizziness is a critical predictor of long-term reduction 198 in quality of life in VS patients (5). However, in contrast to the findings of Carlson et al, we found no significant associations between age, gender, tumor size, and dizziness handicap. 199

200 The significant correlations between dizziness and psychological factors offer a more profound 201 comprehension of dizziness in VS patients. Specifically, a positive correlation was observed 202 between conscientiousness and the physical and functional aspects of dizziness of patients with 203 VS. This indicates that patients with higher levels of conscientiousness may experience 204 disparate patterns of dizziness or demonstrate more effective coping mechanisms. In contrast, 205 elevated levels of depression and anxiety were markedly linked to high levels of both emotional 206 and functional dizziness handicap. These findings are consistent with those of previous studies that have highlighted the role of psychological distress in exacerbating dizziness and its 207 associated disability (6-8). 208

209 The correlation between the somatization index (DSM-IV) and the emotional aspects of 210 dizziness provides further evidence that somatic symptoms and psychological distress might be 211 closely linked. This is consistent with findings from research on chronic subjective dizziness and PPPD, which have demonstrated elevated levels of somatic symptom burden in these 212 conditions (11, 12). 213

214 The positive correlation between social support and the physical and overall handicap of 215 dizziness indicates that patients with more robust social support networks may experience less 216 severe physical symptoms and overall handicap. This finding is consistent with the results of

previous research indicating that social support can mitigate the impact of chronic conditionson quality of life (7).

219 The significant correlations identified in this study underscore the necessity of addressing 220 psychological factors in the management of dizziness in VS patients. The integration of 221 psychological assessments and interventions, such as cognitive-behavioral therapy or vestibular 222 rehabilitation combined with psychological support, may prove beneficial especially in those 223 with premorbid dizziness problems and/or other psychophysiological/emotional problems. This 224 approach could assist in addressing the multifaceted nature of dizziness, thereby improving 225 both physical symptoms and overall QoL. In accordance with the recommended treatment strategies for PPPD, psychotherapy should incorporate an educational component that 226 227 elucidates the manner in which symptoms arise from altered sensory processing and postural 228 control, frequently precipitated by a past stressor or vestibular disorder. Although maladaptive 229 beliefs and postural habits may have developed, they are susceptible to modification. While 230 complete remission of symptoms may not always be attainable, a substantial improvement 231 remains a realistic and promising outcome (26).

232

233 Strength and limitations

234 This study's principal strength is its comprehensive investigation of a range of psychological variables, including premorbid psychological disorders, personality traits, somatization 235 236 tendencies, and current levels of depression and anxiety. By integrating these factors, the study 237 provides a nuanced understanding of how psychological characteristics interact with dizziness 238 severity in VS patients. The study identified several significant correlations between 239 psychological factors and different aspects of dizziness, which adds valuable insight into the 240 complex relationship between these variables. For instance, the observed associations between 241 conscientiousness, social support, and the severity of dizziness highlight the multifaceted nature 242 of dizziness and its psychological impacts.

The cross-sectional design of the study precludes the possibility of drawing causal inferences, as it is unable to ascertain the direction of the relationships between psychological factors and dizziness. To ascertain causality and the temporal dynamics of these factors, longitudinal studies are required. Although the sample size was relatively large, the generalizability of the findings may be limited due to the combined single-center and online approach of the study and the potential for center-specific biases to influence the results. The use of self-report questionnaires may introduce a degree of bias, and the incorporation of objective assessments could enhance the accuracy of the evaluation. The high prevalence of preoperative dizziness among those with postoperative symptoms suggests that a preexisting condition may affect outcomes. However, the study does not fully examine this interaction. Furthermore, the study does not examine coping mechanisms or interventions that could mitigate the impact of psychological factors on dizziness, underscoring the necessity for future research in this domain.

Nevertheless, it is essential to evaluate the psychometric properties of the DHI, which, despite its pervasive utilization, may exhibit suboptimal properties, as evidenced by extant research (27). Despite the DHI's limitations, it remains the most commonly utilized tool due to the lack of a more robust alternative in the existing literature. It is recommended that future research focus on validating and enhancing the current measurement tools, as well as investigating effective coping strategies and interventions to more effectively manage the impact of psychological factors on dizziness.

263

264 Conclusion

265 In conclusion, this study identifies a significant correlation between psychological factors and 266 the severity of dizziness in patients with VSs. It is noteworthy that higher levels of conscientiousness, as well as increased somatization and anxiety, are associated with greater 267 handicap due to dizziness. These findings highlight the necessity of considering psychological 268 269 factors in the management of postoperative dizziness, with the potential to enhance patient 270 outcomes. Thus, careful assessment of psychological factors especially with regard to 271 premorbid emotional and psychophysiological functioning should be implemented in clinical 272 routine. It would be beneficial for future research to focus on longitudinal studies in order to 273 gain a deeper understanding of the causal relationships between psychological factors and 274 postoperative dizziness in VS patients, as well as to identify effective coping strategies or 275 interventions that could be used to mitigate the impact of these factors on dizziness.

Ethical approval

All subjects gave their informed consent for inclusion before they participated in the study. The study was conducted in accordance with the Declaration of Helsinki, and the protocol was approved by the Ethics Committee of University Hospital Halle (No. 2020-008).

Informed Consent Statement

Informed consent was obtained from all subjects involved in the study.

Data Availability Statement

The data presented in this study are available on request from the corresponding author. The data are not publicly available due to privacy reasons.

Conflict of Interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.
