22 **Abstract**

23 Mathematical models of parasite transmission provide powerful quantitative tools for evaluating the
24 impact of interventions for bringing about the control or elimination of community-level disease
25 transmission. A key attribute of such tools is that they allow integration of field observations regarding
26 the effectiveness of an intervention with the processes of parasite transmission in communities to allow
27 the exploration of parameters connected with the optimal deployment of the intervention to meet various
28 community-wide control or elimination goals. In this work, we analyze the effectiveness of the Esperanza
29 Window Trap (EWT), a recently developed black fly control tool, for eliminating the transmission of
30 *Onchocera volvulus* in endemic settings by coupling seasonally-driven onchocerciasis transmission
31 models identified for representative villages in Uganda with a landscape-level, spatially-informed model
32 of EWT trap configurations for reducing Simulid fly populations in a given endemic setting. Our results
33 indicate that when EWT traps are used in conjunction with MDA programs there are significant savings in
34 the number of years needed to reach a specified set of elimination targets compared to the use of MDA
35 alone. Adding EWT after the meeting of these thresholds and stoppage of MDA also significantly enhances
36 the long-term sustained elimination of onchocerciasis. The number of traps required is driven by the trap
37 black fly killing efficiency, capture range, desired coverage, inter-trap distance, size of location, and the
38 spatial heterogeneity obtaining for the fly population in a given village/site. These findings provide
39 important new knowledge regarding the feasibility and effectiveness of the community-wide use of EWT
40 as a supplementary intervention alongside MDA for accelerating and sustaining the achievement of
41 sustainable onchocerciasis elimination. Our coupling of landscape models of EWT deployment with the
42 seasonal onchocerciasis transmission model also highlights how population-level macroparasite models
43 may be extended effectively for modeling the effects of spatio-temporal processes on control efforts.

44 **Author summary**

45 While empirical studies have highlighted the effectiveness of the Esperanza Window Trap (EWT) as a
46 potential tool for reducing biting black fly populations, information regarding how to implement these traps
47 in the field to bring about community-wide elimination of onchocerciasis transmission is lacking. Here, we
48 show how coupling a data-driven seasonal onchocerciasis transmission model with a landscape model of
49 EWT trap networks can provide a flexible and powerful quantitative framework for addressing the
50 effectiveness of deploying EWT in the field for bringing about parasite elimination in conjunction with mass
51 drug administration (MDA). Our results demonstrate that including EWT traps with ivermectin MDA can
52 significantly reduce timelines to reach elimination thresholds, while introducing these traps post-MDA can
53 ensure the sustained long-term elimination of parasite transmission. The optimal trap configuration for
54 meeting these goals will depend on the trap efficiencies for fly capture and killing, trap attractant range, field
55 coverage, inter-trap distance, number of traps used, area of a control setting and the spatial variation
56 observed for the density of biting black flies. This work also highlights how population-level models of
57 macroparasite transmission dynamics could be extended successfully to effectively investigate these
58 questions.

59 **Introduction**

60 Onchocerciasis (river blindness), caused by infection with the *Simulium* black fly-transmitted filarial
61 nematode, *Onchocerca volvulus*, continues to remain a serious tropical disease in many parts of Africa and in
62 certain settings in Latin America (1-3). Current estimates, for example, suggest that at least 14.65 million
63 people may be infected with the parasite, and that up to 217.5 million people continue to be at risk of
64 infection in these regions (1, 4-7). This is despite the institution of long-term large regional and national-
65 scale control programs, beginning with the initiation of vector control-based efforts from the mid-1970s in
66 West Africa before community-wide mass drug administration (MDA) of ivermectin became the mainstay of
67 national interventions from the 1990s (5, 8-10). While the initial focus of these programs was on morbidity
68 control (11-13), the success of using MDA alone in achieving the elimination of onchocerciasis as a public
69 health problem in 11 out of 13 foci in the Americas (13, 14), and in interrupting transmission in many foci in
70 Africa more recently (4, 5, 15, 16), has led to high expectations that the global elimination of the disease
71 using this therapeutic approach may be possible (1, 17). This shift in focus from reduction or control of the
72 burden of the disease to transmission interruption has led to the ramping up of control activities using MDA
73 (7, 17); however, it has also highlighted the difficulties of achieving the long-term interruption of parasite
74 transmission in every infection setting by means of MDA alone (1, 18) . This is particularly the case for
75 populations that continue to remain exposed to high black fly populations and communities facing significant
76 social and operational challenges in delivering the long-term high coverage MDA required for bringing about
77 transmission elimination (1, 17, 19-21). These biosocial and technical challenges have led to the increasing
78 recognition that cost-effective, socially acceptable, strategies that can complement MDA will need to be
79 developed and assessed in order to successfully bring about the global elimination of the disease (22).

80 Recently, several workers have suggested integrating MDA with vector control (VC) to overcome these
81 challenges (17, 23, 24). These workers stress how combining treatment of humans alongside the reduction
82 of the prevailing vector density can serve to act on both microfilarial loads and vector-human contact rates
83 synergistically in a population to facilitate a more rapid achievement of transmission elimination. One such
84 recently investigated VC tool is the Esperanza window trap (EWT), first developed and used in Mexico, and

85 subsequently evaluated in Burkina Faso and Uganda (1, 25-27), which has been shown to constitute a highly
86 effective and easily implementable method for trapping *S. damnosum* black flies (25-28). The trap, utilizing a
87 combination of olfactory cues and visual attractants to lure adult host-seeking blackflies, was initially used as
88 a tool for xenomonitoring (21, 25, 29), but more recent studies have indicated that EWTs may also represent
89 a potent means to reduce the local fly population potentially to levels that may facilitate the breakage of
90 transmission (25, 28). Thus, EWTs baited with human sweat compounds and CO₂ and deployed in
91 households and schools were shown to be able to reduce *S. onhraceum* s.L. by 14-51% in Mexico (26, 30),
92 while field trials carried out using traps baited with sweat-impregnated articles of clothing within classrooms
93 in Northern Uganda showed that these could reduce *S. damnosum* biting rates in classes by as high as 91%
94 (31). However, while these results highlight the utility of using EWTs as an effective VC tool particularly for
95 locations where people congregate for carrying out daily activities, the evidence for their effectiveness in
96 reducing fly numbers when deployed in outdoor settings has been variable (30-32). Moreover, there are also
97 indications that the efficacy of these traps for trapping the same fly species could vary from one country to
98 another (30, 31). These variable experimental results indicate that while EWTs may offer a promising tool
99 for achieving black fly control, there is a need to evaluate the sources of the differences observed in fly
100 trapping effectiveness under diverse transmission conditions if they are to be deployed successfully for
101 assisting with eliminating the transmission of onchocerciasis.

102 Three sets of key questions require addressing for assessing the usefulness of EWTs, and indeed attractant-
103 based insect traps in general, for reducing and breaking community-wide vector-borne macroparasitic
104 disease transmission. The first are questions related to the components of an attractant insect trap network
105 for effectively trapping and killing the target insect over a given landscape. These specifically include
106 quantifying the impacts of trap densities, their placements, and attractiveness as well as effectiveness as a
107 whole for capturing and killing insects in a given environment (33). The second set of questions is concerned
108 with quantitative methods for relating recorded EWT fly collections in a locality to the corresponding local
109 community vector biting rate, and to both vector and human infection incidences or prevalences. Addressing
110 this association will be key to evaluating the utility of the EWT as a tool for bringing about community-wide
111 parasite transmission elimination (34). Finally, assessment of the effectiveness of the tool for facilitating

112 community transmission elimination also requires quantifying how combining EWT with MDA programs can
113 have a synergistic effect in accelerating and sustaining the elimination of *O. volvulus* transmission in settings
114 exposed to different black fly intensities or endemicity.

115 We have recently shown how simulation or computational models of macroparasite transmission can offer
116 important quantitative tools for investigating the above questions by virtue of their ability to relate the
117 components and actions of a control technology with the diverse states and processes governing the
118 transmission dynamics of a disease in a host population (34-36). Indeed, the further capability of modeling
119 frameworks for being able to integrate evidence from trial observations of a control measure in selected
120 locations with the general process-based information contained within a theoretical model also means that
121 such data-driven process-based simulation models can not only recapitulate existing empirical
122 measurements but also predict the effects of the intervention under transmission conditions that have not
123 yet been tested (37, 38). This means that such quantitative tools can offer a key scientific means for exploring
124 the full range of possible transmission effects arising from an intervention via facilitating the effective
125 extrapolation of existing trial observations to all relevant spatial domains or locations of interest (34). This is
126 an important feature as it means that these modeling systems can afford generalizable or systematic insights
127 into the operation of an intervention, which will be difficult to achieve using empirical field trials alone. This
128 critical ability of models for being able to simulate the likely future states of an infection system undergoing a
129 particular intervention in diverse settings has been key to their rising acceptance and adoption by decision
130 makers as a means for evaluating intervention options that may best bring about the achievement of national
131 and global disease management goals (17, 24, 35, 39-42).

132 Here, we describe the development and use of a data-driven process-based modeling framework for
133 investigating the utility of combining EWTs with MDA as a new two-pronged strategy for progressing
134 onchocerciasis elimination under typical endemic conditions. We note that according to WHO guidelines (1,
135 43), the decision for declaring that the ultimate elimination of parasite transmission has occurred in a setting
136 is to be based on human and entomological infection surveys which will be carried out in three phases – with
137 the first phase focused on assessing if specific WHO-defined human infection and infective thresholds in

138 black fly populations below which transmission is thought not possible have been met, followed by
139 additional entomological surveys in phase 2 (termed as the post-treatment phase (PTS)) and subsequent
140 primarily parasitological surveys in phase 3 (the so called ‘post-elimination survey’) for confirming the
141 absence of either ongoing, residual or resurging infections in vector and human populations respectively. As
142 previously (34), we use the community-wide human infection threshold of 1% microfilarial (Mf) prevalence
143 and an ATP (annual transmission potential) value of 20 infective bites per person per year defined originally
144 as transmission elimination targets by the WHO for onchocerciasis in the foregoing analyses (44). We focus
145 on the parameters for the field deployment of EWT plus MDA for enhancing each phase of the WHO
146 transmission interruption assessment strategy in the analysis, with achievement of phases 2 and 3 examined
147 by addressing the ability of the tool for bringing about long-term breakage of transmission post stoppage of
148 MDA.

149 Our simulation system for addressing the utility of EWT plus MDA for accelerating and sustaining
150 onchocerciasis transmission elimination has three major components. First, models of black fly trapping
151 efficacies using various EWT field or network configurations are constructed. These are then combined with
152 our population-level model describing the seasonal population dynamics of onchocerciasis. Finally, the
153 coupled system is integrated with steps that include the estimation of initial conditions, launching of
154 simulations, and carrying out analyses of model solutions for evaluating the impact of the supplementary
155 EWT strategy for enhancing the efforts of MDA alone in meeting the infection and transmission elimination
156 thresholds described above (45). We begin by presenting the mathematical basis of our capture probability
157 model for EWTs based on the concept of an effective black fly attraction range and killing efficiency, and
158 various parameters related to the deployment of insect attractant traps in a landscape, such as inter-trap
159 distance, numbers of traps, areal coverage, size of area, and decay of trapping effectiveness (28, 31). We then
160 describe how we couple this landscape-based spatially-explicit trap model with novel extensions of our
161 seasonal population-level model of onchocerciasis transmission to allow simulations of the impact of using
162 various trap configurations for reducing the community-level ATP, and by acting synergistically with MDA
163 for reducing human infection to below the 1% Mf prevalence threshold. We performed these analyses by
164 using transmission models calibrated to site-specific data from four previously described representative

165 onchocerciasis endemic study villages from Uganda (34), which also allowed an examination of the impacts
166 of seasonality and endemicity on transmission outcomes due to the EWT-based interventions. We end by
167 discussing our results in terms of the potential of using EWTs acting in conjunction with MDA for achieving
168 area-wide onchocerciasis elimination. We also highlight how population-level macroparasite transmission
169 models, such as our deterministic onchocerciasis transmission dynamics model, can be effectively extended
170 to address the spatio-temporal complexities that may govern the effectiveness of the EWT tool for bringing
171 about parasite interruption in the real-world. Finally, we touch upon the value of using process-based
172 simulation systems, such as the one developed here, as a means for extending the evidence regarding an
173 intervention obtained from field trials so that higher-order knowledge generalizable to diverse transmission
174 conditions can be discovered and used effectively in policy making.

175 **Methods**

176 [Simulation system overview](#)

177 Our data-driven computational system for carrying out simulations of the effects of EWT combined with MDA
178 versus using MDA alone for reducing and eliminating onchocerciasis transmission at its core comprises the
179 integration of three components (Figure 1). These include firstly the setting up and coupling of mathematical
180 models of black fly capture probabilities over a landscape given various EWT trap configurations and
181 parameters, including different trapping network patterns, trap attractive range, fly killing efficiency, and
182 decay of trap attractiveness (31, 33), with our age structured-seasonal model of onchocerciasis transmission
183 (34) that allows for the incorporation of both MDA and VC using EWT (see below). The parameters of the
184 onchocerciasis model are then identified for a setting in this system via a calibration step, wherein we use
185 our previously developed Monte-Carlo based Bayesian Melding (BM) data assimilation methodology to
186 discover an ensemble of models that best-fit baseline site-specific infection data (35, 40, 46). Once these
187 models are identified for a location, we implement and simulate the effects of control arising from the
188 deployment of different EWT trap configurations and MDA strategies by linking their respective effectiveness
189 in reducing the community-wide vector biting rate (EWT traps) as well as infection in the human population

190 (MDA) on the overall dynamics of *O. volvulus* transmission in step three (31, 34). More specifically, here, we
 191 perform a comparative analysis of the impacts of using MDA alone versus combined MDA and EWT by
 192 evaluating: 1) the timelines predicted for each of these interventions to cross the specified community-wide
 193 Mf prevalence (=1%) and ATP (=20) elimination thresholds, and 2) their subsequent ability for bringing
 194 about long-term transmission interruption post-stoppage of MDA.

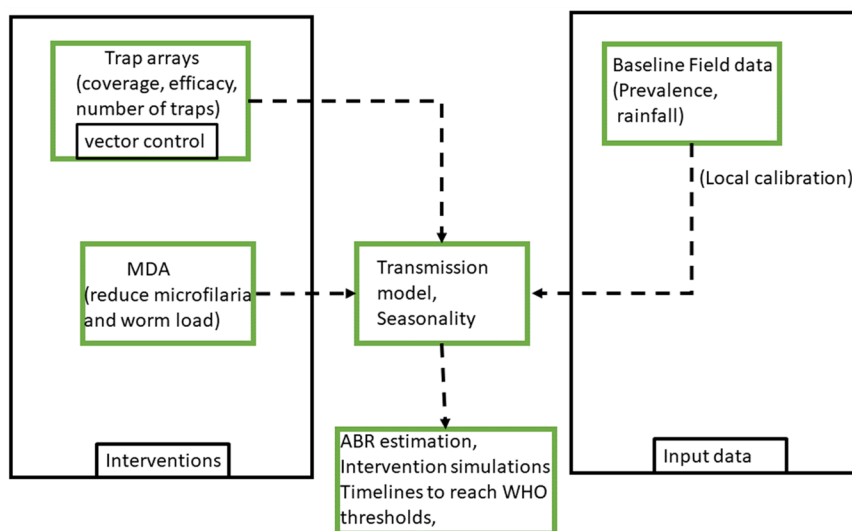

Figure 1. The computational framework for integrating interventions (EWT vector control and MDA interventions), the seasonal age-structured transmission model of onchocerciasis, and baseline field data.

195

196 The mathematical model for quantifying EWT fly capture probability over an 197 area

198 We begin by assuming that each EWT represents a square of dimension of $l \times l$ (Figure 2(a)). Typically, an
 199 array of such traps is placed at the village/site of interest; a possible array of traps is shown in Figure 2(b)
 200 assuming that the village is a rectangular box with an area A . The inter-trap distance is d while each
 201 individual trap in the array has a capture or attractant radius r . The capture radius defines a circular area
 202 around a trap where all the flies are trapped if they fly within this radius. If there are N_t number of traps, then
 203 the areal coverage C_{Tr} in such a trap configuration or network can be defined as:

$$C_{Tr} = \frac{A_c}{A} \quad (1)$$

204 where $A_c = N_T \pi r^2$ is the combined capture area of all the traps. The total number of traps N_T is then related
205 to capture radius of individual traps r and the inter-trap distance d as follows:

$$N_T = \left(\frac{\sqrt{A} - 2r}{d} + 1 \right)^2 \quad (2)$$

206 The above equations assume that the capture probability of a trap is unity within the capture or fly attractive
207 radius of the trap and zero otherwise; this in turn can be used to determine the optimal distance d between
208 traps to achieve a desired number of traps given a particular coverage, C_{Tr} . When the capture probability of a
209 trap is a continuous function of trap distance (instead of the Heaviside function considered here), the
210 computation of capture probabilities via an array of traps becomes cumbersome as the capture probabilities
211 of individual traps overlap. On the other hand, when fly capture by an individual trap is modeled by a hard

Figure 2. (a) An EWT trap with capture radius r and dimensions $l \times l$. (b) A rectangular array of EWT traps placed over a landscape with a separation distance d .

212 radius of capture probability as described above, this approximation can be used to provide estimations of
213 the upper limits on the number of traps required to achieve a given coverage as shown by Equation (2).

214 Heterogeneous fly distribution

215 The above capture equations (Equation (1) and Equation (2)) represent the situation where the black fly
216 population is homogeneously distributed and is assumed to bite hosts uniformly across a setting. In reality,
217 fly biting and population distribution are likely to be spatially heterogeneous (47, 48). This spatial
218 heterogeneity can govern the optimal number of traps required to achieve the desired coverage levels. To
219 calculate the number of traps in a spatially heterogeneous setting, we ideally require knowledge of the exact
220 distribution of a fly population in such locations. However, the use of a discrete distribution, such as the
221 Dirac-delta function to represent the localization of flies within an area of interest, wherein we assume that
222 there are discrete areas in a setting with flies and areas without any flies (49), can allow the effective
223 calculation of the number of traps required under this simplifying condition. Thus, assuming that the total
224 area of sites where the flies are absent is A_{Δ} , the coverage Equation (1) and the number of traps Equation (2)
225 can be modified to obtain an areal trap coverage under heterogeneous fly biting, C_{Thet} as:

$$\begin{aligned} C_{Thet} &= \frac{\pi r^2}{A - A_{\Delta}} \sum_{i,j}^{N_T, N_f} \delta(n - n_0) \\ &= \frac{\pi r^2 N_f}{A - A_{\Delta}} \end{aligned} \quad (3)$$

226 where N_f is the number of sites where flies are present, N_T is the maximum number traps that can be
227 accommodated for an inter trap distance d , and δ denotes the Dirac-delta function for locating the presence of
228 flies at a specific point, n_0 , over a grid of discrete locations, n , within an area (ie. flies are present if $n = n_0$
229 or absent otherwise) (49). In this formulation, it can be seen that if the trap coverage is set to be the same as
230 in the homogeneous case the effective number of traps is simply equal to the number of sites where flies are
231 present:

$$N_f = \left(\frac{\sqrt{A} - 2r}{d} + 1 \right)^2 \left(1 - \frac{A_\Delta}{A} \right) \quad (4)$$

232 Equation 4 implies that the required number of traps decreases linearly with A_Δ/A , where A_Δ/A is a measure
 233 of the spatial heterogeneity observed for the biting black fly population.

234 Figure 3. An array of EWT traps placed to capture flies in an heterogenous fly environment to achieve a desired coverage. We assume that flies are concentrated at the periphery of the shown region. (a) Placing traps flies by ignoring the fly distribution pattern. (b) Placing traps in the periphery. Both these configuration of trap networks achieve the same coverage but accounting for heterogeneity requires a lower number of traps.

235 To demonstrate how Equation 4 could be used in a field setting, we consider toy examples of fly
 236 heterogeneity and the corresponding optimal trap placement inside a village represented by a rectangular
 237 box as shown in Figure 3. In Figure 3(a) traps are placed by ignoring the fact that flies are concentrated at the
 238 periphery of the village (darker pixels), while in Figure 3(b) traps are placed in just those areas where flies
 239 are present. In this case, it is clear that accounting for fly heterogeneity would require a lower number of
 240 traps than otherwise to achieve a given coverage. The situation demonstrated in Figure 3(b) is similar to the
 241 one studied in reference (31), where the traps were able to reduce bites if placed in the periphery of fields,
 242 close to fly habitats. If traps are deployed by ignoring heterogeneity in flies as in Figure 3(a), then some traps

243 among the array might be ineffective/irrelevant in reducing the number of bites. The number of ineffective
 244 traps in that case is given by the $N_{ineffective}=N_T - N_f$:

245

$$N_{ineffective} = \left(\frac{\sqrt{A} - 2r}{d} + 1 \right)^2 \frac{A_\Delta}{A} \quad (5)$$

246 Equation (5) shows that in contrast to N_f , ineffective traps will increase linearly with the fly heterogeneity
 247 parameter.

248 [Onchocerciasis transmission model](#)

249 The onchocerciasis transmission model used in this study is an immigration-death deterministic model
 250 describing the aggregate-level transmission dynamics of the parasite in both human and black fly
 251 populations. As detailed previously (34, 46, 50), the model is based on a set of coupled partial and ordinary
 252 differential equations, where the population-level age-structured pre-patent $P(a, t)$ and patent $W(a, t)$ worm
 253 burdens, microfilariae counts $M(a, t)$, and acquired immunity $I(a, t)$ in the human host are dynamically
 254 modelled by partial differential equations over time (t) and age (a), whereas the dynamics of infective L3
 255 stage larvae per black fly (L) are modelled by an ordinary differential equation over time. The governing
 256 equations describing the dynamics of these system variables are:

$$\begin{aligned} \frac{\partial P(a, t)}{\partial a} + \frac{\partial P(a, t)}{\partial t} &= \Phi L^* F_1(I(a, t)) F_2(W_T(a, t)) - \mu_w P(a, t) \\ &\quad - \Phi L^* F_1(I(a, t - \tau)) F_2(W_T(a, t - \tau)) \zeta \\ \frac{\partial W(a, t)}{\partial a} + \frac{\partial W(a, t)}{\partial t} &= \Phi L^* F_1(I(a, t - \tau)) F_2(W_T(a, t - \tau)) \zeta - \mu_w W(a, t) \\ \frac{\partial M(a, t)}{\partial a} + \frac{\partial M(a, t)}{\partial t} &= F_3(W_T(a, t)) - \gamma M(a, t) \\ \frac{\partial I}{\partial a} + \frac{\partial I}{\partial t} &= W_T(a, t) - \delta I(a, t) \\ L^* &= F_4(W_T(a, t)) \end{aligned} \quad (6)$$

257 Here, the functions F_x denote the density dependent mechanisms that govern the various transition or
258 development rates of different states in the parasite life cycle (34, 46, 50). Note that some of these functions
259 are dependent on the total worm load ($W_T = W(a,t) + P(a,t)$), while the rest depend on the larval state (L^*)
260 and host immunity (I). Due to the significantly faster time scale of the infection dynamics in black flies
261 compared to worm infection in humans, we further assume that the density of infective stage larvae in the
262 vector population reaches a dynamic equilibrium (L^*) rapidly and use this simplification to simulate the
263 infective stage larval dynamics. Details of all the parameters and functional forms are explained and
264 described in the supplementary document Tables S1, S2.

265 Bayesian Melding (BM)-based calibration of the model

266 We estimated parameters for the onchocerciasis transmission model via calibration of the model to a set of
267 four previously published baseline infection datasets that spanned the range of endemic conditions that
268 typically underlie the transmission of the disease (34) (Table S3). The model calibration exercise to identify
269 best-fitting models for these locations was carried out using the flexible Monte-Carlo based BM data
270 assimilation framework (35, 51). This method uses the following workflow. First, using the known ranges of
271 the model parameter values, we define uniform prior distributions for each parameter and randomly sample
272 with replacement from these distributions to generate $N = 200,000$ parameter vectors. The model is then run
273 with each of the N parameter vectors, which generate N outputs predicting Mf prevalence by age. The
274 simulated Mf prevalences are then compared against the age-stratified Mf prevalence data in each setting by
275 calculating binomial log-likelihoods for each parameter vector. Since the datasets used in this work do not
276 include age-stratified Mf prevalence data, age infection profiles were obtained from the observed overall
277 community prevalence by following the procedure presented in Smith et al (36). Next, a Sampling-
278 Importance-Resampling (SIR) algorithm is used to sample $n = 500$ parameter vectors with replacement from
279 the pool of N parameter vectors with probabilities proportional to their relative log-likelihood values. This
280 step generates the n parameter vectors most likely to represent the observed data. These n posterior
281 parameter vectors are then used to compute distributions of variables of interest from the fitted models

282 pertinent to this study (viz. age-prevalence curves and infection trajectories in both the human and black fly
283 vector populations following interventions). **Note that this approach, which results in the estimation and use
284 of transmission models calibrated to local conditions, also** provides an opportunity for examining the impacts
285 of the variable endemic conditions that are typically observed in the field on onchocerciasis control dynamics
286 (34, 46, 50).

287 Steps to simulate MDA and EWT-based vector control

288 Simulating MDA control

289 We aimed to compare the complementary impact of EWT when added to onchocerciasis ivermectin-based
290 MDA interventions with the outcomes arising from the use of the MDA strategy alone. The impact of MDA is
291 modelled by assuming that the drug instantaneously kills ω and ϵ fractions of the adult worms (both pre-
292 patent (P) worm and patent (W) adult worms) and Mf (M) populations. Because of uncertainty in the efficacy
293 of annual IVM against adult *O. volvulus* parasites, the efficacy parameter ω is varied from 0.05 to 0.3 (39, 41,
294 42, 52-57) in the simulations. The effective population sizes of worms and microfilariae stages after drug
295 treatment are given by:

$$\left. \begin{aligned} P(a, t + dt) &= (1 - \omega C)P(a, t) \\ W(a, t + dt) &= (1 - \omega C)W(a, t) \\ M(a, t + dt) &= (1 - \epsilon C)M(a, t) \end{aligned} \right\} t = T_{MDA} \quad (7)$$

296 where dt represents a short time-period since T_{MDA} , the time-point the i^{th} round of MDA was administered,
297 and the drug coverage at the population level is given by the parameter C . Each round of MDA kills a fraction
298 of each worm stage (via values of ω and ϵ); however, the production of Mf by the surviving worms (53, 57) is
299 reduced by a factor of $(1 - \delta_{reduc}C)$:

$$\frac{\partial M}{\partial t} + \frac{\partial M}{\partial a} = (1 - \delta_{reduc}C)s\alpha\phi[W(a, t), k]W(a, t) - \mu_2 M(a, t), \quad \text{for } T_{MDA_i} < t \leq T_{MDA_i} + T_P$$

300 where $\alpha' = \alpha(1 - \delta_{reduc} C)$ is the reduced fecundity (over a period of T_P months since the i^{th} MDA) of the
301 surviving adult worms at each MDA. The priors for ω , ε and T_P as given in Table S4 in the supplementary
302 document.

303 **Seasonality and simulating vector control using EWT**

304 It has been shown that the use of EWT reduces the number of black fly bites on humans through trapping and
305 killing of these flies when deployed persistently near fly habitats (31). We thus expect that the deployment
306 of these traps across a locality will drive down the overall local black fly population and thereby decrease the
307 aggregate vector-human biting or contact rate in the community (31). We further assume that one instance of
308 EWT deployment constitutes placement of traps over a duration of a month with lures replenished on a
309 monthly basis. On the other hand, seasonality in fly population dynamics, particularly associated with rainfall
310 patterns, is a well-known driver of fly biting rates (22, 31). These factors suggest that simulating the impact
311 of EWT-based vector control necessitates modeling the fly biting rates as a function of seasonal rainfall
312 patterns (34), spatial biting patterns, and effects of deploying EWT traps over a setting on a monthly time-
313 scale (31, 58). Here, we thus simulate the impact of EWT by first combining our previously developed model
314 describing seasonally-varying black fly monthly infective biting rates (MTP) (34), with the vector control
315 action of EWT in reducing the monthly fly biting rate, $MBR(m)$, as follows:

$$MBR(m) = MBR_M \left(\frac{1}{1 - \frac{A_\Delta}{A}} \right) \left(1 - e^{-\left(\frac{R_t(m)}{R_L}\right)^{k_1}} \right) e^{-\left(\frac{R_t(m)}{R_U}\right)^{k_2}} (1 - \eta e^{-\Lambda t} C_{Tr}) \quad (8)$$

316 where MBR_M is the maximum expected biting rate in a homogeneous environment, R_U and R_L represent upper
317 and lower rainfall thresholds above and below which fly biting is greatly reduced, and k_1 and k_2 are shape
318 parameters. Second, in environments with heterogeneous fly biting distribution, we scale up the mean
319 maximum expected biting rate by a factor of $\left(\frac{1}{1 - \frac{A_\Delta}{A}} \right)$ so that the average maximum expected biting rate over
320 the area A of the village is still MBR_M . Finally, the term $(1 - \eta e^{-\Lambda t} C_{Tr})$ describes the reduction in MBR as a
321 function of trap fly killing efficiency η , trap coverage, C_{Tr} , as described in Equation 1 (the uniform biting case)

322 or by Equation 3 (the heterogeneous biting case (C_{Thet})), and decay of trap fly killing effectiveness as defined
323 by the term, $e^{-\Lambda t}$. Note here in passing that this formulation also represents a novel method for
324 incorporating the (discretized) variability in biting fly distributions that may occur in a landscape into a
325 population-level parasite transmission model. The prior parameter ranges for η and Λ are given in Table S4
326 of the supplementary document. The other parameters in Equation 8 were obtained via the calibration of this
327 rainfall dependent seasonal MBR model to monthly biting data from the control sites (no vector control)
328 using BM with a pass/fail filter as described in (45).

329 [Modeling EWT and MDA intervention scenarios](#)

330 We investigated the additional impact of combining EWT with MDA as a two-pronged integrated VC-drug
331 treatment strategy for accelerating onchocerciasis transmission elimination by running our coupled EWT
332 trap-transmission dynamics simulation model to mimic the effects of different control scenarios related to
333 various EWT configurations and MDA strategies. These included modeling: 1) the impacts of various EWT
334 configurations (variations in trap capture or attractant radius, fly killing efficiency, inter-trap distance,
335 coverage and trap numbers) in reducing ATP, and 2) comparing annual and switch MDA (annual MDA for 10
336 years followed by a switch or change to bi-annual MDA) interventions alone versus including EWT into these
337 drug regimens on the timelines required to cross target community-wide M_f (=1%) and ATP (=20)
338 thresholds. Transmission models fitted to the four study sites used here were further employed to explore
339 the impact of endemicity on the timelines to elimination arising from the implementation of the above
340 intervention scenarios. Further, different EWT deployment frequencies were also simulated to investigate
341 the impacts of using EWT a month before the peak fly biting season, for three months over the peak biting
342 season and at monthly intervals during the year. This allowed examination of the impact of seasonality in the
343 black fly population dynamics on the optimal timing of EWT deployment for reducing the ATP in a
344 community. Note here that while our transmission model is calibrated to reductions in MBR based on
345 empirical data from the EWT field experiments that specifically focused on the monthly effectiveness of the
346 traps for reducing this variable (31), we predict the corresponding effect on ATP by multiplying the

347 estimated MBRs (Equation 8) by the monthly population averaged $L3^*$ values, and then summing the
348 resulting monthly transmission potentials (MTPs) to obtain the yearly ATP (34):

$$ATP(year) = \sum_m MTP(m) = \sum_{m=1...12} L^* \times MBR(m) \quad (9)$$

349 All the vector control scenarios in combination with MDA were modelled at the WHO-recommended drug
350 coverage of 80%.

351 **Impact on long-term transmission elimination and recrudescence**

352 We addressed this critical question by evaluating the behavior of the model trajectories once population
353 infection prevalences in each of the four study sites are predicted to cross the threshold of 1% Mf following
354 MDA, and all further drug applications are stopped. The impact of including EWT versus no vector control on
355 elimination and recrudescence was compared post stoppage of MDA at two time points – five years post MDA
356 (to cover the PTS assessment period) and fifteen years post MDA (to evaluate the longer-term impact of EWT
357 on parasite elimination). Following Sharma et al.(59), we calculated the probability that transmission
358 extinction has been achieved in a site due to an applied intervention by quantifying the proportion of the
359 best-fit SIR model prevalences that were declining or declined to zero (ie. models giving rise to Mf prevalence
360 curves with significant negative slopes) by the end of the 5 or 15-year simulation period following the
361 crossing of the 1% Mf threshold value. The recrudescence probability for a given site was similarly calculated
362 as the proportion of the total SIR selected model runs that managed to revive and generate positive increases
363 in Mf prevalence (ie. give rise to Mf curves with significant positive slopes) by the end of each of the above
364 simulation periods once MDAs are stopped. Finally, the curves having non-significant and fluctuating positive
365 or negative slopes are considered as those exhibiting transient dynamical behavior (59).

366

367 **Results**

368 **Identifying locality-specific seasonally-driven onchocerciasis transmission models**

369 The impact of using EWT in the field in conjunction with annual and switch MDA on the timelines required to
370 breach the community-wide 1% Mf prevalence and 20 ATP thresholds was investigated in this work using
371 our data-driven seasonal MBR-based transmission model calibrated to four endemic village communities in
372 Uganda (34). The fits of the model to baseline MF age-prevalences observed in each of these study sites using
373 the BM-based data assimilation approach are shown in Figure S1 in the Supporting Information. Note as
374 described previously (34, 35, 46), given uncertainty in parameter values, we identify 500 best-fitting models
375 to characterize the local parasite transmission dynamics in a setting. The good fits of the models to data
376 portrayed in Figure S1 amply highlight the capability and versatility of the BM framework for reliably
377 capturing and differentiating between the transmission dynamics of onchocerciasis that prevailed pre-
378 intervention in the four settings.

379 **EWT parameters and the annual transmission potential (ATP)**

380 We began our investigation of the impact of using EWT for eliminating parasite transmission from *Simulid*
381 populations by evaluating the resulting village-wide reductions predicted for ATP as a function of differences
382 in the parameters related to the deployment of traps (or the configuration of the trap network) in an endemic
383 area. The results illustrated in Figure 4 are for the transmission model estimated for the village of Masaloo,
384 and are based on assuming that the village encompasses a rectangular area of 1 km^2 , each trap has an fly
385 killing efficacy of 70% (31) and a capture or attractant radius of 200m, and that traps are deployed on a
386 monthly basis for a year. The simulations show firstly that decreasing the inter-trap distance, d , will decrease
387 the ATP in this village, such that approximately at an inter-trap distance of 490 m (vertical solid line in Figure
388 4 (a)) the ATP threshold of 20 infective bites per person per year will be breached. Figure 4 (b) on the other
389 hand highlights how changes in the inter-trap distance will affect the areal coverage, C_{Tr} , required to keep
390 the ATP below the threshold of 20 infective annual bites per person. Thus, while an inter-trap distance of

391 approximately 600m will result in a coverage value of 50%, this will clearly be insufficient to breach the ATP
392 threshold. By contrast, only the decrease of this distance to 490m will allow the crossing of this threshold as
393 a result of the increase brought about in areal coverage to approximately 60%.

394 The results in Figure 4 (c) and Table 1, however, indicate that the number of traps required to breach the 20
395 ATP threshold is determined by both trap coverage and the area of a village. Thus, Figure 4 (c) shows that
396 given a trap fly killing efficacy of 70%, capture radius of 200m, an inter-trap distance of 490m and assuming
397 that the area of Masaloo is 1 km^2 , the total number of traps required to achieve a coverage of 60 % (for
398 breaching the ATP threshold in this example) is approximately 5 traps, all placed along a rectangular array as
399 shown in Figure 3 for the homogeneous biting case (solid blue curve). The required number of traps for
400 different coverages and village areal sizes along with corresponding inter-trap distances are further recorded
401 in Table 1, which show that while the number of traps required to achieve 60-70% coverage will generally
402 increase with area (for all fly distribution patterns), for a given areal size, this number will decline
403 dramatically as the trapping radius and distance between traps increase. This three-way relationship
404 indicates that as the capture radius of the trap increases, traps can be placed at greater between-trap
405 distances, which in turn will lower the required number of traps for crossing a given ATP threshold.
406 Additionally, the optimal coverage (and hence number of traps) needed generally to cross the ATP threshold
407 is also influenced by trap efficacy in killing the trapped flies. This relationship is shown in Figure 4 (d), which
408 demonstrates that as fly killing efficacy, η , increases, the ATP threshold can be achieved at a lower coverage
409 and vice-versa (as denoted by the orange curve). Importantly, the results also indicate that there is a critical
410 trap fly killing efficacy (approximately 45% in the present example) below which the ATP threshold cannot
411 be achieved within a year even when coverage is maximal (100%). By contrast, achieving any of the efficacy
412 and coverage values above the orange curve will lead to the ATP threshold of 20 infective bites per person
413 per year being reached within a year of monthly EWT deployment (Figure 4(d). These results are derived
414 from the models fitted to the village of Masaloo. Similar results were obtained for the other three study
415 villages investigated here, indicating the generality of these findings.

416

Figure 4. Curves in (a)-(b) show mean (solid blue) and 95 % confidence intervals (dashed blue) for ATP changes when an array of traps is deployed. The ATP decreases to the values as shown, starting from the baseline median value, after deployment of EWT for a year to reach the ATP threshold of 20 bites per year per person. Trap fly killing efficacy in these simulations is assumed to be 70 %. In (a), the lower inter-trap distances mean greater reduction in ATP, whereas in (b) higher coverage corresponds to greater reduction in ATP. The dashed-black horizontal line in (a) and (b) shows the ATP threshold of 20 bites per person per year. (c) The relationship between number of traps and the corresponding coverage achieved for a homogeneous fly distribution scenario (blue line) for two different values of the fly heterogeneity parameter $\frac{A_\Delta}{A}$ (solid-red $\frac{A_\Delta}{A} = 0.2$ and dashed-red line $\frac{A_\Delta}{A} = 0.4$). (d) The relationship between coverage and fly killing efficacy of traps, η , for attaining the 20 ATP threshold. The vertical black line in (a) - (d) show the values of inter-trap distance, coverage and number of traps required to cross the ATP threshold, while the horizontal dashed line in (d) corresponds to a trap fly killing efficacy of 70%, the value of efficacy used for (a)-(c). Importantly, the efficacy and coverage values in the region above the orange curve in (d) will result in the ATP threshold reached within a year. Each trap has a capture radius of 200 m and the study site for this figure is Masaloa.

417

418 Spatial heterogeneity in fly distribution, EWT coverage, and ATP

419 We used the ratio A_Δ/A as a measure of spatial heterogeneity in the distribution of the fly population at a
 420 given site (total area with no flies A_Δ over total area A) to calculate the number of traps required to achieve a
 421 desired coverage under the heterogeneous fly biting scenario. Equation 3 implies that the number of traps to
 422 meet a given coverage decreases as the fly population heterogeneity A_Δ/A parameter increases for a village
 423 with area A . This outcome can be seen in Figure 4(c) for two values of fly distribution heterogeneity

424 parameter $\frac{A_{\Delta}}{A} = (0.2, 0.4)$ and assuming an area of 1 km^2 for Masaloo. However, in general, the number of
425 traps required to achieve the same coverage for a given trap fly killing efficiency is driven by values of A_{Δ} and
426 A , the village size, and both the trapping or attractant radius and between trap distance. This can be seen
427 from the results given in Table 1, which shows firstly that for a given mix of trapping radius and inter-trap
428 distance, the number of traps a village requires to meet the same coverage will decrease as heterogeneity
429 increases. Secondly, for a given fly distribution, the number of traps required to meet a particular coverage
430 will also decrease with increasing trapping radius and inter-trap distance. On the other hand, while the
431 number of traps required to achieve the higher coverage of 90-100% will be greater than for achieving the
432 lower 60-70% coverage for all values of biting fly distributions, these can be placed at smaller inter-trap
433 distances to attain the increased coverage for the same trap efficiency. Finally, these calculations also provide
434 a guide as to the feasibility of using EWT as a vector control measure in different settings varying in areal size
435 and fly distribution. Thus, while in smaller sized village settings, eg. in the case of the 1 or 5 km^2 areas studied
436 here, the number of traps required to attain a coverage of 60-70% can be as low as 1 to 25 when the trapping
437 radius and biting heterogeneity is highest (i.e. for 200m and $\frac{A_{\Delta}}{A} = 0.8$), these can be as high as 86 to 98 for the
438 same conditions and trap killing efficiency in the largest area (i.e. 10 km^2) examined (Table 1). Although
439 these predictions are for the simplified rectangular areal case, they do suggest that feasibility considerations
440 might limit the use of traps alone in large areal settings, especially when trap capture radius is low and high
441 coverages are required even in the case when fly biting heterogeneity is substantial (eg. for radius of 100m,
442 $\frac{A_{\Delta}}{A} = 0.8$, and village size of 10 km^2 , the number of traps to attain 90-100% coverage can be as high as 573-
443 637 (Table 1)).

444 [Projected impacts of EWT and MDA on intervention durations for achieving parasite](#) 445 [elimination](#)

446 Next, the seasonal MBR-based transmission model was coupled with EWT field deployment configurations
447 and either annual or switch MDA for simulating the timelines needed to reach the two elimination thresholds
448 investigated. The baseline models identified for each of the 4 study villages were used to further evaluate

449 different EWT temporal deployments, viz. traps placed monthly, before and during the peak biting season,
450 used alongside either of the MDAs in these simulations. The area of the simulation village is assumed to be
451 1 km^2 while the trap capture radius and fly killing efficiency is set to 200 m and 75% in all the simulations.
452 Simulations were run for both the homogeneous versus heterogeneous fly biting scenarios. All the
453 simulations were also carried out using a MDA coverage of 80%, while the EWT coverage was varied. Note
454 also that given we identify 500 models to provide an adequate representation of the parasite transmission
455 dynamics in a locality, the intervention durations predicted for an intervention are based on when 95% of
456 these models cross the 1% Mf and ATP (=20) thresholds respectively in each study site.

457 Figures 5 and 6 show the durations in years required to cross the Mf and ATP elimination thresholds for
458 annual and switch MDA without (the base case) and with EWT deployed at coverages ranging from 60% -
459 70% predicted for the village of Masaloo under the homogeneous fly biting scenario – predictions of the
460 timelines for all four sites for both these MDA regimes alongside various EWT coverages are summarised in
461 Tables S5 – S9. The number of years of MDA required to cross the thresholds for Masaloo with MDA alone
462 were found to be as follows: ATP is reached by an average of 12 years with annual MDA, whereas it takes a
463 mean of 11 years with switch MDA (Figures 5 and 6; Table S5). The corresponding timelines to breach the Mf
464 threshold are, however, 20 and 15 mean years for each of these MDA regimens (compare Figure 5 (a) versus
465 6 (a); Table S5). On the other hand, when EWT is deployed monthly together with annual and switch MDA,
466 the ATP threshold for this village is predicted to be reached in as little as a mean of just 1 year, while the time
467 to reach the corresponding 1% Mf threshold is reduced to means of 18 and 14 years (Figures 5(b) versus
468 6(b); Table S5). Interestingly, while the frequency of using EWT (i.e., a month before peak fly biting season,
469 during the three months of the peak biting season, and monthly throughout the year) had a significant impact
470 in reducing the timelines in years to breach the ATP threshold for each village, with most savings obtained for
471 monthly deployment and least in the case of usage just before the peak biting season, this factor did not have
472 an effect on the years saved with respect to crossing below the Mf threshold (Table S5). Overall, however, the
473 results indicate that a significant number of intervention years will be saved when EWT is used alongside
474 MDAs (as opposed to MDA alone), with savings in mean years achieved ranging from 1-17 years in the case of
475 combined annual MDA (80% coverage)-EWT (60-70% coverage) compared to 1 to 12 years when switch

476 MDA is applied with EWT at the same coverage levels (Table S5). Reducing average EWT coverage (from 65%
477 to 45%) and hence number of traps in each village will, as expected, significantly reduce these savings in
478 intervention years (and conversely increase timelines to reaching either threshold), although again this
479 impact will primarily be seen for the 20 ATP rather than the 1% Mf threshold (Tables S6 – S9).

480 [The impact of heterogeneous fly distribution on timelines to elimination](#)

481 In the scenario where fly biting is heterogeneously distributed, such as occurring only in the periphery of a
482 village, the simulations indicate that paradoxically the times required to reach the community-level 1% Mf
483 and 20 ATP thresholds will be significantly higher than those predicted for the homogeneous setting where
484 the average biting rate is uniform across the village (Figure 7). Indeed, this simplified approach for
485 incorporating fly biting heterogeneity reveals a steeply rising nonlinear relationship between the parameter
486 $\frac{A\Delta}{A}$ and the times to reach both the thresholds. This relationship can be observed from the results displayed in
487 Figure 7 when EWT at fly killing efficacy ranging between 70 to 80% is deployed monthly at a coverage of 60
488 to 70%.

489 Figure 8 further depicts the number of years saved by the use of combined EWT and annual MDA compared
490 to when yearly MDA alone is used in relation to variations in the fly biting heterogeneity and trap coverage.
491 The results show, firstly, that combining EWT with MDA under both the homogeneous and heterogeneous fly
492 distribution scenarios will result in significant numbers of years saved for breaching both thresholds in
493 comparison with using MDA only (Kruswall – Wallis test comparing timelines to the Mf and ATP thresholds
494 for each of the EWT/MDA scenarios shown in Figure 8 versus MDA alone: $p < 0.05$ in each case). For the
495 homogeneous scenario, the mean number of intervention years saved can range from between 7 to 10 years
496 depending on trap coverage and the threshold target (whether Mf or ATP). By contrast, this can reach as high
497 as between 10 to 40 years in the case of the heterogeneous fly biting scenario.

498 The results further show that increasing trap coverage from 40-50% to 60-70% will have only a moderate
499 impact on the number of years saved under the homogeneous biting scenario, particularly in the case when
500 the 1% Mf threshold is used (Figure 8(a)). By contrast, increasing EWT coverage will add substantially to the

501 number of years saved for both thresholds when the fly population is heterogeneously distributed in a
502 setting (Figure 8(b)). These results are for Masaloa but similar patterns are also observed for all four study
503 villages (Tables S10-S14).

Table 1 Relationship between number of traps, trapping radius, inter-trap distance, and heterogeneity in fly biting distribution accounting for size of a setting. Trap fly killing efficiency is 0.7-0.8. Results are from the use of the best-fitting onchocerciasis models for Masalao.

505 [Impact of EWT and MDA intervention scenarios on elimination and recrudescence](#)
506 [probabilities.](#)

507 Table 2 summarizes the estimated probabilities of achieving either of these outcomes firstly when both
508 annual MDA and switch MDAs alone are stopped once the 1% Mf threshold is crossed, and no other
509 interventions are introduced. The results highlight that stopping these MDAs after the 1% Mf threshold is
510 crossed will result in zero probability of transmission elimination during the immediate 5-year post MDA
511 stoppage period that corresponds to WHO's recommended PTS period. Following this period, however,
512 elimination probabilities will increase gradually, such that by year 15 post MDA stoppage, these will reach
513 moderately high levels ranging from 15-47% (Table 2). Intriguingly, a similar pattern of increasing
514 recrudescence of infection is also observed as the simulation period extends from 5 years to 15 years post
515 stoppage of MDA. The results indicate that this negative outcome (increasing recrudescence of transmission
516 over time post stoppage of MDA) is a direct function of the fact that the fraction of transient model curves (as
517 noted by the figures following the ~ sign in the table) that arise immediately following the crossing of the 1%
518 Mf threshold in each study site will decay slowly over time, with larger fractions of these models either
519 declining gradually to zero or exhibiting positive resurgences by year 15 post MDA stoppage (Table 2).
520 However, while these patterns are found to occur irrespective of whether annual MDA or switch MDA was
521 simulated, an interesting finding was that annual MDA performs better than the more intensive switch MDA
522 strategy for inducing longer term (year 15) transmission elimination whilst correspondingly reducing
523 recrudescence of infection in each site. This appears to be mainly due to the fact that annual MDA generates
524 lesser transient dynamics in the model outcomes compared to switch MDA (Table 2). Finally, there is some
525 indication that the long-term probability of resurgence or recrudescence of infection may be related
526 positively with baseline Mf prevalence, increasing as baseline prevalences increase.

Figure 5. Mean (solid curves) and 95 % confidence intervals (dashed curves) of Mf prevalence (blue) and annual transmission potential-ATP (red) in the study site Masaloo as a function of time when: (a) only annual MDA and (b) annual MDA and monthly EWT are used in the homogeneous fly biting scenario. The times to reach the two thresholds (vertical red (20 ATP) and blue (1% MF prevalence)) are significantly reduced by the use of annual MDA and monthly EWT as compared to MDA alone. Here the EWT coverage is 60% to 70% assuming a trapping radius of 200 meters. The fly killing efficiency of the traps is assumed to be 70% to 80%.

Figure 6. Mean (solid curves) and 95 % confidence intervals (dashed curves) of Mf prevalence (blue) and annual transmission potential-ATP (red) in the study site Masaloo as a function of time when: (a) only switch MDA (annual MDA for 10 years followed by bi-annual MDA) is used, and (b) when switch MDA regime is used in tandem with monthly EWT in the homogeneous fly biting scenario. The times to reach the two thresholds (vertical red line (20 ATP) and blue line (1% MF prevalence)) are significantly reduced as compared to MDA alone. Here the EWT coverage is 60% to 70% assuming a trapping radius of 200 meters. The fly killing efficiency of the traps is assumed to be 70% to 80%.

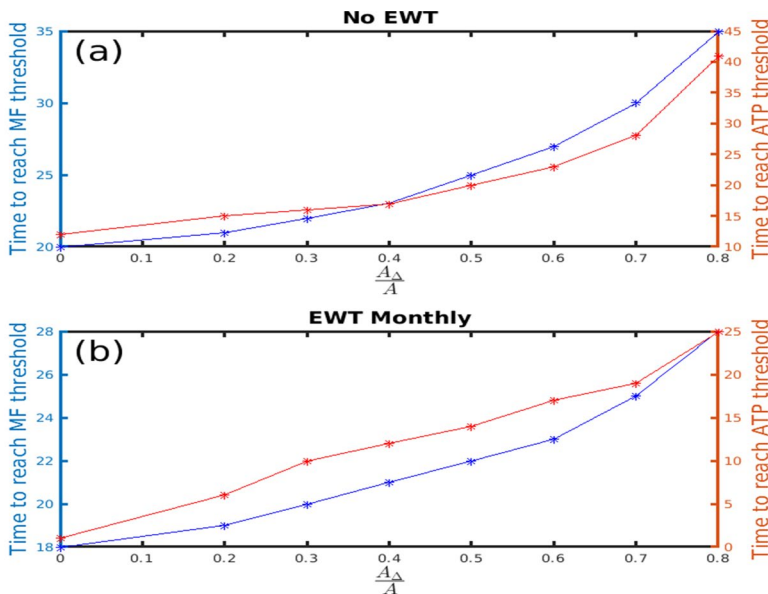

Figure 7. The time to reach the Mf and ATP thresholds as a function heterogeneous biting. Both (a) and (b) show the time to reach Mf elimination (blue curve) and ATP (red curve) thresholds in the study site of Masaloa as a function of time when: (a) annual MDA alone is used, and (b) when annual MDA is used in tandem with monthly EWT. The times to reach the WHO set thresholds increase nonlinearly as biting heterogeneity increases. Here the EWT coverage is 60% to 70% assuming a trapping radius of 200 meters. The fly killing efficacy of traps is 70% to 80%.

Figure 8. Bar plots indicating years saved in reaching the ATP (red) and Mf (blue) thresholds when EWT is deployed monthly alongside annual MDA in comparison with the use of annual MDA alone for increasing coverage values in the (a) homogenous fly biting case and (b) for the heterogeneity factor $\frac{A_{\Delta}}{A} = 0.8$. The results in shows that the combined use of traps and yearly MDA increases the number of years saved in reaching Mf and ATP thresholds for a given coverage compared to when using MDA only. For the homogeneous scenario in (a), the mean number of intervention years saved range from between 7 to 10 years depending on trap coverage and the threshold target (whether Mf or ATP). By contrast, this reaches as high as between 10 to 20 years in the case of the heterogeneous fly biting scenario as shown in (b). Note that the y-axis is shown on a log scale. The study site is Masaloa. The killing efficacy of traps is 70% to 80%.

529 The corresponding effects of including EWT post-stoppage of MDA when deployed monthly either during the
530 peak biting season or throughout the year for a moderate level of mean trap fly killing efficacy (75%) and
531 coverage (65%) configuration on transmission elimination/recrudescence are shown for each of the four
532 villages in Tables 3-4 (see Tables S15, S16 for results for high efficacy and coverage EWT). The predictions
533 indicate that in contrast to when EWT is not introduced (Table 2), the deployment of these traps following
534 the stoppage of MDAs will dramatically increase long-term onchocerciasis transmission elimination whilst
535 significantly suppressing the probability of recrudescence over both the short as well as longer-terms. Thus,
536 the inclusion of the traps will generate very high elimination probabilities (up to as high as 97%) but only if
537 they are deployed over the long-term (15 years in the present simulations), with the period immediately post
538 stoppage of MDA marked by significant transient dynamics (with between 96% to 100% of curves exhibiting
539 this feature during the first 5 years post MDA stoppage). Importantly, these results do not differ appreciably
540 whether monthly EWT is deployed only during the peak biting season or annually (compare Table 3 versus
541 4), although slightly higher probabilities of transmission elimination result when traps are deployed
542 monthly. Increasing the fly killing efficacy and coverage of EWT to levels as high as a mean of 95% for each of
543 these control parameters will have the strongest impact in reducing the recrudescence probability to 0 at
544 both 5- and 15-years post MDA, while increasing the long-term probability of transmission elimination to as
545 high as 99% (Tables S15, S16). This latter finding implies that deploying just 7-8 EWT traps during the peak
546 biting season in a village of size 1 km^2 will be sufficient to suppress high probability recrudescence and
547 achieve long-term high probability transmission elimination. A further notable feature of the results
548 displayed in Tables 3 and 4 is that the deployment of EWT after the stoppage of MDA may suppress
549 resurgence of infection uniformly across all the study sites, i.e. irrespective of baseline infection prevalences.
550 These results are for the homogeneous fly biting case; except for increased timelines to cross the 1% Mf
551 threshold, qualitatively the same elimination/recrudescence patterns were also observed for the
552 heterogeneous biting case.

Table 2. Transmission elimination and recrudescence probabilities estimated for each study site 5 and 15 years after stoppage of annual and switch MDA regimes. The transient behavior as described in the methods section is indicated by the ~ sign.

Study Villages (baseline Mf prevalence (%))	Annual MDA upto 1% WHO threshold				
		Elimination probability (%)		Recrudescence probability (%)	
	Time to cross threshold (year)	After 5 years	After 15 years	After 5 years	After 15 years

558

559 Discussion

560 The Esperanza Window Trap (EWT) is a recent addition to community-directed VC approaches which
561 empirical field studies have shown could serve as a means for bringing about significant reductions of
562 *Onchocerca*-transmitting black flies (25, 26, 28, 30, 31). Further, it has been demonstrated that EWT can be
563 deployed effectively by community members such that it could also constitute a measure for overcoming the
564 problems of implementing the sustained long-term black fly control required to meet the endgame challenges
565 of achieving onchocerciasis eradication (21, 34). However, currently no study exists where the combined
566 effects of MDA and EWT have been investigated for reducing infection in both the vector and human
567 populations to levels that can result in the achievement of community-wide transmission elimination of the
568 parasite. EWT deployment at the village/site scale for achieving black fly control also requires understanding
569 of the factors that will underlie the configuration of the trap in the field, including the density of traps and
570 where to place them, needed to bring about optimal area-wide fly reduction in a given landscape (33). Here
571 we have sought for the first time to shed light on this central issue connected to the significance of using EWT
572 as a transmission elimination tool by adapting and coupling a population-level model of onchocerciasis
573 transmission with models of various EWT trap networks deployable in the field. More specifically, we used
574 the developed trap network-onchocerciasis transmission modeling system to address how operational
575 parameters connected with the field deployment of EWT, such as efficacy of traps in trapping and killing
576 *Simulium* flies, number of traps and coverage of a setting, inter-trap distance, capture radius, and
577 heterogeneity in fly distribution in a community (33, 58), may affect the abundance of the Simulid fly
578 population, and in combination with reductions in human infection brought about by MDA, can contribute to
579 the community-wide elimination of onchocerciasis transmission.

580 Our first analysis in this work examined the feasibility of using EWT to eliminate parasite transmission from
581 the black fly population in a community, focusing on the number of traps required to achieve this goal under
582 various trap network parameters, transmission conditions, and areal settings (Figure 4, Table 1). Our
583 simulations highlight that while the ATP threshold of 20 infective bites per person per year may indeed be
584 effectively breached quickly (even within a year) through the monthly deployment of EWT traps when these

585 are arranged in a rectangular array in a community (the results shown in Figure 4 and Table 1 reflecting the
586 outcomes predicted for the meso-endemic village of Masaloa although similar results were obtained for the
587 other three study sites), the numbers of traps required to actually achieve this goal will vary as a complex
588 function of trap fly killing efficacy, trapping radius, inter-trap distance, fly biting heterogeneity and size of a
589 setting. Thus, for example, if the trapping radius of a trap and inter-trap distance are large (such as the 200m
590 and 490-564m investigated here), the number of traps given a homogeneous fly biting scenario and a fly
591 killing efficacy of 70-80%, for achieving the ATP threshold by means of a moderately high trap coverage (60-
592 70%) and monthly trap placements for a year, can vary from as little as just 5 in a small size setting (1 km^2)
593 to as high as 487 in the case of a large size community (10 km^2) (Table 1). These numbers will increase with
594 coverage, eg. to 8 and up to 796 for this same scenario if the trap coverage is increased to levels as high as 90-
595 100%. A key finding, however, is that as spatial heterogeneity in fly biting increases, the number of traps
596 required to achieve the same goal will decrease significantly compared to the homogeneous biting case,
597 although even at the highest trap radius/inter-trap distance studied here up to 98 traps will still be required
598 (at the 60-70% coverage level) to cross the ATP threshold at the most heterogeneous situation modelled (ie.
599 $\frac{A_A}{A} = 0.8$) in the largest area examined here (10 km^2) (Table 1). The results displayed in Table 1 also indicate
600 that the number of traps needed to achieve the ATP threshold is highly sensitive to trap capture or fly
601 attractant radius and may become infeasibly high if this radius, and hence the inter-trap distance, decreases
602 to low levels.

603 Another important result in this regard which has major implications for the design of effective EWT trapping
604 networks is that the trap coverage (and therefore number of traps) needed to cross the 20 ATP threshold via
605 placement of traps every month for a year is found to depend strongly on the trap fly killing efficacy (Figure
606 4d). Thus, while an efficacy of 70% will require a trap coverage of just over 60% for a trap network consisting
607 of traps with a capture radius of 200m, placed every 490m, and deployed in a setting of size 1 km^2 , much
608 higher coverages will need to be achieved to meet the goal of achieving this target within a year if the fly
609 killing efficacy drops below 70% (Figure 4d). Indeed, there is a critical fly killing efficacy (approximately
610 45%) below which the ATP threshold cannot be achieved within a year even at maximal coverage, indicating
611 the strong sensitivity of the trap network to the fly killing efficacy of the trap.

612 These predictions highlight on the one hand the inadequacy of simply transferring evidence regarding fly
613 killing effectiveness based on restricted field trials for evaluating the utility of using EWT for bringing about
614 area- or community-wide interruption of transmission from the vector population. Indeed, our results show
615 that such evaluations must be made only by considering the effects of a given EWT trapping configuration or
616 network on parasite transmission dynamics, including the biting distribution of the vector, in a locality. These
617 results also underscore that high trap coverages, and thus infeasibly high trap numbers, will be required to
618 achieve vector-based elimination targets rapidly, which might limit the use of EWT traps if only much lower
619 coverages can be attained from using fewer traps and longer inter-trap distances (see Table 1 for a
620 comparison of the number of traps needed at 60-70% and 90-100% coverages for different trap capture
621 radii). This, however, will lengthen the timelines required to attain the ATP elimination target used in the
622 present simulations.

623 By contrast, the simulations of including EWT with MDA on the timelines required to reach the 20 ATP and
624 1% Mf thresholds investigated here using our MBR seasonality incorporated onchocerciasis transmission
625 model demonstrate that both of these thresholds can be achieved faster by coupling MDA strategies with
626 EWT compared to using MDAs alone (Figures 5-8 and Tables S5-S14). Overall, including EWT in the MDAs
627 (for trap killing efficacy of 75%, capture radius of 200m and MDAs delivered at a coverage of 80% in a setting
628 covering an area of 1 km^2 and experiencing homogeneity in fly biting) can potentially save between 1-12
629 years across the 4 study sites for combined annual MDA/EWT and 1-17 years when EWT is combined with
630 switch MDA (Table S5). A noteworthy feature of these results is also that the ATP threshold will be achieved
631 much faster than the corresponding Mf threshold in each village setting (and therefore saving more
632 intervention years if used as a target) when EWT is coupled with either of the MDA strategies irrespective of
633 the biting fly distribution in a setting (Figure 8). As we have shown previously this outcome is primarily a
634 function of the shorter life span of parasite larval stages and greater susceptibility of filarial vectors to VC
635 measures compared to the markedly longer life expectancy and comparatively lesser susceptibility of the
636 adult parasite populations residing in human hosts to drug treatments (34, 35). Note also, as we have
637 highlighted previously (34), while this result indicates that targets based on infection indicators in the vector
638 (ATP) may be significantly more sensitive for early detection of transmission interruption, MDA will still be

639 important for reducing the intensity of the remaining worm infections in humans in order to achieve the
640 permanent reduction of transmission especially in settings where in-migration of black flies is thought to be
641 very likely.

642 A related significant finding is that while the frequency of using EWT (viz. a month before peak fly biting
643 season, during the three months of the peak biting season, and monthly throughout the year) has little impact
644 on the predicted timelines required to achieve the Mf threshold, using monthly deployment of EWT alongside
645 the two MDAs modelled here by contrast can significantly reduce the years required to breach the ATP
646 threshold compared with using MDA alone (Figures 5-8; Tables S5-S14). This outcome was observed
647 irrespective of the fly biting variation, but an unanticipated finding is that times to reach both the 1% Mf and
648 20 ATP thresholds were found to increase for all interventions, including in the case of inclusion of EWT with
649 MDA, as fly biting heterogeneity in a setting increases (Figure 7). This is because the spatial heterogeneity in
650 vector biting as modelled here implies markedly higher than average densities of biting flies in certain
651 sections of a community or village, which will accordingly translate to requiring longer times to breach the
652 community-wide aggregated ATP and Mf elimination thresholds. On the other hand, high levels of vector
653 control coverage can be achieved in the heterogeneous biting scenario by using lower number of traps as
654 compared to the corresponding homogeneous setting. This is because placing the traps where flies are
655 concentrated rather than everywhere saves resources in terms of trap numbers without compromising on
656 coverage. However, a subtle but critical finding in this regard is that while increasing EWT coverage will only
657 have moderate effects in the homogeneous biting case, achieving high coverages in those areas where most
658 infective vector biting occurs will add substantially to the number of years saved for both thresholds (Figure
659 8(b)). This finding will increase the feasibility of using EWT as a control measure for accelerating
660 onchocerciasis elimination, but it will require baseline surveys of fly biting habitats within a setting to be
661 performed before deploying an effective EWT configuration (number of traps, inter-trap distance) for a
662 location of a specific size.

663 However, in general, the finding overall in this study of a nonlinear association between the number of traps
664 required, fly biting distribution, coverage and areal size on timelines to reach the two thresholds studied for a

665 given trap fly killing efficacy, capture radius and inter-trap distance means that: 1) trap numbers will not
666 scale linearly with changes in areal size, ie. the number of traps used in a site will not translate simply to
667 twice the number required for another site with double the area, and 2) the number of traps required will
668 vary between sites with different areas even when they exhibit the same fly distribution pattern. This
669 outcome again highlights the importance of considering the interaction between a given trap configuration
670 and parasite population dynamics in settings varying in spatial fly biting patterns when evaluating the
671 effectiveness of using EWT with MDA for progressing the meeting of set elimination targets.

672 Our third major result from this study pertains to simulations of the impact of adding EWT to MDA regimens
673 for sustaining long-term transmission elimination once the community-wide 1% Mf threshold is crossed and
674 MDA is stopped fully. This is becoming a critical topic of study given findings from both field and modeling
675 studies which indicate that achieving these or similar thresholds may not lead to interruption of transmission
676 in every setting (9, 60). More recent modeling studies also suggest that this outcome may intriguingly reflect
677 the emergence of transient dynamical behavior near elimination thresholds, which could result in long-term
678 low-level persistence of filarial parasitic systems (59). To imitate the current MDA interventions and these
679 endgame questions that have emerged regarding ensuring that long-term elimination of transmission is
680 sustained, we introduced EWT only after the 1% Mf threshold is crossed and MDA is stopped and again
681 compared annual versus switch MDA strategies in this exercise. The results shown in Tables 2-4 and in Tables
682 S15 and S16 highlight firstly the profound impact that introduction of EWT into either MDAs can have in
683 enhancing the achievement of sustainable transmission elimination especially when EWT is implemented
684 long-term compared to when no further interventions, including EWT, is introduced once MDAs are stopped.
685 Thus, while long-term application (at least for 15 years) of EWT at even at moderate efficacy
686 (75%)/coverage (65%) levels can result in in very high elimination probabilities (up to 94%) in the study
687 villages when deployed monthly during the peak biting season (Table 3) and up to as high as 97% (much
688 higher if higher efficacy and coverage levels are used (Tables S15, S16)) when used on a monthly basis (Table
689 4), the corresponding probabilities of transmission elimination achieved in the absence of EWT will only
690 increase to 15-47% by year 15 post MDA stoppage with significant resurgences of infection predicted at both
691 5 and 15 years post MDA depending on the MDA regimen and village (Table 2). A further significant finding of

692 import is that zero elimination is predicted for all the strategies with and without inclusion of EWT modelled
693 here at year 5 post-MDA (Tables 2-4), largely because of the induction of transient transmission dynamics
694 (majority of model curves exhibiting fluctuating low-level declines and increases in infection (59))
695 immediately following the crossing of the 1% Mf threshold.

696 These results imply firstly that while on the one hand deploying EWT even at moderate efficacy/coverage
697 levels post MDA can increase onchocerciasis elimination probabilities whilst suppressing recrudescence of
698 infection once the 1% Mf threshold is crossed compared to the situation when EWT is not implemented, this
699 impact will only become apparent when EWT is implemented long-term after the crossing of this threshold.
700 The finding of transient behavior immediately following the crossing of the 1% Mf threshold further implies
701 that while infection levels may remain at low levels - even below the 1% Mf value - during the short term (for
702 at least 5 years) after MDA is stopped, there will still be a possibility of significant resurgence of infection over
703 the longer-term in the absence of VC measures, such as EWT. This outcome, ie a delayed resurgence of
704 infection once the transient period passes, has major implications for post elimination surveillance. It
705 suggests that such surveillance will need to be extended beyond the currently proposed PTS/PES periods
706 (43) to facilitate a more reliable assessment of transmission stoppage in a setting especially when no VC
707 measures are deployed during the post-MDA period (59). A final point of interest regarding the results arising
708 from the deployment of EWT after the stoppage of MDA is that it will also overcome the impact of baseline
709 endemicity levels by suppressing the resurgence of infection uniformly across sites differing in these initial
710 transmission conditions (Tables 3, 4). As remarked previously (36, 46, 61), this outcome indicates how
711 including VC measures during the endgame phase of an elimination program can have the additional
712 important effect of overcoming the inherent between-site heterogeneity in parasite transmission dynamics,
713 affording thereby a more reliable strategy for bringing about filarial transmission elimination across
714 disparate localities.

715 On a more epistemological level, our results have provided additional elaborations of the role that
716 mathematical models which can integrate elements of an intervention with parasite transmission dynamics
717 can play in generating genuinely new knowledge regarding how a specific intervention would serve to meet a

718 set population-wide disease management goal (45, 62). In particular, here, we have demonstrated how
719 primary information or hypothesis about the efficacy of EWT traps in reducing the black fly population
720 obtained through focused field observations can be extended through our coupled EWT-onchocerciasis
721 transmission model into producing higher-order insights regarding the use of EWT traps in a community for
722 meeting set elimination thresholds, and following this for bringing about long-term sustainable transmission
723 elimination. The new information gleaned from these simulations regarding the specifics of the trap network
724 or configuration (number of traps, impacts of fly killing efficacy, trap capture radius, inter-trap distance and
725 placement of traps over space and time taking into account vector biting distribution and seasonality)
726 represent critical variables for meeting these goals effectively, which are often not fully explored or are
727 challenging to examine using empirical studies alone. This ability of mathematical models, especially when
728 used in conjunction with methods (such as the BM methodology used here) to assimilate information
729 regarding local transmission conditions, to extend the evidence from one set of observations, ie. from field
730 studies regarding the effectiveness of the EWT for reducing fly abundance at a particular spatial and temporal
731 scale, for the generation of novel higher-order out-of-sample predictions about other variables and processes
732 related to the overall operation of a dynamical system via the structures and parameters of a transmission
733 model indicates on the one hand the limitations of making inferences based on restricted empirical data
734 alone. Conversely, the results underscore the value of coupling structurally appropriate parasite transmission
735 models with such data for allowing a more comprehensive and reliable assessment of the potential of an
736 intervention, including guiding its optimal design, for facilitating community-wide parasite control across
737 disparate endemic settings.

738 Our coupling of EWT trap network configurations with the seasonal MBR-based onchocerciasis transmission
739 model has also presented new modeling constructs for how to incorporate the effects of variable spatio-
740 temporal processes into a population-level vector borne macroparasite transmission model. In particular, we
741 show how rainfall-driven seasonality in black fly biting abundance and how spatial heterogeneity in such
742 abundances that may occur in landscapes of varying areal sizes can be structurally integrated with a
743 population-level onchocerciasis model to gain more realistic insights of the impacts of control efforts to
744 achieve the elimination of the transmission of *O. volvulus* in the field. The formulations by which we

745 incorporate these heterogeneities into our base onchocerciasis transmission model as described in this paper
746 (see specifically the text around Equation 8) thus constitute major innovations in enhancing the capabilities
747 of data-driven population-level deterministic models for advancing investigations of the complex
748 transmission and control dynamics of macroparasitic diseases in the real-world. We indicate that similar
749 extensions could also be conceptualized and implemented into population-level parasite transmission models
750 for other macroparasitic diseases, which would allow leveraging of their higher tractability and simplicity (as
751 compared to stochastic or individual-based models) whilst improving their capability to handle the complex
752 spatio-temporal heterogeneities, such as those addressed in this work, that are very likely to underlie the
753 real-world disease transmission and extinction dynamics in the field.

754 A limitation to our study is that the exact form of the potential fly biting distribution in communities is not
755 addressed explicitly. The general principles regarding trap placement and numbers given trap fly killing
756 efficacy and coverage discussed in this paper can be expanded to include more realistic spatial distribution
757 functions for the biting black fly population, although the analysis will be mathematically involved (33). The
758 most common approach to trap deployment, as modelled here, is to place traps on a regular grid of cells
759 across a spatial domain, but if sites most likely to result in catches of established or invading black flies are
760 known, then it might be possible to set the traps in these optimal fly habitats. Research studies will be
761 required to determine such optimal habitats for trap placement to take advantage of the lower trap numbers
762 that would be required in such circumstances. Furthermore, given that the number of traps required to form
763 an effective attractant-based trap network is strongly sensitive to trap insect-killing efficacy and fly capture
764 radius, future empirical work to quantify these parameters for different lures, including how these will
765 change as lures age, is needed. The movement of flies over a landscape is another area where the present
766 modeling system can be made more realistic. If better data becomes available on black fly dispersal behavior,
767 then it might be possible to include a movement model for the fly population in our EWT simulation system
768 (63, 64), although if the dispersal behavior is also affected by host physiology and mobility as well as by
769 habitat patchiness in a setting then it might call for the extension of the present models into more spatially-
770 explicit simulation systems, such as the agent-based vector-borne disease modeling frameworks being
771 investigated for onchocerciasis by other authors (39). Finally, we have used elimination targets initially

772 proposed by WHO (WHO, 2016) in all the simulations carried out in this work. Our previous modeling studies
773 have indicated that such breakpoints are not global, can vary by endemicity, and may be lower than the
774 thresholds used here (34, 46, 50), although note that the present threshold values may apply in the presence
775 of black fly control (34, 46). While this indicates a need for reevaluating and confirming the targets required
776 for determining whether transmission has been interrupted, the key conclusions of our study, viz. that adding
777 EWT VC to MDA will significantly reduce timelines to elimination targets, and following this, will enhance the
778 achievement of sustained long-term transmission elimination compared to MDA alone in communities will
779 not change although the actual durations over which both goals will be met would (34, 46).

780 **Acknowledgment**

781 E.M. and T.R.U. thank the National Institute of Allergy and Infectious Diseases (<https://www.niaid.nih.gov/>)
782 for financial support of this study (Grant R01AI123245). The funders had no role in study design, analysis,
783 decision to publish, or preparation of the manuscript.

784 **Author Contributions**

785 Conceptualization: E.M. and S.B. Formal Analysis: S.B., S.S., W.Z.; M.E.S., E.M. Provided Data: T.R.U. Code
786 Organization: K.N. Writing- original draft: S.B. and E.M. Writing – review and editing: All authors.
