69 ***Abstract***

70 The ongoing outbreak of Marburg virus disease (MVD) in Rwanda marks the third largest
71 historically, though it has exhibited the lowest fatality rate. Genomic analysis has identified a
72 lineage with limited internal diversity most closely related to a genome sequence from a sporadic
73 case sampled in 2014 in Uganda, though the lineages have diverged from a common ancestor that
74 was circulating for decades in the animal reservoir.

75 Notably, the data also provide evidence that the outbreak resulted from a single zoonotic
76 transmission event with limited human-to-human transmission, rather than multiple independent
77 zoonotic transmission events. The Rwandan MVD outbreak prompted a thorough investigation
78 that included contact tracing, clinical assessment, travel history, sequencing, and serology testing,
79 to trace the virus's origin. Results of investigations linked the index case to a mining cave inhabited
80 by *Rousettus aegyptiacus* (the Egyptian fruit bat), where three individuals tested seropositive for
81 IgG and IgM, further supporting the zoonotic origin of the outbreak through human-animal
82 interactions.

83

84 ***Background***

85 Since its discovery in 1967, the Marburg virus disease (MVD) has emerged as a significant global
86 health threat, resulting in several outbreaks characterized by alarmingly high case fatality rates
87 ranging from 22% to 90% (1). The first reported instances of MVD occurred in simultaneous
88 outbreaks in Marburg and Frankfurt, Germany, as well as in Belgrade, Yugoslavia (now Serbia)
89 (2). To date, there have been 19 recorded outbreaks, 563 confirmed cases, and 428 deaths
90 worldwide (4). On September 27, 2024, Rwanda reported its first ever cases of MVD (5). The

91 ongoing outbreak in Rwanda has confirmed 66 cases, with a case fatality rate of approximately
92 23% (5).

93

94 MVD has two distinct variants: Marburg virus (MARV) and Ravn virus (RAVV), with MARV
95 being the more prevalent variant, responsible for the majority of sporadic MVD outbreaks
96 worldwide. MARV is a negative-sense single-stranded RNA virus from the Filoviridae family,
97 similar to Ebola and possesses inverse-complementary 3' and 5' termini (3). MVD is
98 predominantly a zoonosis, transmitting to humans from either the bat natural reservoir or through
99 intermediate hosts, including non-human primates. The mechanisms by which bats regulate viral
100 replication and maintain complex immunity in contrast to humans remain unclear due to a lack of
101 bat-specific research tools necessary for comparative studies, such as antibodies for flow
102 cytometry, genomics, and transcriptomics (1,2). Studies confirm that MARV's natural reservoir
103 is the Egyptian fruit bat (*Rousettus aegyptiacus*) (6). The virus can cause viral hemorrhagic fever
104 in both humans and primates. However, the precise transmission dynamics between the natural
105 reservoir and humans or primates are insufficiently understood, though exposure to contaminated
106 excretions from fruit bats is likely a contributing factor (6). The virus is transmitted from human
107 to human, particularly through direct contact with body fluids like blood, saliva, semen, and other
108 body fluids from infected individuals (7).

109

110 The Marburg viral genome consists of 19,114 nucleotides encoding for seven proteins, including
111 glycoprotein (GP), nucleoprotein (NP) virion protein 30 (VP30), VP35, VP24, VP40 and large
112 viral polymerase (3).

113

114 Genomic characterization of MARV strains has revealed substantial genetic diversity across its
115 global phylogeny, but exhibits limited genomic variation within outbreaks (8).

116 Sequencing of the Marburg genome has provided deeper insights into viral evolution and identified
117 critical mutation hotspots during adaptation to new hosts, particularly in the VP40 protein and the
118 NP-VP35 intergenic region (9). These mutations can influence the virus's ability to evade the
119 immune system, therefore enhancing its pathogenicity.

120

121 *Statement of the specific scope of the study*

122 In this study, we used a near real-time genomics sequencing approach to characterize the Marburg
123 virus in blood samples obtained from patients in the ongoing outbreak in Rwanda. Our aim was to
124 use the genomic sequencing data to identify and characterize the virus and understand its evolution
125 and transmission dynamics during the current outbreak. This research underscores the importance
126 of continuous genomic surveillance which not only facilitates outbreak tracking but also informs
127 public health strategies for effectively controlling this deadly pathogen.

128

129 *Results*

130

131 Phylogenetic analyses support that the outbreak resulted from a single zoonotic transmission event
132 with limited human-to-human transmission rather than multiple independent zoonotic
133 transmission events (**Figure 1A**). Multiple independent zoonotic transmissions would have
134 resulted in a set of more diverged sequences introduced from the genetically diverse viral
135 population in the reservoir (10). The probable index case was a man in his 20's with an
136 occupational exposure to fruit bats (*Rousettus aegyptiacus*) in a mining cave environment, who

137 exhibited symptoms highly consistent with the classic clinical presentation of MVD. Additionally,
138 serological testing of three contacts of the index case exhibited MARV antibodies, further
139 supporting epidemiological tracing of the index case. The outbreak lineage is most closely related
140 to a sequence sampled in Kampala, Uganda in September 2014 from a healthcare worker (HCW),
141 with no secondary cases observed (KP985768). The source of the zoonotic transmission in 2014
142 was never identified (11). However, the Rwanda-Uganda sister lineages are significantly diverged
143 from one another, separated by 82 nucleotide substitutions (**Figure 1A**). In Bayesian phylogenetic
144 reconstructions, we estimate that the two lineages diverged from a common ancestor that circulated
145 in the animal reservoir in November 2008 [95% highest posterior density, or HPD: May 2007 and
146 June 2010] (**Supplementary Figure 1 A-B**).

147
148 The outbreak lineage in Rwanda is nested within a larger clade that includes diversity sampled
149 from bats in southwestern Uganda from 2007 onwards, along with two human cases identified in
150 Uganda in 2017 (**Figure 1A, B**). The closest bat virus (JX458855) was sampled from a juvenile
151 Egyptian fruit bat (*Rousettus Aegyptiacus*) in 2009 from Python Cave in Queen Elizabeth National
152 Park, a popular tourist attraction in south western Uganda (**Figure 1B**) (6). The lineage in Rwanda
153 is significantly diverged from JX458855, sharing a common ancestor that likely circulated in the
154 reservoir as early as June 2006 (95% HPD: December 2004 to November 2007) (**Supplementary**
155 **Figure 1 A-B**). *Rousettus aegyptiacus* are a cave dwelling species, with spillover events and
156 limited outbreaks frequently associated with mining activities. This includes outbreaks and
157 sporadic cases linked to Python cave and the Kitaka mine that is only 50 km away in 2007 and
158 2008, which both hosts *Rousettus aegyptiacus* colonies of over 50 000 bats. (6,10,12). The
159 divergent relationship of the Rwandan Marburg virus outbreak lineage indicates that the virus's

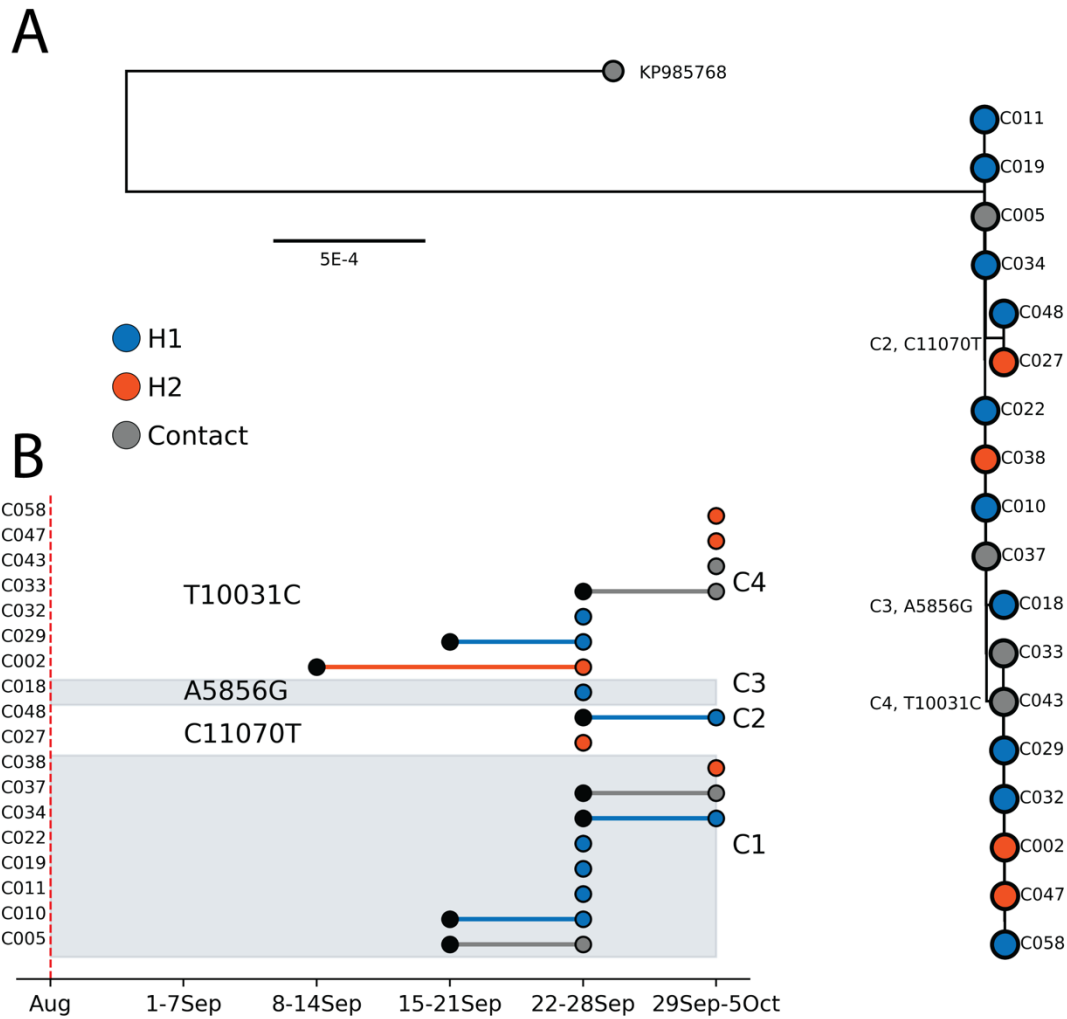

160 dispersal through host networks involved larger scale animal movement over a long period of time,
161 rather than a direct ancestral connection to the *Rousettus aegyptiacus* colony in southwestern
162 Uganda.
163

164
165 **Figure 1:** A) Maximum likelihood phylogeny of the global MARV dataset. Tips are annotated by
166 country of isolation. This study's tips are relatively enlarged. B) Map of Uganda and Rwanda.
167 The city of patients in this study (Kigali) is annotated in dark red. Python Cave and Kitaka Mine
168 in Ibanda district in southwestern Uganda are annotated in light blue and yellow, respectively.

169
170 The index patient's close relative was admitted to Hospital 1 (H1) at the end of August 2024 but
171 succumbed to the illness prior to the definitive diagnosis of MVD. It is highly probable that this
172 patient infected healthcare workers (HCWs) at H1, where MVD was subsequently confirmed at
173 the end of September 2024. From 22-28 September, 26 cases were reported in HCWs at H1 and
174 H2, respectively. The limited genetic variation among the outbreak sequences was consistent with

175 a very recent common ancestor, the short sampling period, and previous observations from the
176 Angola MARV outbreak (**Figure 2A**) (12). A cluster of eight identical sequences was sampled,
177 spanning the full sampling period (C1 in **Figure 2A, B**). The majority of the C1 sequences were
178 isolated from healthcare workers (HCWs) at H1 from 22-28 September, with reported symptom
179 onset as early as mid-September (**Figure 2B**). A C1 sequence was sampled from a HCW at H2 at
180 the end of September, suggesting infection from an unsampled C1 case in H2 or dissemination
181 between the two healthcare facilities. There are recorded cases of healthcare workers moving
182 between healthcare settings H1 and H2. This is further supported by cluster C2, consisting of two
183 healthcare workers from H1 and H2 respectively that share the synonymous SNP C11070T relative
184 to C1. Both C2 cases report symptom onset and were sampled in the later weeks of the epidemic.
185 There are a further seven identical sequences (C4) sampled between H1 and H2 across the full
186 sampling period that are one synonymous SNP (T10031C) away from C1. C002, a healthcare
187 worker employed at both H1 and H2, is believed to have acquired the infection at H1. This
188 individual subsequently became the index case at H2, leading to a nosocomial cluster at H2 and
189 infections at H1. Overall, there were only three synonymous SNPs observed in the outbreak clade:
190 A5856G (n=1 sequence), T10031C (n=7), and C11070T (n=2). A5856G and T10031C as well as
191 C11070T are outside of the CDS of the GP and VP24 genes, respectively. There is therefore no
192 evidence that post-emergence substitutions enhanced human transmission.

193

194 **Figure 2:** A) Maximum likelihood phylogeny of the outbreak clade, with the Kampala outgroup.

195 Sequences are colored with associated hospital. SNPs reconstructed relative to the common

196 ancestor are annotated in text, as are the clusters defined by the SNP presence. The coordinates

197 are relative to NC_001608 B) Epidemiological timeline of the sampled sequences in Figure 2A,

198 as annotated on the y-axis. The first black marker, if present, indicates the week of symptom onset

199 if distinct from week of sampling, with the second indicating the week of sampling. Sequences are

200 colored by their associated hospital (H1, H2), and partitioned by SNP presence into clusters, as

201 annotated in text. Red dashed line indicates the contact of the index case admitted to H1.

202

203 An exhaustive investigation of all cases was conducted which led to identifying the index case.
204 This in-depth process involved a comprehensive collection of diverse data sources including
205 clinical records, travel history, antibody serology testing results, and contact tracing information.
206 This evidence revealed that the earliest patient was traced back to a mining cave and exhibited
207 symptoms highly consistent with the classic clinical presentation of MVD. Additionally, serology
208 testing results from three contacts linked to the index case exhibited antibodies of persons exposed
209 to Marburg virus. This suggests that the mining cave may have served as a potential habitat for the
210 MARV animal reservoir, particularly the fruit bat (*Rousettus aegyptiacus*). Following up on these
211 findings, the Rwanda Ministry of Health through a multisectoral collaboration launched an
212 investigation surveillance with the aim of screening fruit bats, mainly cave dwellers, for Marburg
213 virus (**Supplementary Figures 2 A, B and C**).

214

215 ***Discussion***

216 The Rwanda MVD outbreak exhibited substantial human-to-human transmission, primarily
217 involving healthcare personnel, as is often observed with viral hemorrhagic fever (VHF) outbreaks
218 closely associated with nosocomial and occupational infections (18). However, Rwanda
219 effectively contained the spread from further reaching the broader community. Positive cases were
220 promptly isolated and treated with monoclonal antibodies and antivirals, achieving a favorable
221 case fatality rate of approximately 23%. This underscores the ongoing need to enhance healthcare
222 personnel's knowledge and attitudes regarding VHF case management.

223 Through evolutionary and phylogenetic analysis, we observed that the early outbreak sequences
224 represented very limited genomic variation, indicating that the outbreak originated from a single
225 zoonotic transmission event. The Rwandan lineage shared a common ancestor with sequences

226 originating from diversity sampled in bats in southwestern Uganda, thought the lineages had
227 diverged over decades in the animal reservoir. It is likely that enhanced zoonotic surveillance will
228 reveal many unsampled intermediates that can clarify the ecological pathways of transmission
229 between bat colonies in Uganda and Rwanda. Previous research indicates that bats can harbor
230 MARV for extended periods, with active mining areas in Rwanda providing ideal habitats for bats
231 and increasing the likelihood of zoonotic transmission (19).

232
233 We observed three synonymous single nucleotide polymorphisms (SNPs) outside the coding
234 regions of the GP and VP24 genes, respectively. Studies have shown that the Marburg virus VP24
235 protein interacts with the nucleoprotein (NP) and other cellular membranes, facilitating the release
236 of new virions from infected cells (20). Additionally, research highlights that MARV VP24
237 directly interacts with the human and bat Keap1 proteins, which modulate antioxidant responses
238 to support viral replication, a strategy likely critical for viral persistence and host adaptation (21).
239 Genomic sequencing of MARV in Rwanda has yielded critical insights into viral circulation
240 dynamics. However, as these SNPs fall outside of coding regions, it is unlikely that they
241 functionally contribute to enhanced viral fitness on any scale. Our results should be interpreted
242 within the context of our smaller sample size, which only covers the first two weeks of the
243 outbreak.

244
245 This research underscores the importance of continuous genomic surveillance which not only
246 facilitates outbreak tracking but also informs public health strategies for effectively controlling
247 this deadly pathogen. In addition, previous research indicates that bats can harbor MARV for
248 extended periods, with active mining areas in Rwanda providing ideal habitats for bats and

249 increasing the likelihood of zoonotic transmission. Furthermore, Rwanda's location in a region of
250 consistent turbulent outbreaks, including Ebola, Rift Valley fever, COVID-19, dengue, and
251 Marburg, underscores the importance of regional and international collaboration to enhance
252 outbreak preparedness and responses for global health security.

384 **Acknowledgments**

385 We gratefully acknowledge the support of the Government of Rwanda and the Ministry of Health,
386 through the Rwanda Biomedical Center, for facilitating and supporting this sequencing work. We
387 extend our sincere appreciation to both the African Centre of Excellence for Genomics of
388 Infectious Diseases (ACEGID) and the Africa Centre for Disease Control and Prevention (Africa

389 CDC) for their invaluable contributions. This work was made possible through the collaborative
390 efforts of development partners and stakeholders, to whom we are deeply grateful.

408 All the sequence data are available upon request on https://github.com/rbx-bfx/illumina_vsp.

409

410 *Materials and Methods*

411 **Ethics declaration**

412 The study was approved by the Rwanda National Ethics Committee (FWA Assurance No.
413 00001973 IRB 00001497 of IORG0001100-Protocol approval notice: N° 121/RNEC/2024).

414

415 **Patient sample collection**

416 We obtained whole blood samples from suspected patients presented with clinical symptoms (high
417 fever, severe headaches, muscle aches, fatigue, nausea, vomiting, and diarrhea) of MDV. Sample
418 testing was performed at Rwanda Biomedical Centre/National Reference Laboratory whereby
419 samples were kept in a cold chain prior to plasma separation and analysis.

420

421 **Nucleic acid extraction**

422 Viral RNA was extracted from 140µl plasma using the QIAamp Viral RNA Mini Kit (Qiagen,
423 Hilden, Germany), following the manufacturer's instructions adapted to the in-house standard
424 operating procedures with an elution volume of 60µl. The extracted RNA was quantified using a
425 Qubit fluorometer, and the samples were stored at -80°C until further analysis.

426

427 **RT-PCR and genomic sequencing**

428 For the detection and amplification of the target regions of the MVD, we employed the use of
429 RealStar® Filovirus Screen RT-PCR Kit 1.0 (Altona Diagnostics, Hamburg, Germany), which is
430 based on real-time PCR technology, for the qualitative detection and differentiation of Ebola and
431 Marburg virus specific RNA in human EDTA plasma. The RT-qPCR was conducted following
432 manufacturer's user guide and performed on CFX96 BIORAD machine. The amplification
433 followed an initial denaturation at 95°C for 5 minutes, followed by 40 cycles of denaturation at
434 95°C for 30 seconds, annealing at 55°C for 30 seconds, and extension at 72°C for 1 minute,

435 concluding with a final extension at 72°C for 5 minutes. The amplified products were analyzed via
436 2% agarose gel electrophoresis to confirm successful amplification and appropriate product size.
437 Following amplification, library construction was performed on 30 samples using the Illumina
438 RNA Prep with Enrichment (L) Tagmentation (IRPE) workflow and the Illumina Viral
439 Surveillance Panel v2 kit (VSP v2 kit). Total RNA extracts were converted to cDNA, tagmented
440 and thereafter amplified. Genomic region of interest was captured using a hybrid capture method.
441 Probes were isolated using magnetic pulldown which are selectively enriched for the desired
442 regions. Enriched libraries were quantified using dsDNA HS assay and Qubit fluorometer.
443 Libraries were thereafter denatured and normalized at a final loading concentration of 0.8pM.
444 Paired-end sequencing was performed using a NextSeq 550 with a 300-cycle mid-output cartridge,
445 with the sequencing depth aimed at a minimum coverage of 100x to ensure robust variant
446 detection.

447

448 **Bioinformatics Analysis**

449 **Genome Assembly**

450 We employed a reference-based genome assembly pipeline to analyze the sequencing data
451 generated using the Illumina Viral Surveillance Panel (VSP) v2 Kit (described above). This
452 workflow integrates several steps including; quality control, host genome filtering, and viral
453 genome assembly to accurately reconstruct viral sequences from targeted sequencing.

454 To ensure that only high-quality data were processed downstream, raw sequencing reads were first
455 processed with *fastp v. 0.23.24 (13)* for trimming adapters and filtering out low-quality bases.
456 Following this, human host genome sequences were filtered out by aligning the cleaned reads to
457 the human genome (hg38) using *Bowtie2 v.2.5.4 (14)*. Unmapped reads, presumed to be of viral

458 origin, were retained for downstream analysis. These de-hosted reads were then aligned to a
459 Marburg virus reference genome (NC_001608.3) using *Minimap2 v.2.28 (15)*,
460 The sequences had 70-97% genomic coverage. We manually masked two mutations in respective
461 consensus sequences that were adjacent to potential misalignment.

462

463 **Variant Calling and Consensus Generation**

464 Variant calling was performed using both *ivar 1.4.3 (16)* and *LoFreq v.2.1.5 (17)*. A depth
465 coverage threshold of 50 reads per nucleotide position was applied to ensure robust and reliable
466 variant detection. This threshold was also applied to the generation of consensus sequences which
467 was also done using *ivar 1.4.3.*,

468

469 **Phylogenetic**

470 We combined our eighteen higher quality sequences (coverage $\geq 70\%$) with all publicly available
471 MARV sequences available on Genbank (N=81). To root the tree, we included 8 Ravn virus
472 sequences included as an outgroup, which were pruned from the tree and excluded in all
473 subsequent analyses. We aligned the sequences using *Mafft v 7.52 (22)* and reconstructed a
474 phylogenetic tree using *IQTree 2.2.5 (23)* under modelfinder plus (24), with ultrafast bootstrapping
475 (25). We performed the initial ancestral state reconstruction using *Treetime v0.9.3 (26)*.

476

477 **Bayesian phylogenetic reconstruction**

478 The current genomic data does not provide sufficient temporal signal to estimate the rate of
479 evolution in the outbreak clade. However, we were not interested in estimating the time to the most
480 recent common ancestor (tMRCA) of the outbreak clade, as determining the emergence timing of

481 the outbreak clade will more likely depend on the epidemiological and contact history of the index
482 case. We wanted to estimate tMRCA of the outbreak clade and its closest human and zoonotic
483 outgroups to better understand its potential zoonotic emergence pathway. We therefore
484 reconstructed the time-resolved phylogeny under a fixed local clock. We assumed a fixed value of
485 $1e-3$ substitutions per site per year as a plausible rate of evolution for a RNA virus in the early
486 stage of an outbreak for the defined outbreak clade. We allowed the remainder of the tree to evolve
487 under a lognormal prior centered on $5e-4$. (27) We used a two-phase coalescent model: the tree
488 from the MRCA (Rwandan lineage) onward was modeled with an exponential growth model, with
489 the earlier phase modeled as a constant-population size coalescent model. We ran two independent
490 chains of 100 million states to ensure convergence, discarding the initial 10% of each chain as
491 burn-in. The chains were then combined with LogCombiner. For all subsequent analyses, we
492 assessed convergence using Tracer, and constructed a maximum clade credibility (MCC) tree in
493 TreeAnnotator 1.10 (28).

Figures

B Uganda

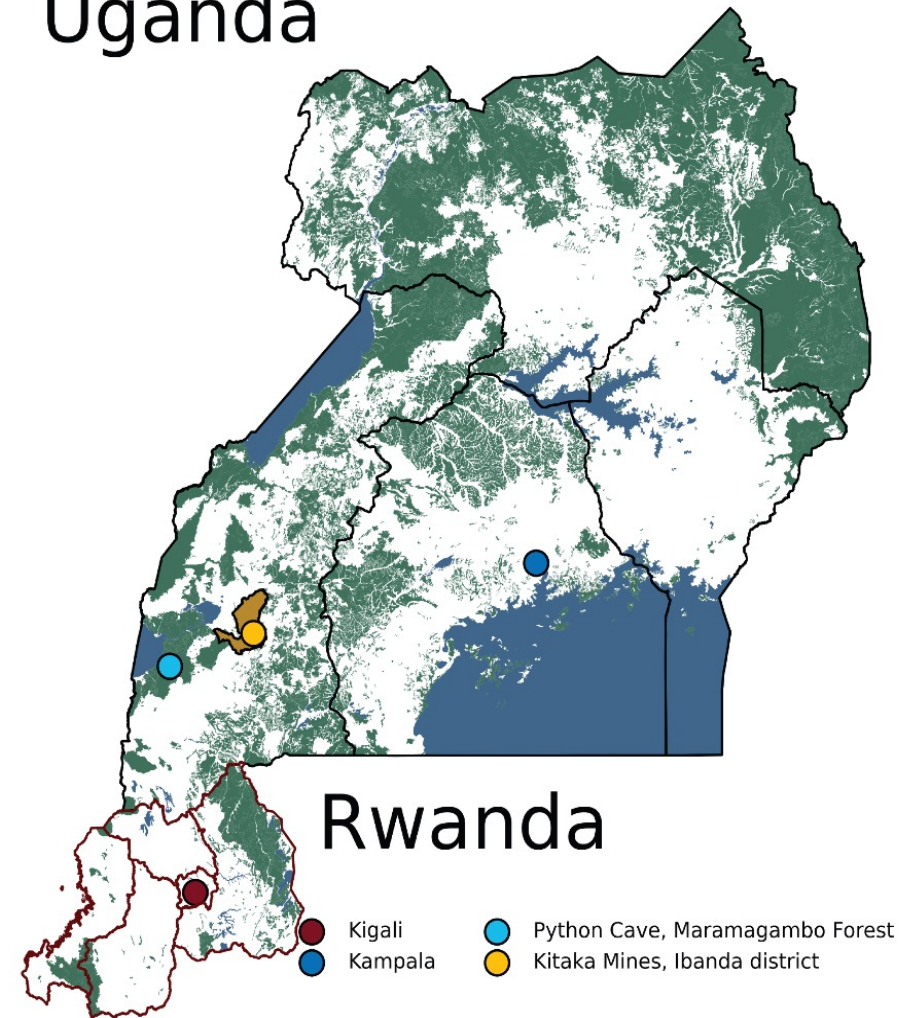

Figure 1: A) Maximum likelihood phylogeny of the global MARV dataset. Tips are annotated by country of isolation. This study's tips are relatively enlarged. B) Map of Uganda and Rwanda. The city of patients in this study (Kigali) is annotated in red. Python Cave and Kitaka Mine in Ibanda district in southwest Uganda are annotated in light blue and yellow, respectively.

Figure 2: A) Maximum likelihood phylogeny of the outbreak clade, with the Kampala outgroup. Sequences are colored with associated hospital. SNPs reconstructed relative to the common ancestor are annotated in text, as are the clusters defined by the SNP presence. The coordinates are relative to NC_001608 B) Epidemiological timeline of the sampled sequences in Figure 2A, as annotated on the y-axis. The first black marker indicates the date of symptom onset, with the second indicating the date of sampling. Sequences are colored by their associated hospital (H1, H2), and partitioned by SNP presence into clusters, as annotated in text
