## 27 Abstract

28 **Background:** Herpesvirus infections may trigger Autoimmune neuroinflammatory  
29 diseases (ANDs), but their causal role is uncertain. This study used Mendelian  
30 randomization (MR) to investigate the causal effects of herpesvirus antibodies on ANDs.

31 **Methods:** We assessed 22 herpesvirus antibodies and five ANDs—multiple sclerosis  
32 (MS), neuromyelitis optica (NMO), myasthenia gravis (MG), Guillain-Barré syndrome  
33 (GBS), and chronic inflammatory demyelinating polyneuropathy (CIDP)—using five MR  
34 methods. MR-PRESSO, MR-Egger, and Cochran's Q statistic identified pleiotropy and  
35 heterogeneity. Bonferroni correction set the significance threshold at  $P < 4.545 \times 10^{-4}$ .

36 Validation used UK Biobank and FinnGen data, with meta-analysis for inconsistent  
37 results. **Results:** Significant positive causal effects were found for Epstein-Barr virus  
38 encoded nuclear antigen-1 (EBV EBNA-1) (OR=3.009), EBV viral capsid antigen (VCA)  
39 p18 (OR=8.700), and human herpesvirus 7 (HHV7) U14 (OR=3.359) antibody levels  
40 on MS risk, and HHV7 U14 (OR=10.641), Varicella zoster virus glycoprotein E and  
41 glycoprotein I (VZV gE and gI) (OR=17.220) antibody levels on NMO risk. VZV gE and gI  
42 (OR=2.542) antibodies increased MG risk, while EBV ZEBRA (OR=0.592) reduced  
43 MS risk. Negative effects of EBV EA-D and ZEBRA antibodies on NMO were also noted.

Validation confirmed the effects of EBV EBNA-1, EBV VCA p18 antibodies on MS, and VZV gE and gI on antibody MG, while EBV ZEBRA and HHV7 U14 antibodies effects on MS were not validated. **Conclusions:** The study suggests a causal link between specific herpesvirus antibodies and the risk of MS, NMO, and MG.

**Keywords:** Autoimmune neuroinflammatory diseases, multiple sclerosis, neuromyelitis optica, myasthenia gravis, Epstein-Barr virus, human herpesvirus, varicella zoster virus, antibody

## Introduction

Autoimmune neuroinflammatory diseases (ANDs) are a category of disorders in which the immune system mistakenly targets and attacks the nervous system, resulting in inevitable structural and functional damage[1, 2]. Autoimmune neurological diseases (ANDs) include mainly multiple sclerosis (MS), neuromyelitis optica (NMO), Guillain-Barré syndrome (GBS), chronic inflammatory demyelinating polyneuropathy (CIDP) and myasthenia gravis (MG). MS and NMO affect the central nervous system (CNS), GBS and CIDP affect the peripheral nervous system (PNS), and MG affects the neuromuscular junction (NMJ). These conditions lead to neuronal or axonal damage, demyelination, damage to the nerve-muscle junction and other pathological changes [3, 4].

The incidence and prevalence of autoimmune diseases are increasing worldwide every year, but the exact causes of these diseases remain unknown; however, it is

thought that a mixture of genetic and environmental factors play a role in their development [5]. Infections seem to be a common trigger for autoimmune diseases [6].

Several viruses of the Herpesviridae family have been implicated as an important risk factor for ANDs, Epstein-Barr virus (EBV) has been implicated as a major cause of multiple sclerosis [7], the risk of MS increases 32-fold following infection with EBV [8]. Human herpesvirus 6A (HHV-6A) has been associated with a higher risk of developing multiple sclerosis. Cytomegalovirus (CMV) infection may be associated with the occurrence of aquaporin-4 antibody-positive NMO spectrum disorder (AQP4 IgG+ NMOSD) [9]. CMV and EBV are also frequently identified as antecedent pathogens of GBS [10]. Case reports of CIDP have found associations with CMV and EBV [11].

The association between EBV infection and the pathogenesis of MG remains controversial [12, 13]. Meanwhile, the associations between viruses of the Herpesviridae family and MG remain unclear. Existing observational studies and case reports have limited sample sizes, which reduces the statistical power to detect true associations and increases the likelihood of random error. In addition, it is difficult to draw causal conclusions from observational evidence due to residual confounding and reverse causation [14].

Mendelian randomisation (MR) is a novel approach that may offer more effective solutions to the above shortcomings. MR uses genetic variations that affect exposure as instrumental variables (IVs) to assess the causal relationship between exposure and outcomes. Because alleles are randomly assigned at conception, they are unaffected by confounding factors and disease states. By using genetic variants as IVs, MR can reduce

the confounding effects of environmental factors and avoid reverse causation bias [15, 16].

Previous MR studies have found no association between herpes simplex virus (HSV) infection and MS [17], whereas varicella infection is associated with MS [18]. Compared to viral infections, antibody immune responses may not only serve as markers of infection exposure, but also potentially provide clues to the pathophysiological mechanisms associated with ANDs. However, whether there is a causal relationship between these common herpesvirus-induced antibody immune responses and ANDs is unknown, and to the best of our knowledge, our study will be the first to investigate the causal relationship between herpesvirus antibodies and ANDs, thereby further exploring new potential therapeutic targets and potentially informing vaccine selection for patients with ANDs.

## Materials and Methods

### Study Design

MR analysis is a statistical technique used to identify causal relationships, particularly within observational data. It uses genetic variants that influence exposure as instrumental variables (IVs) to assess the causal relationship between exposure and outcomes. A key advantage of MR analysis is its ability to mitigate bias arising from confounding and reverse causation, as genetic variations are generally not influenced by environmental or behavioural factors [15, 16]. MR studies will help to overcome current obstacles in investigating the relationship between antibody immune responses following herpesvirus infection and various ANDs, thus facilitating a more accurate investigation of direct causal relationships.

## Data Source

Our study investigated the immune response of 22 antibodies to five types of herpesvirus infection: Anti-CMV IgG seropositivity, CMV pp28 antibody levels, CMV pp52 antibody levels, CMV pp150 antibody levels; Anti-EBV IgG seropositivity, EBV early antigen-D (EA-D) antibody levels, EBV encoded nuclear antigen-1 (EBNA-1) antibody levels, EBV viral capsid antigen (VCA) p18 antibody levels, EBV ZEBRA antibody levels; Anti-HHV6 IgG seropositivity, Anti-HHV6 IE1A IgG seropositivity, HHV6 IE1A antibody level, Anti-HHV6 IE1B IgG seropositivity, HHV6 IE1B antibody level, HHV6 p101k antibody level, Anti-HHV7 IgG seropositivity, HHV7 U14 antibody levels, Anti-HSV1 IgG seropositivity, HSV1 mgG-1 antibody levels, Anti-HSV2 IgG seropositivity, HSV2 mgG-1 antibody levels; Varicella zoster virus glycoprotein E and I (VZV gE and gI) antibody levels.

The above immune responses were investigated in a Genome-Wide Association Study (GWAS) involving a total of 8,735 individuals for case-control phenotypes and an average (range) of 4,286 (276-8,555) samples per quantitative analysis [19].

Genome-wide summary data for MS consisting of 47,429 cases and 68,374 controls from the European population were obtained from the International MS Genetics Consortium (IMSGC) [20]. To further validate the positive results, UK Biobank (1679 cases and 461254 controls, <https://gwas.mrcieu.ac.uk/datasets/ukb-b-17670/>) and FinnGen (2620 cases and 449770 controls, [https://r11.finnngen.fi/pheno/G6\\_MS](https://r11.finnngen.fi/pheno/G6_MS)) for MS were used.

NMO-related GWAS data were obtained from the largest and most recent NMO

GWAS meta-analysis, which included 215 NMO cases and 1,244 controls [21].

The largest MG GWAS reported by Chia et al. was used for the primary analysis in this study, which included 1,873 cases and 36,370 controls [22] (<https://www.ebi.ac.uk/gwas/>). The MG GWAS focused only on cases positive for anti-acetylcholine receptor antibodies (anti-AChR), excluding individuals positive for antibodies to muscle-specific kinase (anti-MuSK). For external validation, summary statistics were obtained from the UK Biobank (224 cases and 417,332 controls, <http://www.nealelab.is/uk-biobank>) and the FinnGen (504 cases and 449,570 controls, [https://r11.finnngen.fi/pheno/G6\\_MYASTHENIA](https://r11.finnngen.fi/pheno/G6_MYASTHENIA)).

For GBS, data were obtained from the FinnGen Biobank with 489 cases and 445,865 controls ([https://r11.finnngen.fi/pheno/G6\\_GUILBAR](https://r11.finnngen.fi/pheno/G6_GUILBAR)). Genetic associations for CIDP were derived from 456,348 individuals of European ancestry from the UK Biobank using a fast genome-wide association generalised linear mixed model and were obtained from the catalogue [23]. Detailed information of Data used in our study was shown in supplementary table 1.

## Instrumental Variable Selection

We screened single nucleotide polymorphisms (SNPs) that showed a significant association with exposure factors in the exposure GWAS ( $P < 5 \times 10^{-8}$ ). When the number of SNPs was less than 10, we relaxed the SNPs selection criterion to a p-value threshold of  $p < 1e-07$  or  $p < 1e-06$ , with a minimum standard of  $p < 1e-05$  [24]. SNPs with minor allele frequencies (MAF  $< 0.01$ ) were also deleted, and linkage disequilibrium (LD) between SNPs was resolved by clustering ( $R^2 < 0.001$  within a 10 Mkb clustering

distance). Palindromic SNPs were removed. The exposure and outcome data sets were then harmonised. The proportion of variance explained by instrumental variables was calculated using the formula:  $R^2 = 2 \times \beta^2 \times \text{EAF} \times (1 - \text{EAF}) / (2 \times \beta^2 \times \text{EAF} \times (1 - \text{EAF}) + 2 \times \text{SE}^2 \times N \times \text{EAF} \times (1 - \text{EAF}))$ , where N is the sample size [25]. The power of the genetic instrument was assessed using the F-statistic, calculated as  $F = R^2 \times (N - 2) / (1 - R^2)$ . An F-statistic greater than 10 indicates a strong instrument, IVs with F-statistics less than 10 were considered weak and thus excluded from the analysis. The SNiPA(<https://snipa.org/snipa3/>) and GWAS catalogue(<https://www.ebi.ac.uk/gwas/home>) was used to check that the SNPs were not associated with other relevant confounders, such as smoking, body mass index (BMI), physical activity, serum 25-hydroxyvitamin D levels.

## Mendelian Randomization Analysis

When there was only one IV, the Wald ratio method was utilized. In cases where two IVs were present, Inverse Variance Weighted (IVW) method will be used. With more than two instrumental variables (IVs) available, univariable Two-Sample MR (TSMR) was used to estimate the total causal effects of antibody immune response on ANDs, we applied five MR analysis methods: IVW, MR Egger, Weighted Median, Simple Mode, and Weighted Mode, IVW served as the primary approach for result interpretation [26].

To clarify whether there were reverse causal relationships between ANDs and antibody immune responses, we also conducted reverse Mendelian randomization.

To account for multiple comparisons, the Bonferroni correction was utilized. We set a significance threshold of  $\alpha = 0.05/n$  (where n represents the number of comparisons) to

mitigate the increased risk of false positives from multiple testing [27]. This correction method helps maintain the overall Type I error rate at an acceptable level while controlling for the familywise error rate. Therefore, a P-value below 4.55E-04 (calculated as 0.05 divided by the product of 22 comparisons and 5 outcomes) was considered statistically significant.

MR Egger intercept test and Outlier (MR-PRESSO) were used to detect the presence of pleiotropy. When the P-values for MR Egger intercept and MR-PRESSO are less than or equal to 0.05, it suggests the presence of pleiotropic IVs. To address this, we iteratively performed MR Egger intercept and MR-PRESSO tests, removing any outliers each time, until no horizontal pleiotropy was detected. Furthermore, we also employed visual inspection of the scatter plot and forest plot to test the MR “no horizontal pleiotropy”. Additionally, Cochran’s Q statistic was used to assess the degree of heterogeneity among all IVs. P-value from the Q-test greater than 0.05 indicates that there is no significant heterogeneity among the IVs.

To assess the robustness of the identified causal associations, we conducted two sensitivity analyses: the MR-Egger intercept test and leave-one-out analysis. The intercept from the MR-Egger test estimates the degree of directional pleiotropy, while the leave-one-out analysis determines if the significant results are influenced by any single SNP.

## Meta-analysis

For MS and MG, when the MR results of the discovery and replication phases were inconsistent, the meta-analysis was performed to assess combined causality. The choice

of effect model was based on the heterogeneity of the results. If there was little significant heterogeneity with  $I^2 \leq 50\%$ , the fixed-effects model was used to combine the results. Otherwise, the random effects model was used.

The statistical analyses in this study were performed using R version 4.4.1, including TwoSampleMR, MRPRESSO and Metafor. The study protocol and details were not pre-registered

## Results

### Selection of Instrumental Variables

Detailed information on the IVs of antibody immune responses to five types of herpesvirus is shown in Supplementary Table 2. The P value thresholds for anti-CMV IgG seropositivity, CMV pp28 antibody levels, CMV pp52 antibody levels, CMV pp150 antibody levels, anti-EBV IgG seropositivity, anti-HHV6 IgG seropositivity, anti-HHV6 IE1A IgG seropositivity, HHV6 IE1A antibody levels, anti-HHV6 IE1B IgG seropositivity, HHV6 IE1B antibody levels, HPV6 p101k antibody levels, anti-HHV7 IgG seropositivity, anti-HSV 1 IgG seropositivity, HSV1 mgG-1 antibody levels, anti-HSV2 IgG seropositivity and HSV2 mgG-1 antibody levels were  $1e-05$ , HHV7 U14 antibody levels were  $1e-07$ , EBV EA-D antibody levels, EBV EBNA-1 antibody levels, EBV VCA p18 antibody levels, EBV ZEBRA antibody levels and VZV gE and gI antibody levels were  $5e-08$ . rs1808192 in HHV7 U14 antibody levels, rs34811474 in anti-HSV 1 IgG seropositivity and rs13204572 in VZV gE and gI antibody levels were deleted as they were associated with BMI. IVs for MS, NMO, MG, CIDP, GBS are shown in Supplementary Tables 3, 5, 7, 9, 11, respectively. All F values of the IVs were greater than 10, indicating that weak

instruments were excluded.

## Antibody Immune Response Following Herpesvirus Infection on MS

In this study, the antibody unit was the logarithmic transformation of the antibody median fluorescence intensity. We observed a causal effect of a 1-unit increase in EBV EBNA-1 antibody levels, EBV VCA p18 antibody levels and HHV7 U14 antibody levels correlating with an increasing risk of MS [IVW: odds ratio (OR) = 3.009, 95% CI: 2.377-3.807,  $P=4.772e-20$ , adjusted  $p=2.250e-18$ ; IVW: OR=8.700, 95% CI: 6.128-12.351,  $P=1.059e-33$ , adjusted  $p=1.165e-31$  and IVW: OR=3.359, 95%CI: 2.034-5.546,  $P=2.187e-06$ , adjusted  $p=2.406e-04$ ]. In addition, causal evidence was also found for a differential effect of a 1-unit increase in EBV ZEBRA antibody levels (IVW: OR = 0.592, 95% CI: 0.491-0.713,  $P = 3.195e-08$ , adjusted  $p = 3.515e-6$ ), the analysis did not reveal causal relationships between other antibodies and the risk of MS (Fig 1, S Table 4). To validate the above results, we also used the UK Biobank and FinnGen MS datasets, with detailed results shown in Table 1. In all three datasets, the causal effects of EBV EBNA antibody levels and EBV VCA p18 antibody levels on MS were significant; however, the MR results of HHV7 U14 antibody levels and EBV ZEBRA antibody levels on MS differed between the three datasets, and the meta-analysis did not confirm that the overall effects of these on MS were significant.

**Abbreviations:** MS: multiple sclerosis; EBV: Epstein-Barr virus; HHV: human herpes virus; IVW: IVW: inverse variance weighted; REMA: Random Effects Meta-Analysis.

## Pleiotropy and Sensitivity Analysis for MS

Heterogeneity was observed among the IVs of EBV EBNA-1 antibody levels ( $Q=27.055$   $P=1.414e-4$ ), EBV VCA p18 antibody levels ( $Q=70.545$   $P=1.147e-12$ ), HHV6 IE1A antibody levels ( $Q=17.036$   $P=0.048$ ) and anti-HSV2 IgG seropositivity ( $Q=13.885$   $P=0.031$ ) in terms of their effect on MS (S Table 4). All p-values from the MR Egger intercepts and MR-PRESSO global tests were greater than 0.05, indicating the absence of outlier SNPs and no evidence of horizontal pleiotropy between the IVs and outcomes. Leave-one-out analysis showed that the results remained consistent regardless of which individual SNP was excluded (S Fig 1-22).

It is noteworthy that the final IVs of HHV7 U14 antibody levels and Varicella zoster virus glycoproteins E and I (VZV gE and gI) antibody levels, filtered by the above steps, consist of only two SNPs. IVs of the former have no heterogeneity ( $Q=2.823$   $P=0.093$ ), single SNP MR analysis showed the similar result (rs7773105:  $P=2.175e-05$ , adjusted  $P=0.002$ , OR=2.562, 95%CI:1.660-3.956; rs805282:  $P=3.911e-12$ , adjusted  $P=4.300e-11$ , OR=4.277, 95%CI: 2.97-6.448), we consider the causal relationship between HHV7 U14 antibody levels and MS to be reliable. However, there was significant heterogeneity between these two IVs of VZV gE and gI antibody levels ( $Q=53.561$   $P=2.507e-13$ ). In the single SNP MR analysis, the significance of the effects of these two IVs on MS varied

(rs9270551:  $P = 2.78E-276$ , adjusted  $P = 3.058e-274$ , OR = 0.557e-06, 95% CI: 0.369e-03 - 0.843e-03; rs9272285:  $P = 1.052E-03$ , adjusted  $P = 0.116$ , OR = 0.106, 95% CI: 0.028-0.406). In particular, rs9270551 was strongly associated with MS ( $P = 1E-200$ ), suggesting the presence of horizontal pleiotropy. Therefore, based on the MISGC databases, we used rs9272285 as an IV for VZV gE and gI antibody levels for MS. To further investigate the association between VZV gE and gI antibody levels and MS, we also performed MR analysis based on the MS datasets in UK Biobank and FinnGen with the following results: OR (95%CI) =1.000(0.999-1.001),  $P=0.299$  (UK Biobank), 0.2171830962485 OR (95%CI) =0.820 (0.5978-1.124)  $P=0.217$  (FinnGen), so there wasn't the causal relationship between VZV gE and gI antibody levels and MS.

## MS on Antibody Immune Response

Reverse Mendelian randomization revealed that MS does not have significant reverse causal effects on antibodies to the aforementioned herpesvirus antigens, with all p-values greater than the adjusted p-value ( $4.550e-04$ ) (S Fig 23).

## Antibody Immune Response on NMO

There is a causal relationship between elevated levels of two EBV-related antibodies and a reduced risk of NMO. These two antibodies are EBV EA-D antibody levels (IVW: OR = 0.043 95% CI: 0.010-0.196,  $P = 4.546e-05$ , adjusted  $p=0.005$ ) and EBV ZEBRA antibody levels (IVW: OR = 0.079, 95% CI: 0.043-0.147,  $P = 7.587e-16$ , adjusted  $p=8.345e-14$ ). Conversely, an increased risk of NMO could be caused by higher antibody levels of HHV7 U14 (IVW: OR =10.641 95% CI: 3.025-37.429,  $P=2.285e-04$  adjusted  $p=0.025$ ) or VZV gE and gI (IVW: OR =17.220 95% CI: 9.760-30.380,  $P=8.727e-23$

adjusted  $p=9.599e-21$ ). Antibodies to other viruses of the Herpesviridae family had no causal effect on the risk of NMO (Fig 2, S Table 6).

287

288 Fig 2 MR estimate results of antibodies of five herpesviridae viruses on NMO.

## 289 Pleiotropy and Sensitivity Analysis for NMO

290 Heterogeneity was observed in the IVs for EBV EA-D antibody levels ( $Q=6.892$ ,  
291  $P=0.075$ ), EBV EBNA-1 antibody levels ( $Q=70.545$ ,  $P=6.776e-4$ ), EBV ZEBRA antibody  
292 levels ( $Q=34.471$ ,  $P=0.011$ ), HHV6 IE1A antibody levels ( $Q=29.584$ ,  $P=0.042$ ) and  
293 HHV6 IE1B antibody levels ( $Q=31.661$ ,  $P=0.034$ ) on NMO (Supplementary Table 6). The  
294 MR-PRESSO global test indicated the presence of horizontal pleiotropy between the IVs  
295 for EBV EBNA-1 antibody levels on NMO ( $P=0.001$ ), EBV ZEBRA antibody levels  
296 ( $P=0.022$ ) and HHV6 IE1B antibody levels ( $P=0.034$ ). However, the p-values of the  
297 Egger intercept were greater than 0.05 and no significant outliers were detected. The  
298 leave-one-out analysis confirmed that no single SNP significantly altered the overall

299 results. Therefore, the results still have some informative value.

300 For the IVs of EBV ZEBRA antibody levels, the p-value of the MR-PRESSO global  
301 test was less than 0.05, but the Egger intercept was greater than 0.05. All five MR  
302 statistical methods showed a consistent direction of effect, similar effect estimates and  
303 OR values (Supplementary Table 6). The leave-one-out analysis again showed that the  
304 results were robust to the exclusion of any single SNP (Supplementary Fig 9). Thus, the  
305 overall results continue to support the existence of a causal relationship between EBV  
306 ZEBRA antibody levels and NMO.

307 Pleiotropy tests for the IVs of other antibodies showed no outlier SNPs and no  
308 evidence of horizontal pleiotropy between them and the outcomes (Supplementary Table  
309 6). Leave-one-out analysis consistently showed that excluding any single SNP did not  
310 affect the results (S Fig 1-22).

## 311 **NMO on Antibody Immune Response**

312 Reverse causal effects of NMO on antibodies were not found (S Fig 24).

## 313 **Antibody Immune Response on MG**

314 We found a causal effect between increased VZV gE and gI antibody levels and an  
315 increased risk of MG (IVW: OR = 2.542 95% CI: 1.972-3.277, P =5.897e-13 adjusted p=  
316 2.594e-12). No significant associations were found between other antibodies and MG  
317 (Fig 3). In addition, the UK Biobank and FinnGen MG datasets were used to validate this  
318 result, with detailed results shown in Table 2. In all three datasets, the causal effect of  
319 VZV gE and gI antibody levels on MG was all significant.

320

321 **Fig 3** MR estimate results of antibodies of five herpesviridae viruses on MG.

322 **Table 2.** MR estimate results of antibodies of VZV gE and gI antibody levels on MG.

| Exposure                      | Outcome | Author and datasets | Method | OR (95%CI)                 | P         | Adjusted P |
|-------------------------------|---------|---------------------|--------|----------------------------|-----------|------------|
| VZV gE and gI antibody levels | MG      | Jiang L et al.      | IVW    | 2.542(1.972-3.277)         | 5.897e-13 | 2.594e-12  |
|                               |         | UK Biobank          | IVW    | 1.00024(1.000035-1.000445) | 0.022     | /          |
|                               |         | FinnGen             | IVW    | 2.619(1.768-3.880)         | 1.576e-06 | /          |

323 **Abbreviations:** MG: myasthenia gravi; VZV: varicella zoster virus; IVW: inverse variance

324 weighted; REMA: random effects meta-Analysis.

## 325 Pleiotropy and Sensitivity Analysis for MG

326 IVs of EBV EA-D antibody levels (Q=44.715, P=0.004) and EBV ZEBRA antibody

327 levels (Q=37.615, P=0.004) show significant heterogeneity (Supplementary Table 8).

328 Although MR-PRESSO identified pleiotropy, the Egger intercept did not indicate

significant pleiotropy and no significant outliers were detected. IVs from other antibodies did not show heterogeneity and pleiotropy (S Table 8). The leave-one-out analysis gave similar results, even after excluding individual SNPs (S Fig 1-22).

## **MG on Antibody Immune Responses**

The adjusted P values from the MR analysis indicated that there was no causal relationship between MG and any of the 22 types of antibody immune response (S Fig 24).

## **Causal Relationships Detected Between Antibody Immune Responses and GBS/CIDP**

We found no forward or reverse causal relationships between the 22 antibody immune responses to five types of herpesviruses and GBS and CIDP (Fig 4-5 ; S Fig 26-27). IVs for HSV1 mgG-1 antibody levels on CIDP showed heterogeneity ( $Q = 44.905$ ,  $P = 0.03$ ) ( S Table 12 ). Pleiotropy was detected by MR-PRESSO but not by the Egger intercept, and the MR-PRESSO global test did not identify any significant outliers. Leave-one-out analysis showed no significant differences in MR results after removing individual SNPs (S Fig 1-22).

**Fig 4 MR estimate results of antibodies of five herpesviridae viruses on GBS.**

**Fig 5 MR estimate results of antibodies of five herpesviridae viruses on CIDP.**

All other results, including those for GBS and CIDP, passed the heterogeneity and pleiotropy tests. The sensitivity analysis did not identify any SNPs that significantly affected the overall results.

## Discussion

As the MR results showed, EBV EBNA-1 antibody and VCA p18 antibody were positively correlated with MS. Levels of EBV ZEBRA antibody were negatively correlated with MS in the IMSGC and UK Biobank datasets, but not in FinnGen, and the meta-analyses did not confirm a causal relationship. In addition, HHV7 U14 antibody levels were positively associated with MS in the IMSGC dataset, but not in the UK Biobank or FinnGen datasets, and the overall causal relationship was not established by the meta-analyses.

Negative associations between EBV ZEBRA and EA-D antibody levels and NMO were shown in this study. Conversely, a positive association was found between NMO and antibody levels of VZV gE, VZV gI and HHV7 U14. VZV gE and gI antibody levels showed a positive association with MG.

The above results suggest an important role for EBV antigen-associated antibodies in the pathogenesis of AND. EBV infects and persists in human B cells by exploiting the B cell environment to sustain its life cycle while evading the host immune system through minimal expression of viral proteins [28]. Several antibodies to EBV proteins can be detected in EBV carriers. These proteins include EBNA-1 (BKRF1), a latency protein; VCA p18 (BFRF3), a structural protein of the mature virus; ZEBRA (BZLF1), a lytic cycle protein; and EA-D, a basic component of the viral DNA replication complex. [28, 29].

371 Previous studies have confirmed that higher antibody levels against EBNA-1 and VCA  
372 p18 (or VCA) are associated with an increased risk of MS; in individuals with genetic  
373 factors associated with lower EBNA-1 IgG titres, the onset of MS was delayed by 3.5  
374 years [30, 31], [32]. A region within the carboxyl half of EBNA1 (amino acids 385-420)  
375 induces elevated antibody levels in MS patients and shows the strongest association with  
376 MS risk compared to antibody levels against other domains of EBNA1 [33]. EBNA1-  
377 specific antibodies are found in the cerebrospinal fluid (CSF) of some MS patients; these  
378 antibodies may play a role in the formation of oligoclonal bands, which are antibodies  
379 produced by clonal B-cell-derived plasma cells in the central nervous system and are a  
380 hallmark of MS [34]. Injection of a peptide derived from the aa395-420 region of EBNA1  
381 into mice with experimental autoimmune encephalomyelitis (EAE) exacerbated CNS  
382 autoimmunity [34, 35].

383 Our research confirms a causal relationship between antibodies to EBNA-1 or VCA p18  
384 and MS. However, the exact mechanisms by which these two antibodies cause MS are  
385 not yet clear. Based on the current evidence, molecular mimicry of EBNA-1 and VCA  
386 p18 may play some role. Antibodies against VCA p18 (BFRF3) cross-react with the  
387 cytoplasmic protein septin-9 [36]. Septin-9, a cytoplasmic protein that forms filaments,  
388 may play a role in cytokinesis, exocytosis, neurite outgrowth and cell cycle control. While  
389 it is widely expressed in various tissues, it is emerging as an intriguing candidate  
390 autoantigen for MS due to gene mutations that cause hereditary neuralgic amyotrophy  
391 [37]. In the CNS, septin-9 is mainly found in neurons and its expression is upregulated  
392 after trauma [38]. Antibodies to EBNA1 have been observed to cross-react with

anoctamin 2,  $\alpha$ B-crystallin, myelin basic protein (MBP) and glial cell adhesion molecule [33, 34, 39]. However, the pathogenic role of these antibodies remains unclear because successful cell-depleting therapy for MS does not affect antibody-producing plasma cells in the short term. Moreover, such treatment does not seem to reduce oligoclonal bands [7]. These two antibodies may become new therapeutic targets in MS, particularly in patient groups with high levels of these antibodies and poor response to other treatments.

ZEBRA (BZLF1) was considered to be a major environmental factor associated with MS and a significant contributor to the disease process [40]. BZLF1 was found in 46% of MS brains, mainly associated with chronic lesions, and in 44% of non-MS brain tissue [41]. ZEBRA is recognised as one of the viral immediate early genes that play an important role in the transition of EBV from latency to lytic replication [42], Reactivation of latent EBV infection is associated with disease activity in MS patients; however, research results are controversial [43-45]. Meanwhile, increasing EBV ZEBRA antibodies have not been found in MS [46], the role of ZEBRA antibodies in MS remains unclear.

Previous research found that anti-EA seropositivity was significantly higher in the NMOSD group compared to the HC group and MS patients [47, 48], but another study suggested that exposure to Epstein-Barr virus was not associated with an increased likelihood of NMO compared to healthy subjects [49]. Although our research suggests that BV ZEBRA and EA-D antibody levels may be associated with a reduced risk of NMO, further studies are needed to confirm this. Based on the advantages of MR statistics, this study suggests that EBV antibodies may provide new clues for NMO treatment. In particular, for NMO patients with high levels of EBV antibodies, understanding the

415 different roles of different antibodies in the pathogenesis of NMO may facilitate the  
416 exploration of personalised treatment approaches.

417 Current research on the association between HHV infection and the risk of MS has  
418 yielded controversial results, [50-52], This controversy is reflected in the results of this  
419 MR analysis. A meta-analysis found that CMV IgG seroprevalence was lower in people  
420 with MS than in controls in Europe [53]. However, our study does not support a causal  
421 relationship between CMV antibody immune response and risk of MS. Although one MR  
422 study suggested a causal relationship between herpesvirus infection and MS, we did not  
423 find a causal relationship between VZV gE and gI antibody levels and MS [18].

424 At present, the relationship between HHV and NMO is not very clear. Our study  
425 suggests that HHV may be one of the important pathogens of NMO, and HHV 7 U14  
426 antibody may be detrimental to NMO, but its exact pathogenic role in NMO requires  
427 further investigation. VZV has been considered as a precursor infectious agent of NMO  
428 [54-56], Causal association between chickenpox infection and NMO was also recently  
429 confirmed by MR study [57], Our study further confirmed a causal effect of VZV gE and gI  
430 antibody levels on NMO. VZV infection is an important risk factor for NMO, and  
431 vaccination against VZV may help to reduce the risk of NMO. For NMO patients with high  
432 levels of VZV gE and gI antibodies, the immune response and related pathogenic  
433 mechanisms induced by VZV infection could potentially become a new therapeutic  
434 approach.

435 Among 22 types of antibody immune response, only VZV gE and gI antibody levels  
436 were found to be associated with MG. The resultant GWAS data from two different

datasets both confirm this causal association, suggesting that unlike in MS, the pathogenic role of VZV in MG was robust, which may imply new therapeutic targets for MG, especially for patients with high levels of this antibody.

This study has a number of important strengths. First, we effectively reduced the influence of confounding factors and improved the accuracy and reliability of our results by using a novel MR analysis method. Second, our comprehensive analysis explored the causal relationships between 22 antibody immune responses to five herpesvirus infections and five types of ANDs. This provided a detailed understanding of their interactions. Third, we applied a rigorous correction procedure to ensure the robustness and validity of our findings. For positive results, we cross-validated with additional publicly available GWAS outcome data. We also conducted further meta-analyses to resolve any inconsistencies. These measures helped to reduce the risk of false positives. They also strengthened the credibility of our conclusions.

Although this study provides valuable insights, it has several limitations that should be acknowledged. First, the use of summary level data in MR analyses, although powerful, may introduce bias due to the assumption of linearity and the inability to explore non-linear relationships. In addition, the generalisability of the findings is limited by the demographic and genetic composition of the datasets used, which are predominantly of European ancestry. This raises questions about the applicability of the results to more diverse populations. Another limitation is the potential for pleiotropy, where genetic variants used as instruments may affect the outcome through pathways other than the exposure of interest, leading to biased estimates. Although we used

methods to mitigate pleiotropy, such as MR-PRESSO, the possibility of residual confounding cannot be completely excluded. Finally, the study relies on the availability and quality of existing GWAS datasets, which may vary in their coverage and accuracy of antibody measurements, potentially affecting the robustness of the findings. Future studies should aim to validate these findings in more diverse populations and with individual-level data to better understand the complex relationships between herpesvirus antibodies and autoimmune neurodegenerative diseases.

## Conclusion

The results of this study reveal predicted causal effects of EBV EBNA-1 antibody, EBV VCA p18 antibody on MS, HHV7 U14, VZV gE and gI antibody, EBV EA-D antibody and EBV ZEBRA antibody on NMO, VZV gE and gI antibody on MG, This might suggest potential role for above antibodies in the pathogenesis of ANDs, also This finding highlights the need for further exploration into the specific mechanisms of above antibodies in the pathophysiological processes of ANDs, providing an important theoretical basis for the development of more effective treatment strategies in the future.

## Declarations

### Ethics approval and consent to participate

Publicly available datasets were used for all data in our study. Informed consent was obtained from all participants prior to enrollment, and ethical approval was obtained for each cohort.

## Consent for Publication

All authors provide their consent for the publication of this manuscript.

## Availability of data and materials

The original papers presented in this study can be found in the supplementary materials.

## Competing Interests

The authors declare that they have no competing interests. The research, data interpretation, and conclusions presented in this manuscript were not influenced by any financial, personal, or professional conflicts.

## Funding

Grant from Science and Technology Program of Guangzhou : Key Lab of Guangzhou Basic and Translational Research of Pan-vascular Diseases ( 202201020042 ) ; Youth Pre-employment Training Programme Research Fund ( 2023ZC07 ) ; Natural Science Foundation of Hunan Province - Regional Joint Fund ( 2024JJ7012).
