58 **Abstract:**

59 **Background:**

60 Environmental exposures to chemical toxicants during gestation and infancy can dysregulate
61 multiple developmental processes, causing lifelong effects. There is compelling evidence of PFAS-
62 associated immunotoxicity in adults and children. However, the effect of developmental PFAS
63 exposure on infant T-cell immunity is unreported, and, if present, could be implicated in immune-
64 related health outcomes.

65 **Objectives:**

66 We seek to model longitudinal changes in CD4+ T-cell subpopulations from birth through 12
67 months and their association with in-utero PFAS exposure and postnatal CD4+ T-cell frequencies
68 and functions.

69 **Methods:**

70 Maternal-infant dyads were recruited as part of the UPSIDE-ECHO cohort during the first trimester
71 between 2015 and 2019 in Rochester, New York; dyads were followed through the infant's first
72 birthday. Maternal PFAS concentrations (PFOS, PFOA, PFNA, and PFHXS) were quantified in serum
73 during the second trimester using high-performance liquid chromatography and tandem mass
74 spectrometry. Infant lymphocyte frequencies were assessed at birth, 6- and 12-months using mass
75 cytometry and high-dimensional clustering methods. Linear mixed-effects models were employed
76 to analyze the relationship between maternal PFAS concentrations and CD4+ T-cell subpopulations
77 (n=200). All models included a PFAS and age interaction and were adjusted for parity, infant sex,
78 and pre-pregnancy body mass index.

79 **Results:**

80 In-utero PFAS exposure correlated with multiple CD4+ T-cell subpopulations in infants. The greatest
81 effect sizes were seen in T-follicular helper (Tfh) and T-helper 2 (Th2) cells at 12 months. A log₂-unit
82 increase in PFOS was associated with lower Tfh [0.17% (95%CI: -0.30, -0.40)] and greater Th2
83 [0.27% (95%CI: 0.18, 0.35)] cell percentages at 12 months. Similar trends were observed for PFOA,
84 PFNA, and PFHXS.

85 **Discussion:**

86 Maternal PFAS exposures correlate with cell-specific changes in the infant T-cell compartment,
87 including key CD4+ T-cell subpopulations that play central roles in coordinating well-regulated,
88 protective immunity. Future studies into the role of PFAS-associated T-cell distribution and risk of
89 adverse immune-related health outcomes in children are warranted.

90 Introduction

91 The immune system development begins in the fetus during gestation and continues after birth.
92 Different immune cell types arise from precursors, which can differentiate and develop in a
93 regulated manner.¹⁻³ Environmental exposure to harmful agents such as chemical toxicants or
94 deficits in nutrition during gestation and infancy can dysregulate multiple developmental processes
95 influencing health over a lifetime.⁴⁻⁷ Among these harmful agents, exposure to per- and
96 polyfluoroalkyl substances (PFAS) stands out due to their widespread prevalence and persistence
97 in the environment,⁸ and their well-documented associations with several adverse health
98 outcomes across the lifespan, including impaired reproduction, growth, neurodevelopment and
99 liver, kidney and immune dysfunction.⁹⁻¹⁴ PFAS are a group of synthetic chemicals characterized by
100 interconnected carbon and fluorine (C-F) atom chains.⁸ The strong C-F bond makes PFAS
101 resistant to environmental and physiological breakdown processes and allows them to accumulate
102 and persist in the environment and human tissues.¹⁵ In the U.S., over 97% of the population has
103 detectable concentrations of PFAS in their blood¹⁶, and similar findings have been reported in
104 studies from Spain,¹⁷ Germany,¹⁸ and China.¹⁹ In addition to blood, PFAS have been detected in
105 human lungs, brain, bone, liver, and kidneys.¹⁵ PFAS have also been detected in the placenta, cord
106 blood, and breast milk,²⁰⁻²⁵ which further emphasizes the potential for early life exposures.

107 One consistent observation is an inverse association between PFAS concentrations and antibody
108 responses to vaccinations in adults and children.^{9,10,26-30} It is unclear which immune system
109 components are affected by PFAS to generate a net effect of lower humoral responses. The
110 production of antibodies results from the collaboration between multiple types of immune cells.³¹
111 When the immune system is stimulated by vaccinations or infections, cells from the innate
112 compartment, such as macrophages and neutrophils, trigger inflammatory processes that activate
113 cells of the adaptive immune system (T and B-cells), which can then establish immune memory.
114 Immune memory is the ability of cells to retain antigen-specific information from prior exposures to
115 facilitate a faster and more targeted response upon subsequent encounters. Antibody production
116 by B-cells is influenced by CD4+ T-cells, which consist of different specialized subpopulations
117 tailored to the immune response needed for a specific pathogen or antigen.³² These include Th1,
118 Th2, Th17, T follicular helper cells (Tfh), and T regulatory cells (Treg).³³ Each CD4+ T-cell subset
119 carries a unique set of functions that influence B-cells by modulating the strength, specificity, and
120 durability of their produced antibodies.³⁴ For example, long-lived B-cells rely on Tfh cells for

121 durable antibody production because Tfh cells promote germinal center formation in lymph nodes
122 via IL-21 secretion.³⁵⁻⁴⁰ This interaction leads to B-cell proliferation, somatic hypermutation, and
123 isotype class switching, ultimately resulting in high-affinity antibodies.^{35,37} Other CD4+ T-cell
124 subpopulations modulate antibody class switching by fine-tuning the context of the immune
125 response required.⁴¹⁻⁴⁴ How early life exposures to PFAS affects these cell types is crucial for
126 discovering how PFAS ultimately leads to changes in immune responses. This longitudinal study
127 aims to identify alterations in CD4+ T-cells related to developmental PFAS exposure as a first step
128 in understanding pathways implicated in PFAS-related immune dysfunction.

129 **Methods:**

130 ***Study design***

131 Between December 2015 and April 2019, first-trimester pregnant women were recruited from
132 outpatient clinics affiliated with the University of Rochester and enrolled in the Understanding
133 Pregnancy Signals and Infant Development and Environmental Influences on Child Health
134 Outcomes (UPSIDE-ECHO) study after informed consent. UPSIDE-ECHO is an ongoing prospective
135 birth cohort designed to study prenatal exposures in relation to perinatal and child health
136 outcomes in the Rochester, NY, area⁴⁵ that is part of the NIH ECHO program.⁴⁶ Eligibility criteria
137 included maternal age 18 years or older, singleton pregnancy, no known substance abuse problems
138 or history of psychotic illness, and the ability to communicate in English. Participants with major
139 endocrine disorders (e.g., polycystic ovary syndrome) and high-risk pregnancies at baseline were
140 not enrolled; additionally, infants born prior to 37 weeks of gestation or with congenital anomalies
141 or significant health problems were excluded (n=9). Study visits, including physical exams,
142 biospecimen collection, and questionnaire completion, were completed at each trimester and at
143 birth, 6 and 12 months postnatally. This study protocol was approved by the University of Rochester
144 School of Medicine and Dentistry Institutional Review Board (#58456).

145 ***Maternal and infant blood collection***

146 During the second trimester of pregnancy (21 ± SD:1.8) gestational weeks), maternal serum from
147 blood collected into EDTA tubes was frozen at -80°C until the time of analysis. For infant blood
148 samples, cord blood was collected by venipuncture into sodium heparin tubes immediately after
149 birth. Infant blood was collected into sodium heparin tubes at 6 and 12 months. Peripheral blood
150 mononuclear cells (PBMC) were isolated using a Ficoll-Paque density gradient (GE Healthcare –

151 cytiva) and immediately cryopreserved in freezing media consisting of 10% heat-inactivated Fetal
152 Bovine Serum (FBS)(Seradigm) and 10% DMSO (Amresco) at a cell concentration ranging from one
153 to five million cells per mL.

154 ***PFAS analysis***

155 Maternal serum isolated from the second trimester of pregnancy was sent to Wadsworth Center's
156 Human Health Exposure Analysis Resource (HHEAR) Laboratory Hub for PFAS measurement. PFAS
157 were measured using high-performance liquid chromatography (HPLC) and tandem mass
158 spectrometry (MS/MS) detection and quantification, as described in Honda et al. (2018).⁴⁷ Fourteen
159 PFAS were measured: NETFOSAA, NMFOSAA, PFBS, PFDA, PFDODA, PFHPA, PFHXA, PFHXS,
160 PFNA, PFOA, PFOS, PFOSA, PFPEA, PFUNDA. The limit of detection (LOD) for individual PFAS
161 varied from 0.02 to 0.03 ng/mL. To reduce exposure misclassification, four PFAS with 100%
162 detection rate, namely PFOA, PFOS, PFNA, and PFHXS were included in the present analysis.
163 Several quality control samples namely certificated standard reference materials (NIST SRM 1957
164 and SRM 1958), HHEAR QC pools, procedural blanks and matrix spikes were included in the
165 analysis. The coefficient of variation in concentrations of four PFAS in SRMs, QC pools and matrix
166 spikes between batches was <10%.

167 ***Infant T-cell phenotyping***

168 Thawing, stimulation, and staining of PBMCs for mass cytometry were performed as detailed
169 previously Scheible et al. (2012) and McDavid et al. (2022).^{48,49} To control for batch effect and
170 variability, all timepoints (birth, 6, and 12 months) from individual infant subjects were phenotyped
171 in experimental batches that included 20 individual samples maximum. Each experimental batch
172 also included one to two healthy adult PBMC controls that were carried across multiple batches.
173 Cryopreserved sample vials were thawed at 37°C in a water bath and washed twice with 10mL of
174 RPMI 1640 (Corning) supplemented with L-glutamine, 10% heat-inactivated Fetal Bovine Serum
175 (FBS) (R10), and 25U/uL Universal Nuclease (R10+n). Cord blood samples (CBMC) were treated
176 with 3 mL 1x BD Pharm Lyse (BD Biosciences) supplemented with 25U/uL Universal Nuclease for 15
177 minutes to lyse red blood cells. Washed cells were rested overnight at 37°C in a 5% CO₂ incubator.
178 After overnight rest, samples were counted on a dual-fluorescence cell counter (Cellometer K2;
179 Nexcelom/Revvity); samples less than 70% viable were excluded from the assay (5.9% of samples
180 at birth, 14.6% at 6 months and 12.7% at 12 months). Cells were resuspended in R10 at a

181 concentration of 30 million-cells/mL, and 3 million cells were stimulated for 2 hours with 2ug/mL of
182 *Staphylococcus aureus*, Enterotoxin Type B (SEB). GolgiPlug (BD Biosciences) and monensin
183 (Sigma; 10 mM stock in EtOH) were added at 2 hours and further stimulated for 8 hours at 37°C.
184 Stimulated cells were washed with stain buffer (PBS + 2%FBS + 25U/uL Universal Nuclease) (SBn)
185 and stained for 30 minutes at room temperature (RT) with unique combinations of metal-
186 conjugated anti-human CD45 antibodies (Supplemental Table 1: Parameter Type, Barcodes) in a ‘6-
187 choose-3’ or ‘7-choose-3’ live-cell barcoding scheme.^{50–52} Barcoded samples were washed,
188 resuspended in SBn, and then transferred into a single 15mL culture tube. The pooled sample was
189 filtered, centrifuged, and stained for 30 minutes at RT with a cocktail of metal-conjugated anti-
190 human antibodies for surface molecules (Supplemental Table 1: Parameter Type, Surface). Next,
191 cells were washed with SBn then stained with Cell-ID Cisplatin-194Pt (Fluidigm/Standard BioTools)
192 at 500nM/mL concentration for 5 minutes at RT. Cells were washed with SBn and
193 fixed/permeabilized for 30 minutes at RT with Foxp3 Fixation-Permeabilization buffer (eBioscience)
194 followed by a wash with Permeabilization Buffer (Perm-B) (eBioscience). Cells were intracellularly
195 stained for 30 minutes at RT with Perm-B containing a cocktail of metal-conjugated anti-human
196 antibodies (Supplemental Table 1: Parameter Type, Intracellular). Cells were washed, then fixed
197 with 1 mL of 1.6% formaldehyde (Pierce) in PBS containing 500 nM of Cell-ID Intercalator-103Rh
198 (Fluidigm/Standard BioTools) and incubated overnight at 4°C. Fixed cells were washed with PBS,
199 counted, and resuspended at a concentration of 13.75 million-cells/mL in filtered FBS with 10%
200 DMSO (Amresco). Cells were aliquoted in Protein Lo-Bind tubes (Eppendorf) (2.75 million cells in
201 200ul) and stored at -80°C. Following aliquoting and freezing, individual aliquots were prepared for
202 acquisition on a CyTOF 2 or Helios mass cytometer (Fluidigm/Standard BioTools) by washing twice
203 with 2 mL ultrapure water and resuspending in 3 mL ultrapure water containing 0.1x EQ Four
204 Element Calibration Beads (Fluidigm/Standard BioTools). Aliquots were acquired using a Super
205 Sampler (Victorian Airships).

206 *Mass cytometry clustering pipeline*

207 After the acquisition, source data was normalized using the Normalization Passport in CyTOF
208 Software with default settings (Fluidigm, 7.0.5189). Normalized data was analyzed using a custom
209 R-based workflow (github.com/nlaniewski/SOMnambulate). Briefly, unique live-cell barcoded pools
210 were debarcoded to generate sample-specific .fcs files. FlowSOM⁵³ was used to generate clusters
211 representing major PBMC immune cell populations (Supplemental Table 1: FlowSOM dimension,

212 PBMC). Based on per-cluster feature expression, annotations were defined. Selecting for only
213 CD3+, CD4+, and CD8+ clusters representing T-cells, a second FlowSOM was generated using an
214 expanded set of both surface and intracellular markers to define T-cell-specific sub-clustering
215 results (Supplemental Table 1: FlowSOM dimension, T-cells). As with the PBMC clusters, per-
216 cluster feature expressions were examined to define functional annotations. To aid in the
217 interpretation of FlowSOM clusters, the nodes that comprise the self-organizing map (SOM) were
218 visualized using Uniform Manifold Approximation and Projection (UMAP).⁵⁴ Default parameters
219 were used to embed the nodes into two dimensions, using the same markers as those used to
220 generate the respective SOM. Nodes (circles) were individually sized to represent the mean
221 proportion of assigned cells and colored by their assigned cluster annotation. For each FlowSOM
222 result (PBMC; T-cell), all cells were mapped on a per-sample basis, and the proportion of cells
223 attributed to each cluster was calculated. The proportions used in subsequent visualizations and
224 statistical models represent the percent of CD4+ T cells.

225 ***Measurement of covariates and selection of potential confounding variables.***

226 After study enrollment in the first trimester, trained staff administered a questionnaire to obtain
227 information on lifestyle, living environment, past pregnancies, medical conditions, medications
228 used before, during, and after pregnancy, and sociodemographic information. Sociodemographic
229 information, including self-reported maternal race and ethnicity, was collected at baseline,
230 recognizing that these social constructs are associated with environmental exposures and
231 maternal and child health outcomes.^{55,56} Infant birth weight and sex at birth were obtained from
232 electronic health records. Confounding variables were selected using a directed acyclic graph
233 (DAG) informed by previous reports demonstrating an association with PFAS and T-cells
234 (Supplemental Figure 1).^{10,57} These were the categorical variables parity, infant sex, mode of
235 delivery, maternal race, maternal education, and Medicaid during pregnancy, and the continuous
236 variables maternal age, pre-pregnancy body mass index (BMI), annual income, and infant birth
237 weight. The minimally sufficient set of variables from the DAG were categorical parity (0, 1, or 2+),
238 infant sex at birth, and continuous pre-pregnancy BMI.

239 ***Statistical analysis***

240 Descriptive characteristics for the entire sample are presented in Table 1. Specifically, frequencies
241 and percentages for categorical variables, as well as means with standard deviations for

242 continuous variables are reported in this table. Wilcoxon rank-sum test was used for comparing
243 mean differences between two groups for a continuous variable, Wilcoxon signed-rank test was
244 used to assess mean differences between two time points. The association between two
245 continuous variables was evaluated using Spearman's rank correlation test.

246 Owing to the longitudinal assessment of T-cell outcomes at multiple visits, two separate but
247 related Linear Mixed-Effect regression (LMER) modeling strategies were employed to associate T-
248 cell outcomes with individual PFAS concentrations, infant age, and their interactions. In both
249 models, infant age is considered as a categorical variable with three levels (birth, 6 and 12 months),
250 of which birth is considered as the baseline. In the first set of LMER models, a log-transformation
251 designed to reduce the skewness is applied to the PFAS concentration levels: $x_{ij} =$
252 $\log_2(\text{Conc}_{ij} + 1)$, where Conc_{ij} represents the original PFAS concentration level for the i th subject
253 at the j th visit. In the second set of LMER models, PFAS concentration levels were dichotomized as
254 “above median” or “below median”, permitting the estimation of differences in T-cell outcomes
255 over time as discrete categories according to the categorical interactions between infant age and
256 binary PFAS concentration levels. We call the second set of models as differences-over-time
257 models.

258 For both approaches, a model is called a *crude model* if it only includes a PFAS level, infant age,
259 and their interactions. It is called an *adjusted model*, if it also includes the following additional fixed
260 effects: parity (0, 1, or 2+), infant sex, and pre-pregnancy BMI (continuous). A subject-specific
261 random intercept was included in all models to account for serial correlation in the repeated T-cell
262 measures. Unknown parameters in these models were estimated by the Restricted maximum
263 likelihood (REML) criterion. Regression t-test implemented in R package *lmerTest*⁵⁸ was used to
264 assess the statistical significance of a fixed effect of interest; *F*-tests as implemented in function
265 *linearHypothesis()* in R package *car*⁵⁹ was used to test specific linear contrasts between infant
266 ages. Results for the difference-over-time models were presented as differences in marginal mean
267 percent with corresponding 95% confidence intervals, and pairwise comparisons were performed
268 to contrast mean percentages between below and above median PFAS. Model assumptions,
269 including normality, linearity, and homoscedasticity of the residuals, were visually evaluated by
270 inspection of diagnostic plots. A p-value of less than 0.05 was considered statistically significant
271 for individual hypothesis tests. For analyses involving multiple hypotheses, the Benjamini–

272 Hochberg procedure was employed to control the false discovery rate (FDR) at a level of 0.05. All
273 statistical analyses were conducted using R Foundation for Statistical Computing version 4.3.3.⁶⁰

274 **Results:**

275 ***Study Population***

276 The analysis included 200 full-term infants (Supplemental Figure 2). Participants were selected
277 from the larger UPSIDE-ECHO cohort if they had second-trimester maternal PFAS measured and
278 infant T-cell phenotyping from at least one timepoint (birth, 6, or 12 months of age). Cohort
279 characteristics are shown in Table 1. In summary, 71% of participants were between 26-35 years
280 old at enrollment; 62.5% of the cohort self-identified as White, 20% as Asian, 8% as Black, 9% as
281 Hispanic, and 10% as other. 52% reported having at least a bachelor's degree, and 43% were
282 enrolled in Medicaid during pregnancy. Parity was categorized based on pregnancies preceding the
283 current pregnancy (34.5% nulliparous, 39% primiparous, or 26.5% multiparous). The mean
284 gestational age at birth was $39.74 \pm \text{SD}:1.11$ weeks, 76.5% of infants were born vaginally, and 52.5%
285 were assigned male sex at birth. Among the 200 mother-infant pairs who contributed at least one
286 observation to the current study, compared to birth, those with 6- or 12-month data tended to be
287 older at the time of the child's birth, higher income and education, and more likely to report White
288 race (Supplemental Table 2).

289 ***PFAS exposure***

290 Table 2 shows the mean concentration and distribution of four PFAS (PFOS, PFOA, PFNA, and
291 PFHXS) that were detected in 100% of the second-trimester maternal serum samples and,
292 therefore, included in subsequent analysis. The concentrations and distribution of the ten
293 additional PFAS measured are in Supplemental Table 3. PFOS was present at the highest mean
294 concentration (2.87 ± 2.13 ng/mL), followed by PFHXS (1.96 ± 0.92 ng/mL), PFOA (0.68 ± 0.51 ng/mL),
295 and the lowest concentration being PFNA (0.33 ± 0.36 ng/mL). Relative to the NHANES general
296 population concentrations, PFOS, PFOA, and PFNA mean concentrations were lower.⁶¹ PFOA and
297 PFNA were the most strongly correlated ($\text{Rho}=0.64$, $p\text{-value}=0.0001$), followed by PFOS and PFNA
298 ($\text{Rho}=0.58$, $p\text{-value}=0.0002$) and PFOS and PFOA ($\text{Rho}=0.53$, $p\text{-value}=0.0005$). PFHXS showed
299 a moderate correlation with PFOS ($\text{Rho}=0.38$, $p\text{-value}=0.021$) and PFOA ($\text{Rho}=0.30$, $p\text{-value}$
300 $=0.049$); PFNA and PFHXS were the most weakly correlated ($\text{Rho}=0.23$, $p\text{-value}=0.113$).

301 Determinants of exposure for the UPSIDE-ECHO population can be found in Supplemental Table 4.
302 Overall, the concentrations of all PFAS were lower, with higher maternal parity. Maternal PFAS
303 concentrations in serum were lower when the fetal sex was female. Generally, mean PFAS
304 concentrations were higher in white mothers and mothers with higher income and education, and
305 mean PFAS concentrations were lower in older mothers and mothers with higher pre-pregnancy
306 BMI. Participants with Medicaid during pregnancy had lower concentrations of PFAS.

307 ***Infant T-cell clustering and phenotyping***

308 A 36-marker mass cytometry panel (Supplemental Table 1) was used to deeply immunophenotype
309 infant immune cell populations over the first year of life. FlowSOM clustering algorithm was used to
310 identify and group immune populations (Figure 1A). PBMC populations were identified as follows:
311 $\gamma\delta$ T-cells were identified as CD3+ TCR $\gamma\delta$ + cells, cytotoxic T-cells as CD3+ CD8+, helper T-cells as
312 CD3+ CD4+, B-cells as CD19+, NK cells as CD56+, and monocytes as CD14+ cells. UMAP
313 visualization of infant leukocytes revealed separation between the major immune populations,
314 including T-cells, B-cells, NK cells, and monocytes (Figure 1B).

315 To test our specific hypothesis regarding the role of PFAS in T-cell development, we narrowed
316 analyses to CD4+ T-cells. CD4+ T-cells from the first level of clustering (i.e., PBMC) were then
317 selected for a second level of FlowSOM clustering using an expanded set of phenotypic and
318 functional markers to identify unique CD4+ T-cell sub-clusters. This sub-clustering analysis
319 identified 29 unique CD4+ T-cell sub-clusters (Supplemental Figure 3A-B). During the first year of
320 life, naïve (CD45RA+) comprised most of the CD4+ T-cell compartment, while T-cells carrying
321 markers of immunological memory (CD45RO+, CD45RA-) were a small fraction at birth and
322 increased over time (Figure 1C-D). Within the memory (CD45RO+) compartment, canonical CD4+
323 T-cell subpopulations Th1 (IFN γ +), Th2 (IL-4+), Th17 (IL-17A+), Tregs (FOXP3+ CD127-) and Tfh cells
324 (IL-21+) were identified based on the expression of surface and intracellular markers that
325 distinguish functional properties of these subpopulations (Figure 1E, Supplemental Figure 3B-C).
326 The percentages of these CD4+ T-cell subpopulations increased over time (Figure 1F, Supplemental
327 Table 5).

328 ***Maternal PFAS exposure associates with infant CD4+ T-cell frequencies in an age-dependent***
329 ***manner***

330 Figure 2 shows the age-specific adjusted association for PFOS, PFOA, PFNA, and PFHXS and each
331 CD4+ T-cell. The unadjusted and adjusted age-specific estimates for this model can be found in
332 Supplemental Table 6. Overall, the associations between PFAS and CD4+ T-cells were stronger at 6-
333 and 12-months of age versus birth; with statistical evidence of effect measure modification by age
334 for Tfh, Th2, and Th1 cells, but not for Tregs or Th17 cells (Supplemental Table 7 and Supplemental
335 Table 8). These associations were consistent for crude and adjusted models.

336 Tfh cells were inversely associated with maternal PFAS; each doubling of PFOS was associated with
337 a 0.17 (95%CI of β : -0.30, -0.04) lower Tfh percentage measured at 12 months of age, a 0.05 (95%CI
338 of β : -0.16, 0.06) lower Tfh percentage at 6 months, and a 0.08 (95%CI of β : -0.01, 0.16) greater Tfh
339 percentage at birth (p-value for age interaction=0.002). Similar trends were observed between Tfh
340 percentages and PFOA, PFNA and PFHXS (Figure 2A).

341 In contrast, Th2, Th1, and Treg cells were positively associated with maternal PFAS exposure. For
342 Th2 cells, each doubling of PFOA was associated with a 0.30 (95%CI of β : 0.18, 0.41) greater Th2
343 percentage measured at 12 months of age, a 0.25 (95%CI of β : 0.12, 0.38) greater Th2 percentage at
344 6 months, and a 0.05 (95%CI of β : -0.04, 0.14) greater Th2 percentage at birth (p-value for age
345 interaction = 0.000). Similar trends were observed between Th2 percentages and PFOS, PFNA, and
346 PFHXS (Figure 2B). For Th1 cells, each doubling of PFNA was associated with a 0.11 (95%CI of β :
347 0.02, 0.20) greater Th1 percentage measured at 12 months of age and no association at 6 months of
348 age or birth (p-value for age interaction = 0.054). Similar trends were observed between Th1
349 percentages and PFOS, PFOA, and PFHXS (Figure 2C).

350 For Tregs, each doubling of PFHXS was associated with a 0.11 (95%CI of β : 0.01, 0.22) greater Treg
351 percentage measured at 12 months of age, a 0.06 (95%CI of β : -0.02, 0.15) greater Treg percentage
352 at 6 months, and no association at birth (p-value for age interaction = 0.129). Similar trends were
353 observed between Treg percentages and PFOS, PFOA, and PFNA (Figure 2D). No associations were
354 observed between Th17 percentages and the doubling of PFOS, PFOA, PFNA, and PFHXS (Figure
355 2E).

356 ***Maternal PFAS exposure predicts CD4+ T-cell trajectories in infants.***

357 Overall, independently of PFAS exposure group, the trajectory of each CD4+ T-cell subset showed
358 increasing levels over time (Figure 3). Further, PFAS-dependent effects were more pronounced at
359 later ages, especially 12 months of age. This was the case for Tfh, Th2, Th1, and Treg cells, but not

360 for Th17 cells. Unadjusted and adjusted age-specific marginal means and pairwise comparisons
361 for below and above median PFAS can be found in Supplemental Tables 9 and 10, respectively. For
362 Tfh cells and PFOS exposure, the adjusted negative association was strongest at 12 months of age,
363 with a mean value for above median PFOS of $0.86 \pm \text{SD: } 0.05$ (95%CI:0.76, 0.96) versus a mean
364 value for below median PFOS of $1.13 \pm \text{SD: } 0.06$ (95%CI:1.02, 1.24) (p-value for difference=0.002);
365 similar trends were observed for PFOA and PFNA, and no differences were observed for PFHXS
366 (Figure 3A). For Th2 cells and PFOA exposure, the adjusted positive association was present at 6
367 months but stronger at 12 months of age. At 12 months we observed a mean value for Th2 cells for
368 above median PFOA of $0.44 \pm \text{SD: } 0.03$ (95%CI:0.37, 0.50) versus a mean value for below median
369 PFOA of $0.32 \pm \text{SD: } 0.04$ (95%CI: 0.25, 0.39) (p-value for difference = 0.002); similar trends were
370 observed for PFOS, PFNA, and PFHXS (Figure 3B). For Th1 cells and PFNA exposure, the adjusted
371 positive association was observed at 12 months of age, with a mean value for above the median
372 PFNA of $0.37 \pm \text{SD: } 0.02$ (95%CI: 0.32, 0.41) versus a mean value for below median PFNA of $0.30 \pm$
373 $\text{SD: } 0.02$ (95%CI: 0.25, 0.34) (p-value for difference = 0.019); similar trends were observed for PFOS,
374 PFOA, and PFHXS (Figure 3C). For Treg cells and PFHXS exposure, the adjusted positive association
375 was present at 6 months but stronger at 12 months of age; at 12 months we observed a Treg mean
376 value for above the median PFHXS of $0.45 \pm \text{SD: } 0.03$ (95%CI: 0.40, 0.50) versus a mean value for
377 below the median PFHXS of $0.32 \pm \text{SD: } 0.03$ (95%CI: 0.26, 0.38) (p-value for difference = 0.002);
378 similar trends for 12 months but not 6 months were observed for PFOS, PFOA, and PFNA (Figure
379 3D). No differences between the mean value of Th17 cells for above versus below median PFOS,
380 PFOA, PFNA, and PFHXS were observed (Figure 3E).

381 **Discussion**

382 In this prospective cohort study, we investigated the association between maternal PFAS exposure
383 CD4+ T-cell subpopulations in infants over the first year of life. The potential of PFAS to affect the
384 immune system has been widely reported in population studies across the world, with consistently
385 observed reductions in antibody responses to common childhood vaccinations.^{9,12} Yet, the specific
386 immune cell components altered by PFAS exposure remain unknown. We found that increased
387 concentrations of maternal PFAS were associated with a reduction in the percentage of Tfh cells,
388 increased Th2, Th1, and Treg populations, and no differences in Th17 cells. Moreover, each
389 association was stronger from birth to 12 months of age. These findings indicate that the potential
390 effects of prenatal PFAS exposure may become more pronounced as the infant grows older. This

391 could be attributed to ongoing T-cell development in the first year of life, and that certain T-cell
392 subpopulations may not emerge until the infant is exposed to specific stimuli. As time passes and
393 T-cell subpopulations continue to develop, the impact of PFAS exposure on the cells becomes
394 more apparent.

395 The immune system protects against pathogens through a coordinated network of cells, tissues,
396 and organs. CD4+ T-cells orchestrate the immune response, making it specific to the type of stimuli
397 received and aiding in the generation and maintenance of immune memory. Particularly, Tfh cells
398 help direct B-cells to produce long-lasting, high-affinity antibodies essential for immune memory.³⁵
399 This study revealed a negative association between the percentage of Tfh cells and maternal PFAS
400 exposure during pregnancy. A reduction in Tfh cells in infants is consistent with the observed
401 reductions in antibodies to childhood vaccinations.^{27,28,62-66} This provides potential mechanistic
402 insights into this observation because Tfh cells are essential for mature and durable antibody
403 responses.^{35,39,40,67}

404 Given the complexity of antibody responses, it is unlikely Tfh cells are the only immune cell type
405 altered by PFAS exposure. For example, we also observed that Tregs were enhanced with increased
406 maternal PFAS concentrations. Tregs are recognized for their immunosuppressive functions and
407 their capacity to inhibit the activation and proliferation of effector T-cells.^{68,69} Studies have
408 demonstrated that Tregs can reduce immune responses to vaccinations by suppressing effector
409 responses.^{70,71} An increase in Treg cells could suppress T-cell or B-cell responses, thereby
410 attenuating antibody production. More generally, an enrichment in Treg cells could support an
411 immunosuppressed environment, dampening the overall ability to fight infections. Therefore, an
412 increased proportion or function of Tregs could also contribute to reduced antibody titers that have
413 been observed in association with PFAS exposure.

414 In addition to Tfh and Tregs, our study found a positive association between the percent of Th1 and
415 Th2 cells with maternal PFAS concentrations. While Th1 and Th2 cells play important defense roles
416 during infections, excessive Th1 and Th2 activity can be involved in the immunopathogenesis of
417 several chronic health conditions, including allergy and autoimmunity.⁷²⁻⁷⁷ Th1 cells are among the
418 predominant T-cell subpopulations in systemic autoimmune disorders, such as rheumatoid
419 arthritis⁷⁸, as well as organ-specific autoimmunity, such as Type 1 diabetes mellitus⁷⁹, and other
420 debilitating inflammatory disorders such as Crohn's disease.⁸⁰

421 On the other hand, Th2 cells have been associated with the development of atopic and allergic
422 diseases such as atopic dermatitis, eczema, chronic rhinosinusitis, and asthma.^{77,81,82} While
423 studies have associated PFAS exposure with allergic or autoimmune outcomes in children, the
424 findings are inconsistent, with some showing no association.⁸³⁻⁹⁴ Several studies examining the
425 association between PFAS exposure and allergic outcomes in infants have measured IgE levels in
426 umbilical cord serum. For instance, Okada et al. in 2012⁸⁷ reported lower umbilical cord IgE levels
427 at birth associated with higher maternal PFOA, whereas Wang et al. in 2011⁸⁸ found increased IgE
428 levels in cord blood associated with prenatal PFOA and PFOS. IgE plays an important role in the
429 allergic response; however, baseline total IgE levels may not reliably predict allergic outcomes,
430 particularly because they are not specific to a particular allergen. Additionally, a study by Oulhole
431 et al. 2017⁹⁵ found a positive association between PFAS concentrations and basophil counts in 5-
432 year-old infants; while their study did not investigate allergic outcomes, it is well established that
433 basophils play a crucial role in initiating Th2-mediated immunity.⁹⁶ Thus, an enhancement in Th2
434 responses operates in concert with these innate immune cells, which could lead to the
435 development of adverse allergic outcomes. Type 2 cytokines such as IL-4, IL-5, and IL-13 have been
436 associated with asthma development, and Th2 cells are the primary source of these
437 cytokines.^{75,81,82} Similar to allergic outcomes, evidence for the association between PFAS exposure
438 and asthma has been mixed. Studies reporting negative associations between exposure to PFAS,
439 and the risk of asthma were mainly conducted in children under the age of 10,^{91,97} while those
440 reporting a positive association were conducted in adolescents.^{92,94,98} This emphasizes the
441 importance of considering age and longitudinal analysis when studying immune-related outcomes
442 in children.

443 Our findings reveal a 0.30 (95% CI: 0.18, 0.41) greater Th2 percentage associated with PFOA at 12
444 months. While the changes observed in the age-specific percentages of CD4+ T-cells in this study
445 may appear small, these variation sizes have had health implications in previous studies. For
446 instance, an estimated 1.5-2 fold increase in Th2 cells has been noted among infant patients with
447 atopic dermatitis or bronchial asthma compared to healthy controls.^{99,100} Using the mean Th2
448 percentage of 0.38% (\pm SD: 0.38) as a reference in our infants (Figure 1F, Supplemental Table 5), an
449 increase of 0.30 indicates an overall 79% increase in Th2 cells. Further, numerous studies have
450 shown that minor changes in the frequency of circulating T follicular helper (cTfh) cells correlate
451 with antigen-specific antibody levels in humans^{39,101-103}, at ranges similar to the 18% reduction in
452 Tfh cells we observed. Individuals with higher frequencies of cTfh cells typically exhibit more robust

453 antibody responses; this relationship has been observed in vaccine responses to hepatitis B¹⁰³,
454 yellow fever virus¹⁰², and influenza¹⁰¹, as well as among children infected with malaria³⁹.

455 Our findings provide strong evidence that maternal PFAS exposure affects the infant's immune
456 system. Differences in CD4+ T cell subpopulations as a function of maternal PFAS exposure
457 support the idea that PFAS are immunotoxic in human infants. As with all research studies using
458 human populations, this study has several strengths, as well as some limitations. One major
459 strength is that this is a longitudinal study with deep immunophenotyping, high-dimensional
460 analysis, and identification of infant CD4+ T-cell subpopulations. Additionally, since only healthy
461 pregnancies and full-term healthy infants were enrolled in the study, we partly removed the
462 potential for congenital-disease-related changes in CD4+ T-cell subpopulations that could
463 influence immunological outcomes. However, this study is not without limitations. The study
464 sample was relatively small (n=200) compared to larger cohort studies.^{26,27} However, even these
465 larger cohort studies that showed negative associations between PFAS and antibody titers did not
466 include in-depth immunophenotyping. These previous studies, therefore, leave a gap in our
467 understanding of the cells responsible for coordinating the antibody response. Moreover, although
468 it is well established that PFAS can cross the placenta^{20,104} and can be detected in the fetus²¹, in the
469 current study, PFAS were only measured during the second trimester of pregnancy and not directly
470 in the infants. Although this is a limitation, this exposure window is a crucial period for potential T-
471 cell programming and development.^{2,105} Human T-cell development begins around the 8th week of
472 pregnancy and continues after birth during infancy; exposures during T-cell development can
473 significantly affect the immune profile of the offspring.¹⁰⁶ For example, human cohort studies have
474 linked maternal exposure to pollutants and decreased T-cell-dependent immune defenses in
475 infants and children.^{28,107,108} Further evidence that developmental exposures shape T-cell function
476 is provided by experimental studies, which provide strong evidence that in-utero exposure can
477 significantly and durably alter T-cell function later in life.¹⁰⁹

478 Participants in the study had lower mean serum concentrations of PFOS, PFOA, and PFNA but
479 higher PFHXS compared to the general population levels reported by NHANES (2017-2018).⁶¹ The
480 current study provides insights for ongoing risk assessment of PFAS exposures since the legacy
481 PFAS levels are declining over time⁶¹ and our study suggests immunotoxic impacts in early life, even
482 at these lower levels.

483 Our results indicate stronger associations between maternal PFAS exposure and CD4+ T-cell
484 subpopulations later during infancy compared to birth. This is likely due to the fact that T-cells are
485 still developing at birth, and infants have not been exposed to the stimuli needed to activate and
486 differentiate T-cell subpopulations. Ongoing PFAS exposure after birth is a key factor to consider.
487 Recently, PFAS has been detected in human breast milk^{22,23} and could represent a continuous
488 source of maternally derived PFAS exposure in the early postnatal life. Rigorous studies to quantify
489 the variation of PFAS in breast milk and formula or other postnatal exposures and immune
490 development are warranted.

491 In conclusion, we report here an association between in utero exposure to PFAS and decreased
492 percent of Tfh cells and increased percent of Th1, Th2, and Treg cells during the first year of life.
493 These observations support that there are immunomodulatory effects of developmental PFAS
494 exposure. These findings contribute to our understanding of potential mechanisms by which PFAS
495 exposure lowers antibody titers in infants. Moreover, given that imbalances in T-cell subpopulations
496 are associated with other diseases, in-depth profiling of infant T-cells suggests that in utero PFAS
497 exposure may predispose to future immunopathogenesis.

853 **Table 2:** Distribution of perfluoroalkyl substances (PFAS) in maternal plasma (ng/mL).

PFAS	Mean	SD	Min	1 st Q	Median	3 rd Q	Max
PFOS	2.87	2.13	0.61	1.83	2.51	3.22	21.30
PFOA	0.68	0.51	0.06	0.40	0.59	0.83	5.45
PFNA	0.33	0.36	0.06	0.17	0.24	0.35	2.87
PFHXS	1.96	0.92	0.56	1.38	1.75	2.42	7.17

854 PFOS: perfluorooctanesulfonic acid, PFOA: perfluorooctanoic acid, PFHxS: perfluorohexane
855 sulfonic acid, PFNA: perfluorononanoic acid, PFDA: perfluorodecanoic acid, SD: Standard
856 Deviation, Min: minimum, Max: Maximum, LOD: limit of detection, Q: quantile.

874 **Main Text Figure Captions**

875 **Figure 1:** *Identification of CD4+ T-cell subpopulations in infants and their age-associated*
876 *frequencies.*

877 (A) Study design and T-cell analysis pipeline. (B) Uniform Manifold Approximation and Projection
878 (UMAP) representation of FlowSOM nodes colored by major peripheral blood mononuclear
879 cells (PBMC): CD4+, CD8+, CD14+, CD19+, CD56+, TCR $\gamma\delta$; (C) Stacked bar graph denoting the
880 proportion of CD45RA+ and CD45RO+ CD4+ T-cell subpopulations at birth, 6 and 12 months of age.
881 (D-E) UMAP representation of FlowSOM nodes colored by expression of (D) CD45 isoform type
882 (CD45RA+ or CD45RO+) within CD4+ T-cell FlowSOM nodes, and (E) CD4+ T-cell sub-cluster
883 annotations based on the following marker expression: Treg (FOXP3+CD127-), Th1(IFN γ +), Th17 (IL-
884 17A+), Tfh (IL-21+), Th2 (IL-4+), Naïve-cytokine-negative (TN). Circle size on UMAPs represents the
885 relative mean count of total cells assigned to each FlowSOM node. (F) Frequency of CD4+ T-cells in
886 cord blood at birth and PBMC at six and twelve months. Each dot on the boxplots denotes data
887 from an individual infant at the indicated age; scales for boxplots are fixed.

888

889 **Figure 2:** *Maternal PFAS exposure associates with infant CD4+ T-cell frequencies in an age-*
890 *dependent manner.*

891 The plots illustrate the regression lines for the age-specific average marginal effects of the
892 association between continuous maternal PFAS (ng/mL) exposure and infant CD4+ T-cell
893 percentage. Rows represent individual CD4+ T-cells: (A) T follicular helper cells, (B) T helper 2 cells,
894 (C) T helper 1 cells, (D) T regulatory cells, and (E) T helper 17 cells. Columns represent individual
895 PFAS; PFOS, PFOA, PFNA, and PFHXS were log₂ transformed. The colors represent the infant age:
896 birth (grey), 6 months (orange), and 12 months (blue). Each dot represents an individual infant at
897 the indicated age. Age-specific average marginal effects (β) were adjusted for the categorical
898 covariates parity, infant sex, and continuous pre-pregnancy body mass index. Parenthesis next to
899 each age-specific β contains the 95% confidence interval for the estimate. Pairwise comparisons
900 between the age-specific β s are represented by the brackets. Asterisks denote statistically
901 significant (p -value < 0.05), and 'ns' indicates non-statistically significant differences between age-
902 specific β s. Axis are independent for each CD4+ T-cell subpopulation and each PFAS.

903 Supplemental Tables 6, 7, and 8 contain corresponding numeric data.

904

905 **Figure 3:** *Maternal PFAS exposure predicts CD4+ T-cell trajectories in infants.*

906 The plots illustrate differences-over-time between infant CD4+ T-cell subpopulations by a
907 categorical PFAS value (below versus above median value). Rows represent individual CD4+ T-cells:
908 (A) T follicular helper cells, (B) T helper 2 cells, (C) T helper 1 cells, (D) T regulatory cells, and (E) T
909 helper 17 cells. Columns represent individual PFAS (PFOS, PFOA, PFNA, and PFHXS). The colors
910 represent the categorical PFAS value: below the median (pink) and above the median (blue). Dots
911 denote the predicted marginal mean of each CD4+ T-cell subpopulation at the indicated age.
912 Marginal means were adjusted for the categorical covariates parity, infant sex, and continuous pre-
913 pregnancy body mass index. Error bars represent the standard error of the marginal means. P-
914 values denote the statistical significance between marginal means contrasting below vs. above the
915 median PFAS; the contrast was considered statistically significant if the p-value < 0.05. The y-axis is
916 independent for each CD4+ T-cell subpopulation. Supplemental Tables 9, 10, and 11 contain
917 corresponding numeric data.
