

Nurses' Fall Risk Judgements - Cognitive Biases and Contextual Factors

Explaining Variability: A multi-centre cross-sectional study

Abstract

Background: Assessing fall risk is a complex process requiring the integration of diverse information and cognitive strategies. Despite this complexity, few studies have explored how nurses make these judgements. Moreover, existing research suggests variability in nurses' fall risk assessments, but the reasons for this variation and its appropriateness remain unclear.

Objective: This study aimed to investigate how nurses judge fall risk, and the factors associated with their judgements.

Methods: Using purposive sampling, 335 nurses from six hospitals in western Japan participated in an online survey. The participants rated the likelihood of falls in 18 patient scenarios and completed measures of base-rate neglect, belief bias, and availability bias. A linear mixed-effects regression tree was used to identify factors related to their judgements, and a linear mixed-effects regression model examined associations between judgement variability, cognitive biases, and clinical specialty.

Results: Nurses' fall risk assessments were primarily influenced by whether patients called for assistance, followed by the use of sleeping pills, the presence of a tube or drain, and patient mobility status. Judgement variability was linked to nurses' gender, education, clinical specialty, and susceptibility to availability bias.

Conclusion: Variability in clinical judgement may be justified when reflecting personalised, context-specific care. However, inconsistencies arising from cognitive biases are problematic. Healthcare organisations should offer targeted training to enhance contextual expertise and reduce the influence of cognitive biases on fall risk assessments.

Keywords: Nurses, Falls, Risks, Judgement, Cognitive bias, Clinical specialty, Regression tree

Introduction

A patient fall is a major adverse event in healthcare settings. Falls are defined as “inadvertently coming to rest on the ground, floor, or other lower level, excluding intentional changes in position” (World Health Organization, 2007). Each year, a significant number of patients experience falls; for instance, an estimated 700,000 to 1,000,000 falls occur in U.S. hospitals (Agency for Healthcare Research and Quality, 2013), and in Japan, the rate is 2.76 per 1,000 patients (Japan Hospital Association, 2023). Recent studies indicate that 55-60% of patients are at risk of falling (Wu et al., 2019, Yasan et al., 2020), a figure likely to rise as the population ages. Falls can result in severe harm, including death (Takase, 2023), highlighting the importance of addressing this issue. To prevent falls, nurses must assess patients and environmental cues, judge fall risk, and implement appropriate preventive measures (Tanner, 2006).

Nurses’ clinical judgement is crucial in this process, as they are the primary healthcare providers responsible for fall prevention. Clinical judgement involves a reflective and reasoning process, drawing on available data and an extensive knowledge base (Connor et al., 2023). This judgement is a complex cognitive task. Previous studies show that nurses assess fall risk using criteria developed through clinical experience, often relying on cognitive strategies such as adding, subtracting, and weighing various risk factors based on patient characteristics (Takase et al., 2024). Nurses also use fall risk assessment tools, though these have limitations, including variations in criteria and poor predictive validity (Alvarado et al., 2023, Vlaeyen et al., 2021). Assessing fall risk is a complex procedure that requires synthesising information on patient conditions, treatment regimens, and the clinical environment. Despite this complexity, few studies have explored how nurses make these judgements. Moreover, previous research indicates that nurses’ judgements of fall risk can vary (Takase et al., 2024), but it is unclear why this variation occurs or whether it is justified. Such discrepancies can lead to inconsistent care, and if these variations are due to cognitive biases, they may compromise patient safety. Therefore, understanding how nurses make these judgements and identifying the factors that influence them are critical for improving patient care and safety.

Background

Nurses' judgement of risk of falling

The literature identifies various risk factors for falls, which are generally classified into intrinsic (patient-related) and extrinsic (environment-related) categories. Intrinsic factors include sex and age (Wabe et al., 2024), unstable gait and balance (Deandrea et al., 2010, Shao et al., 2023), decline in activities of daily living (Shao et al., 2023), elimination issues such as urgency, frequency of voiding, nocturia, and incontinence (Moon et al., 2021, Noguchi et al., 2016), impaired cognition (Fhon et al., 2023), the use of hypnotics and sedatives (Shao et al., 2023), frailty (Xu et al., 2022), and a tendency to perform tasks independently (Sato et al., 2022). Extrinsic factors include unsafe footwear (Kobayashi et al., 2017), the presence of tubes and drains (Nakanishi et al., 2021), and wet or slippery floors (Lee et al., 2022).

Nurses must make complex judgements based on available information. For example, they need to evaluate a patient's fall risk by weighing each risk factor, determining the relative importance of factors when multiple risks are present, and considering how these risks interact when combined. Previous studies have explored the common risk factors nurses perceive (Innab, 2022, Tzeng and Yin, 2013), as well as the alignment between nurses' assessments of fall risk and patients' perspectives (Choi et al., 2024). However, no study has investigated the specific criteria or algorithms nurses use to make fall risk judgements. Given that nurses' assessments directly influence the initiation of preventive interventions (Rice et al., 2022), further research into the methods and decision-making processes they use to judge fall risk is needed.

Factors related to the variation in judgement

Another issue yet to be fully explored is the source of variation in nursing judgement. Given that clinical judgement involves complex cognitive processes, differences in judgement among healthcare professionals are often inevitable. Variability in clinical judgement and decision-making has been observed among physicians (Hancock et al., 2012, McDonnell et al., 2023, Sutherland and Levesque, 2020), across different professions (Honda et al., 2015, Taggart et al., 2021), between nurses and nursing students (Shinnick and Cabrera-Mino, 2021, Yang and Thompson, 2016), and among nurses themselves (Fernández-de-Maya and Richart-Martínez, 2012, Ferrario, 2003,

Thompson et al., 2009). Regarding the fall risk judgement, Vlaeyen et al. (2021) found that the accuracy of risk judgements varied among physiotherapists, nurses, and nurse aides in nursing homes. Similarly, Takase et al. (2024) reported that the fall risk factors deemed critical by nurses differed between individuals.

Several factors may account for these variations, with clinical context playing a significant role. Patient characteristics, presenting symptoms, and treatments differ by clinical setting, influencing which factors nurses prioritise when assessing fall risk. For example, in rehabilitation or aged care wards where many patients have physical limitations, nurses may place greater emphasis on cognitive dysfunction than gait disturbances alone, as patients with cognitive impairments may engage in risky behaviours despite limited mobility. Conversely, in surgical wards, unstable gait might be a higher priority risk due to the presence of post-surgical drains and potential anaemia. Thus, differing clinical contexts necessitate different risk assessments, contributing to variation in nurses' judgements.

Another potential source of variation in judgement is cognitive bias, defined as systematic tendencies or dispositions that distort information processing, leading to inaccurate judgements or decisions (Crowley et al., 2013, Korteling et al., 2023, Korteling and Toet, 2021). Such biases typically arise when individuals rely on intuition and mental shortcuts (Crowley et al., 2013, Korteling et al., 2023, Korteling and Toet, 2021). While over 50 types of cognitive biases have been identified in healthcare settings (Croskerry and Ryle, 2019), this study focuses on three key biases: base-rate neglect, belief bias, and availability bias. These biases influence probability estimation and logical reasoning, potentially leading to variability in nurses' judgements.

Base-rate neglect refers to the tendency to ignore underlying incidence rates, prior probabilities, or base rates, either by inflating or reducing them (Croskerry, 2003, Croskerry and Ryle, 2019, Kahneman and Tversky, 1982, O'Sullivan and Schofield, 2018). It is a type of representativeness heuristic (i.e., judging based on how representative A is of B) (Blanco, 2020, Tversky and Kahneman, 1973), and often results from disregarding statistical rules (Ceschi et al., 2019). For example, consider the following.

<p>Among the 1000 people that participated in the study, there were 995 nurses and five doctors. John is a randomly chosen participant in this research. He is 34 years old. He</p>

lives in a nice house in a fancy neighbourhood. He expresses himself nicely and is very interested in politics. He invests a lot of time in his career. Which is more likely?
a) John is a nurse.
b) John is a doctor. (Erceg et al., 2022)

Many people chose b) because John's characteristics seem more representative of a doctor. However, given that 99.5% of participants are nurses, a) is statistically more likely. Similarly, nurses may overlook base rates and overestimate or underestimate specific risks. For instance, a nurse might overestimate the fall risk associated with Medication A after seeing one patient fall while on it, despite the medication rarely causing falls. Since fall risk assessment involves predicting future fall probabilities, adherence to probability principles is essential (Wright et al., 2009, Wright et al., 1994). Ignoring these principles may lead to inaccurate judgements.

Belief bias is "the tendency to accept or reject data depending on one's personal belief system, especially when the focus is on the conclusion and not the premises or data" (Croskerry and Ryle, 2019). For example, when asked to assess the validity of the following syllogism:

Premise 1: All Eastern countries are communist.
Premise 2: Canada is not an Eastern country.
Conclusion: Canada is not communist. (Erceg et al., 2022)

Many might incorrectly judge this as valid, as the conclusion appears correct despite faulty logic (denying the antecedent). In fall risk assessment, nurses must use sound logic to avoid bias. If they accept seemingly correct conclusions without evaluating the premises, they may misjudge risk. For example, a nurse might think, "A patient with weak legs is likely to fall. Patient A does not have weak legs. Therefore, Patient A will not fall," which is a logical error.

Availability bias is the tendency to mistakenly judge events as more frequent if they are recent or easily recalled (i.e., readily available in memory) (Croskerry, 2003, O'Sullivan and Schofield, 2018, Tversky and Kahneman, 1973). People tend to recall events that are frequent, recent, distinctive, or associated with other notable events (Tversky and Kahneman, 1973). An example question illustrates this bias:

Which cause of death is more likely?
Commercial airplane crash vs. Bicycle-related (Erceg et al., 2022)

Although the correct answer is “bicycle-related,” many people select “commercial airplane crash” due to its distinctiveness and memorability, especially following recent incidents. Similarly, nurses may overestimate or underestimate risks if certain events come easily to mind. Availability bias is especially relevant in fall risk assessment, as nurses rely on past experiences when judging a patient’s fall risk (Takase et al., 2024). However, basing decisions on memorable but isolated experiences can lead to biased judgements.

While variation due to clinical context may be justifiable, variation due to cognitive biases is not. Thus, identifying and addressing sources of variation is essential. Although a few studies have examined the relationship between clinical context and nurses’ fall risk judgements (e.g., Takase et al., 2024), most studies on cognitive biases in clinical judgement focus on physicians’ diagnostic decisions (e.g., Crowley et al., 2013, Saposnik et al., 2016) or nurses’ assessments of patient acuity or medication administration (Al-Moteri et al., 2022, Essa et al., 2023, Martin et al., 2022). No studies have explored cognitive biases in nurses’ fall risk assessments.

Aims

This study aimed to address two questions:

1. How do nurses judge the risk of falling?
2. What influences their judgements (i.e., what are the sources of variation in their judgements)?

Answering these questions could inform measures to improve nurses’ fall risk judgements.

Methods

Study design

This cross-sectional study is part of a larger investigation into how nurses assess fall risk. The study has two parts: a pilot study (Part 1) and a study addressing the research questions posed above (Part 2). This paper reports the findings of the Part 2 study.

Participants

Using purposive sampling, participants were recruited from six hospitals (public and private) in western Japan, with capacities ranging from 175 to 740 beds and providing

acute, rehabilitation, or extended care. Inclusion criteria required participants to be registered nurses responsible for direct patient care. Exclusion criteria included working in paediatric wards, operating theatres, intensive care units, outpatient departments, or holding managerial roles.

The dependent variable (nurses' fall risk assessment) consisted of $18 \times N$ (sample size) correlated observations. Regression tree analysis and linear mixed-effects modelling were used to address research questions 1 and 2. For the regression tree analysis, simulation studies indicate that a sample of 1,000 independent observations provides reasonable accuracy and precision (Althnian et al., 2021, Rajput et al., 2023, Sordo and Zeng, 2005). To achieve an effective sample size of 1000 with an intraclass correlation (ICC) of 0.25-0.30, 292-339 participants were needed (see Killip et al., 2004). For the mixed-effects model, sample size simulations using the mixedpower R package (Kumle et al., 2021) indicated that, with $b=0.1$ for main effects, $b=0.05$ for interaction terms, and $\alpha=0.05$, a sample of $N=200$ would achieve over 80% power. A total of 900 nurses were recruited to meet these requirements.

Instruments

The following instruments were administered to the participants.

Nurses' fall risk judgements

Patient scenarios were developed to assess nurses' judgement of fall risk. Each scenario comprised six statements about patient conditions: mobility issues, cognitive impairment and personality, urinary issues, presence of tubes (e.g., intravenous lines and indwelling catheters) or drains, medication use, and age. Each condition had three risk levels (1 = low risk to 3 = high risk) (see Table 1). Scenarios were created following a literature review, consultations with three experienced nurses in risk management, and pilot testing with five academic and three practising nurses. Since the full factorial design would yield 729 scenarios, a fractional orthogonal array was generated using the DoE.base R package (Grömping, 2018), resulting in 18 scenarios (see Supplementary Table 1). Nurses rated fall probability from 0-100% in 5% increments, which were later converted to a probability of 0-1.00 in 0.05 increments for the analysis.

[Table 1 around here]

Cognitive biases

Existing scales for cognitive biases contain general statements, with some items irrelevant in Japanese settings. Therefore, new scales were developed specifically for fall risk judgements, targeting base-rate neglect, belief bias, and availability biases, based on established scales. Each scale had three items with two response choices—one indicating bias (scored 1) and the other non-bias (scored 0). The scales were pilot-tested with five academics and three nurses, and then administered to 55 nurses for reliability testing. The Kuder-Richardson 20 (KR20) coefficients of base-rate neglect, belief and availability biases were 0.70, 0.65, and 0.41 respectively. The reliability of the availability bias was low, but an item response analysis showed good discriminant validity. Moreover, a reliable measure of availability bias is lacking (Berthet, 2021), especially in the Japanese context. Thus, we retained the original items. In all the cognitive bias scales, responses were aggregated for a total score from 0 to 3; scores of 2 or more indicated cognitive bias. Sample questions are presented in Table 2.

[Table 2 around here]

Demographics

These questions gathered data on participants' age, sex, highest educational degree, years of clinical experience, and current specialty.

Data collection procedures

After receiving approval from each institution's Director of Nursing, invitation letters were distributed to potential participants in August, 2024. The letter explained the study's purpose, methods, and ethical considerations, and provided a QR code and a URL link to a Google Forms survey. Interested participants were directed to the online survey site to complete the questionnaire, with consent assumed upon submission. Participants had four weeks to complete the questionnaire.

Analysis

Exploratory factor analysis based on a tetrachoric correlation matrix with oblique rotation and KR20 were computed to assess the construct validity and internal consistency of the cognitive bias scales. Descriptive statistics were then computed, and

variable distributions were checked. As will be shown, there was a small portion of missing responses in some question items (2.4% at maximum). Thus, the subsequent analyses were conducted by replacing missing values, i.e., those in the continuous or ordinal variables were replaced with the median values, while those in categorical variables were replaced with the most representative category.

To explore how nurses assess fall risk (research question 1), a regression tree analysis was performed. Each nurse provided 18 responses, one for each patient scenario, resulting in correlated data. Thus, a linear mixed-effects model tree with a random intercept was fitted to account for intraclass correlation, followed by 10-fold cross-validation to calculate explained variance. The glmertree R package (Fokkema et al., 2018) was used.

To identify sources of variation in nurses' judgements (research question 2), a mixed-effects regression model was applied. This model included dichotomised responses on cognitive biases, risk variables (Table 1), clinical specialty, and demographic factors as main effects, along with interaction terms between risk variables and clinical specialty to examine if weighting differed by specialty. Risk variables were collapsed into two levels (combining levels 2 and 3) and clinical specialties into six categories to reduce comparisons and avoid overfitting. Analyses were performed using StataNow (version 18.0, StataCorp, Texas, USA) and R (version 4.4.1).

Ethical considerations

This study complies with the Declaration of Helsinki developed by the World Medical Association, and approval was obtained from the institutional review board prior to the data collection.

Results

A total of 337 nurses completed the online survey, yielding a response rate of 37.4%. Of these, two nurses did not provide their judgements on the patient scenarios, leaving 335 questionnaires for further analysis. The characteristics of the participants are described in Table 3.

[Table 3 about here]

Figure 1 presents the nurses' judgements on the risk of falling, represented as

the estimated probability of falling on a scale from 0 to 1. Scenario 8 (i.e., a patient with a risk level of 3 across all variables) was rated as the highest risk, while Scenario 17 (i.e., a patient with a risk level of 1 across all variables) was rated as the lowest. The ICC of judgements within nurses was 0.279 (standard error = 0.018).

[Figure 1 about here]

Supplementary Table 2 presents the results of factor analysis on the cognitive bias scales, along with their reliability coefficients. As shown in the table, three factors representing base-rate neglect, belief bias, and availability bias were identified, explaining 64.3% of the variance. However, the KR20 coefficients were low, particularly for the base-rate neglect (KR20 = 0.323) and the belief bias scale (KR20 = 0.434). These low reliabilities were due to the majority of nurses consistently choosing biased responses for base-rate neglect (68.66%) and belief bias items (35.52%), resulting in small variances (see Supplementary Table 3). An opposite trend was observed in the availability bias scale.

Figure 2 presents the results of a regression tree analysis, illustrating how nurses judged the risk of patient falls. The first variable used to differentiate between the nurses' judgements was the patient's inability to call for assistance due to cognitive impairment. If a patient could not call for help, the second variable used to differentiate between the judgements was whether the patient had taken a sleeping pill, followed by whether the patient had stable or unstable gait. When a patient had cognitive impairment, could not call for assistance, was taking a sleeping pill, and did not have an unstable gait (but required assistance with ambulation), nurses' judgement of fall risk was highest (see Node 28). Scenario 8 represents this patient's characteristics.

Nurses judged the risk of falling as the second highest when a patient had cognitive impairment, took a sleeping pill, and had an unstable gait (see Node 29, representing Scenario 4). The next highest judgements of fall risk were for a patient with cognitive impairment and unstable gait (Node 26, representing Scenario 7), and for a patient who was hesitant to call nurses, had one tube/drain, and an unstable gait (Node 20, representing Scenario 3).

The regression tree model showed that nurses assigned progressively lower probabilities of falls to the following risk factors in descending order: patients' age, intake of anti-hypertensive agents, and presence of urinary issues. Only the need for

assistance with transfers was associated with a fall probability below 50% (see Node 7), while a patient without any of these conditions was still judged to have a small chance of falling (23.2%).

Finally, the regression tree model suggests that there was variation in nurses' judgement. In fact, the tree accounts for 58.7% of the variance, while a large portion (27.3%) was explained by a random effect.

[Figure 1 about here]

A mixed-effects regression model was used to identify factors that could be associated with this variation (see Table 4; see also Supplementary Table 4 for a correlation analysis). The results indicated that participants' sex, educational background, clinical specialty, and susceptibility to availability bias were associated with differences in nurses' judgement of fall risk, along with the presence of the risk factors listed in Table 1. Female nurses and those with a diploma tended to judge the risk of falling to be higher than their counterparts (6.7% and 4.7% respectively). Nurses working in convalescent rehabilitation or community-based care wards judged patients' risk 9.3% to be higher than those in other specialties. Additionally, nurses more susceptible to availability bias tended to judge the risk as 3% lower than those who were less susceptible.

[Table 4 about here]

Several interaction terms were also significant. Compared to nurses working in gastrointestinal wards, the judgements of nurses in convalescent rehabilitation, community-based care, long-term care, and palliative care wards were less associated with patients' mobility issues (see Figures 3a and 3b). The judgements of nurses specialising in long-term and palliative care were also less associated with whether patients called for assistance, compared to those in gastrointestinal wards (see Figure 3c). Although not reaching $p < 0.05$, rehabilitation and community-based care nurses showed a tendency to attach less importance to whether patients had tubes/drains and were over 65 years old, when judging the risk of falling.

Discussion

This study examined how nurses judge fall risk, with attention to variations related to their clinical specialty and tendencies toward cognitive biases. Regression tree analysis

revealed that nurses' judgements were primarily based on whether patients called for assistance when needed, followed by other fall-related factors such as the use of sleeping pills, mobility disorders, the presence of medical devices, and urinary issues. Patients with cognitive impairment, inability to call for help, use of sleeping pills, and mobility disorders were identified as being at the highest risk. Previous studies have shown that most falls are unwitnessed (Francis-Coad et al., 2020, Takase, 2023), and tend to happen to patients inclined to act independently (Sato et al., 2023). Additionally, factors such as hypnotic use, cognitive impairment, and mobility disorders have been consistently associated with fall risk in numerous studies, including a recent systematic review (Heinzmann et al., 2024). Consequently, patients who engage in activities independently, despite underlying fall risks, are perceived as being particularly vulnerable to falling. Nurses' belief that falls can be prevented by accompanying patients highlights their emphasis on a patient's ability to seek nursing assistance as a primary consideration in fall risk assessment.

Patients who did not call for assistance despite lacking cognitive impairment, having a tube or drain, and experiencing gait issues (e.g., unstable walking or requiring transfer assistance) were also judged by nurses to have a high risk of falling. One study reported that approximately 90% of patients at risk of falling had a tube or drain inserted (Sakai et al., 2016). Given that most participants in this study worked in acute care hospitals, where many patients have tubes or drains, nurses' heightened concern about the impact of these devices on fall risk (Takase et al., 2024) is understandable.

While mobility issues were identified as a key factor in nurses' fall risk judgements, requiring assistance with transfers alone was associated with less than a 50% perceived risk of falling. Several explanations may account for this. First, studies suggest that fall rates do not always correspond to fall frequency (Inoue et al., 2024). Thus, even if mobility impairment is recognised as a high-risk factor, the frequency of falls may be low if few patients exhibit such impairments. Given that the majority worked in acute settings, the number of patients requiring transfer assistance may have been small, leading to fewer incidents. This could create an impression among nurses that fall risk is moderate. Second, nurses may feel confident that falls can be prevented if patients call for assistance. Finally, mobility issues may be viewed as amplifying rather than independently driving fall risk. For instance, a study found that the presence

of mobility impairments heightened fall risk in cognitively impaired patients (Martin et al., 2013). Consequently, in the absence of other risk factors, the overall risk may be considered moderate.

The results also revealed variation in nurses' judgements, which usually stemmed from differences in how they weighed each risk factor (Stamp, 2012, Thompson et al., 2009). In this study, factors such as nurses' gender, educational background, clinical specialty, and susceptibility to availability bias were associated with how they evaluated each risk. The mixed-effects regression model indicated that nurses in convalescent rehabilitation and community-based care wards rated patients' fall risk significantly higher than those on gastrointestinal wards. In these settings, patients are in the process of regaining mobility and transitioning back to their communities, which inherently increases their fall risk (Kato et al., 2022). High fall rates in convalescent rehabilitation wards have been reported in other studies as well (Ainuddin et al., 2019, Kato et al., 2022). By contextualising each scenario within their practice, nurses in these wards might have assessed fall risk more severely than their gastrointestinal counterparts.

Additionally, nurses in convalescent rehabilitation/community-based care, and long-term/palliative care wards perceived the risks associated with mobility disorders and the inability to call for assistance differently from nurses in gastrointestinal settings. For nurses in rehabilitation and community care, mobility disorders had less impact on their judgement compared to those in gastrointestinal nursing. This could be explained by two factors. First, nurses in rehabilitation and community care settings may perceive mobility limitations as universal among their patients, thus not significantly influencing fall risk. A recent study found no difference in mobility between patients who fell and those who did not in stroke rehabilitation (Hong et al., 2024). Alternatively, nurses may believe that patients in these settings have an inherent fall risk, regardless of their mobility status. Kato et al. (2022) found that although patients with functional impairments had a higher risk of falling, recovery from mobility impairment led to greater activity levels, which resulted in increased fall rates over time. This may explain why nurses rated patients without mobility issues as higher risk than their gastrointestinal counterparts.

Similarly, nurses in long-term/palliative care rated the impact on fall risk of

mobility disorders and the inability to call for assistance lower than nurses in gastrointestinal nursing. This may be because nurses in long-term/palliative care settings may not view cognitive or mobility impairments as distinguishing factors for fall risk, as the majority of patients in these wards experience these conditions. Additionally, patients in long-term/palliative care are often frail, dependent, depressed, and suffer from multiple chronic comorbidities, such as congestive heart failure and chronic pulmonary diseases, all of which are associated with increased fall risk (Oren et al., 2022, Prabhakaran et al., 2020, Xu et al., 2022). Thus, a single risk factor may not carry as much weight as it does in other specialties. In contrast, on acute care wards like gastrointestinal medicine and surgery, diseases and treatments can dramatically alter patients' mobility and cognitive function (Milisen et al., 2012, Perell et al., 2001). Consequently, changes in functional status have more visible impacts on fall risk. These differing characteristics of clinical specialties probably explain the variation in how these risk factors are prioritised.

While variation due to contextual clinical judgement may be justified, variation stemming from individual factors such as gender, educational background, and susceptibility to cognitive biases is not justifiable. This is because there is no clinical evidence to suggest that such factors affect fall risk. Gender differences in risk perception are well-documented, with studies consistently showing that females tend to perceive greater susceptibility to and severity of various risk factors (Brown et al., 2021, Harris and Jenkins, 2006, Kim et al., 2018), often resulting in them recommending more preventive measures compared to their male counterparts (Alsharawy et al., 2021). The present study observed a similar phenomenon. Additionally, nurses with diplomas rated the risk of falling significantly higher than their degree-holding counterparts. This contrasts with findings from other studies, which suggest that individuals with higher educational levels tend to perceive higher probabilities of risk (Pfortner and Hower, 2022, Rattay et al., 2021, Röpcke et al., 2024). It is not certain why this difference occurred. One possible explanation is that nurses with diplomas may have received training that emphasised patient safety and risk during their pre-licensure education.

The final source of judgement variation is cognitive bias. Availability bias was observed in 42.39% of nurses, who rated scenarios approximately 3% lower than their counterparts. Although this difference was small, the findings align with previous

research showing that cognitive bias affects nurses' decision-making and practice (Jala et al., 2023, Whyte et al., 2022). Availability bias increases with the ease of recalling relevant examples (Tversky and Kahneman, 1973). Therefore, if nurses recalled recent instances where patients with similar characteristics fell, their fall risk estimates would increase, while recalling instances where such patients did not fall would lead to underestimation. In this study, nurses probably recalled situations where patients with similar characteristics did not fall, which contributed to their underestimation of risk.

Although base-rate neglect and belief bias did not appear to impact nurses' judgements, attention should be given to their susceptibility to these cognitive biases. Our findings revealed that 93.44% of nurses exhibited base-rate neglect, while 69.25% were affected by belief bias. These findings are consistent with those of Al-Moteri et al. (Al-Moteri et al., 2020), who reported that 63% of their sample showed cognitive bias. Base-rate neglect occurs when nurses disregard underlying probabilities, while belief bias arises when nurses base their judgement on the believability of conclusions rather than logic. Given that nurses often express discomfort with probabilities (Lavoie et al., 2020), and rely on intuition (Honda et al., 2015), these findings are not surprising. Correct application of probability theory and logical reasoning is essential for accurate judgement and forecasting (Wright et al., 2009). Therefore, these cognitive biases could still affect nurses' judgements and interventions. Future studies using more reliable instruments would provide a clearer understanding of the impact of these biases.

Implications for nursing management and research

The results of the regression tree analysis suggest that nurses do not assign equal weight to each risk factor. A comparison of nurses' judgements with existing fall assessment scales highlights clear distinctions. For example, in the Morse Fall Scale (Morse et al., 1989), patients' mental status (e.g., forgetting limitations and moving independently) is assigned only half the points (15 points) compared to the use of ambulatory aids (30 points). However, nurses in this study regarded the former as a greater risk. Similarly, in the STRATIFY Risk Assessment Tool (Oliver et al., 1997), all risk factors are equally weighted, yet nurses did not treat them as such, with the weight assigned varying by clinical specialty. Nurses' contextual knowledge, which has not been integrated into existing models, may provide valuable insights for improving fall assessment scales

(Önkal-Atay et al., 2004).

At the same time, nurses and healthcare organisations may need to reconsider their approach to fall prevention. A goal of zero falls may be unrealistic, particularly in rehabilitation units where patients push their physical and cognitive limits to regain optimal functioning (Singh et al., 2019). In their efforts to prevent falls, nurses often instruct patients to call for assistance when ambulating. However, this practice may restrict patients' independence and dignity (Kerr et al., 2023). A shift in focus toward preventing recurrent falls and minimising fall-related injuries may be more practical and patient-centred.

Finally, this study emphasises the importance of reducing nurses' cognitive biases. To achieve this, organisations should offer training in probabilistic reasoning and logical inference to enhance nurses' reasoning strategies (Čavojová et al., 2020). Such training can help reduce base-rate neglect, belief bias, and availability bias. Additionally, encouraging slow thinking and fostering judgement verification through peer consultation can further minimise cognitive bias. Organisations should also establish a framework that supports a reflective clinical culture.

Limitations

The current study has several limitations. First, the scenarios were based on a limited set of fall risks, which may not fully capture the complexity of nurses' judgement strategies. Second, only three types of cognitive bias were examined, and there are many other types that may influence nurses' judgements. Further research is needed to explore the impact of additional cognitive biases and identify their sources of variation. Third, the reliability of the cognitive bias scales was low, partly due to small variances in nurses' responses, which tended to concentrate around specific answers. The low reliability of these scales has been noted in other studies, with potential remedial solutions suggested by Berthet (2021). Developing more reliable, context-specific scales is essential for improving the accuracy of cognitive bias measurement.

Conclusions

Judging fall risk is a complex process that involves identifying risk factors and assessing their relative importance, while also considering potential synergies and

counteractions between them. Contextual factors further influence this judgement, as the significance of risk factors can vary across different clinical areas. Due to this complexity, human judgement is essential, although it is this very judgement that may contribute to clinical variation. While variation in clinical judgement is generally seen as undesirable because it can lead to inconsistent practices, not all variation results in unjustified care. For example, variation in nurses' fall risk judgements may be justified when it reflects personalised, context-specific nursing care. In contrast, errors arising from cognitive bias, which leads to inconsistent judgements, are unjustified. Nurses' clinical judgement is directly linked to the effectiveness of fall prevention measures. Consequently, healthcare organisations should provide targeted training to enhance nurses' contextual expertise while mitigating cognitive biases.

Data availability

Data not available

The participants were assured raw data would remain confidential and would not be shared.

Conflicts of interest

All authors declare no conflict of interest regarding the publication of this article. Although the study received funding, the funder had no involvement in the study's conceptualization, design, data collection, analysis, decision to publish, or manuscript preparation.

Funding statement

This study was supported by JSPS KAKENHI [grant Numbers 22K10749].

Acknowledgements

The authors would like to express their gratitude to Dr. Marjolein Fokkema for her assistance in conducting a linear mixed-effects model tree and a 10-fold cross-validation.

569 **Supplementary Materials**

570 The supplementary file includes patient scenarios used in the study, factor analysis results
571 of the cognitive scales and reliability coefficients, response frequencies for cognitive
572 biases, and Spearman correlation coefficients between variables.

Table 2. Sample items of the cognitive bias scale

<p><u>Base-rate neglect</u></p> <p>Hospital B has 1,000 patient falls each year. About 50 of these falls are due to vertigo, and the remaining 950 are due to unstable gait. Ms. Yasuda is a randomly selected patient at Hospital B. She is a 90-year-old woman admitted for treatment of heart failure. Her face is pale, and when she stands up, she complains, “Sometimes my eyes go completely black”. She sometimes wobbles. Which is more likely?</p> <p>1. Ms. Yasuda falls because of vertigo. (Biased response)</p> <p>2. Ms. Yasuda falls because of unstable gait. (Correct response)</p>
<p><u>Belief bias</u></p> <p>We will now solve syllogisms. First, two premises are presented, following a conclusion. You are to determine if the conclusion follows logically from the premises. Assume that all of the premises are true. Now read the following syllogism and choose 1 if it is logically correct or 2 if it is incorrect.</p> <p>Premise 1: Patients who can move on their own are prone to falls.</p> <p>Premise 2: Ms. A cannot move by herself and is bedridden.</p> <p>Conclusion: Therefore, her risk of falling is low.</p> <p>1. Correct (Biased response)</p> <p>2. Incorrect (Correct response)</p>
<p><u>Availability bias</u></p> <p>Which do you think leads to more deaths? Please choose the one you think causes more deaths.</p> <p>1. Fall (Correct response)</p> <p>2. Traffic accident (Biased response)</p>

Table 3. Characteristics of the participants

Variables		Mean/Frequency	Standard deviation/Proportion
Age		34.06	10.97
Length of experience		10.52	9.45
Sex	Male	35	9.86%
	Female	298	88.96%
	Missing	2	0.60%
Education	Diploma	212	63.28%
	Bachelor & Postgraduate	119	35.52%
	Missing	4	1.19%
Clinical specialty [#]	Respiratory/Cardiovascular wards	28	8.36%
	Convalescent rehabilitation/Community-based Care wards	87	25.98%
	Orthopaedic /Neurology wards	30	8.96%
	Long-term/Palliative care wards	46	13.74%
	Gastrointestinal wards	45	13.44%
	Others	93	27.77%
	Missing	6	1.8%

Note: There are six missing values (1.8%) in age and eight missing values (2.4%) in the length of experience.

[#] Nurses were categorised into six groups based on their main clinical specialty.

Table 4. The results of a mixed-effect model

Fall risk	b	Robust SE	z	p	95% CI

Variance explained by outcome cluster means via random intercept variation					0.272	
Variance explained by the whole model					0.590	

Figure 1. The means and standard deviation of nurses' judgement of the risk of falling in each scenario

Variance explained by all predictors via
fixed slopes = 0.314

Variance explained by the whole model
(including random slope) = 0.587

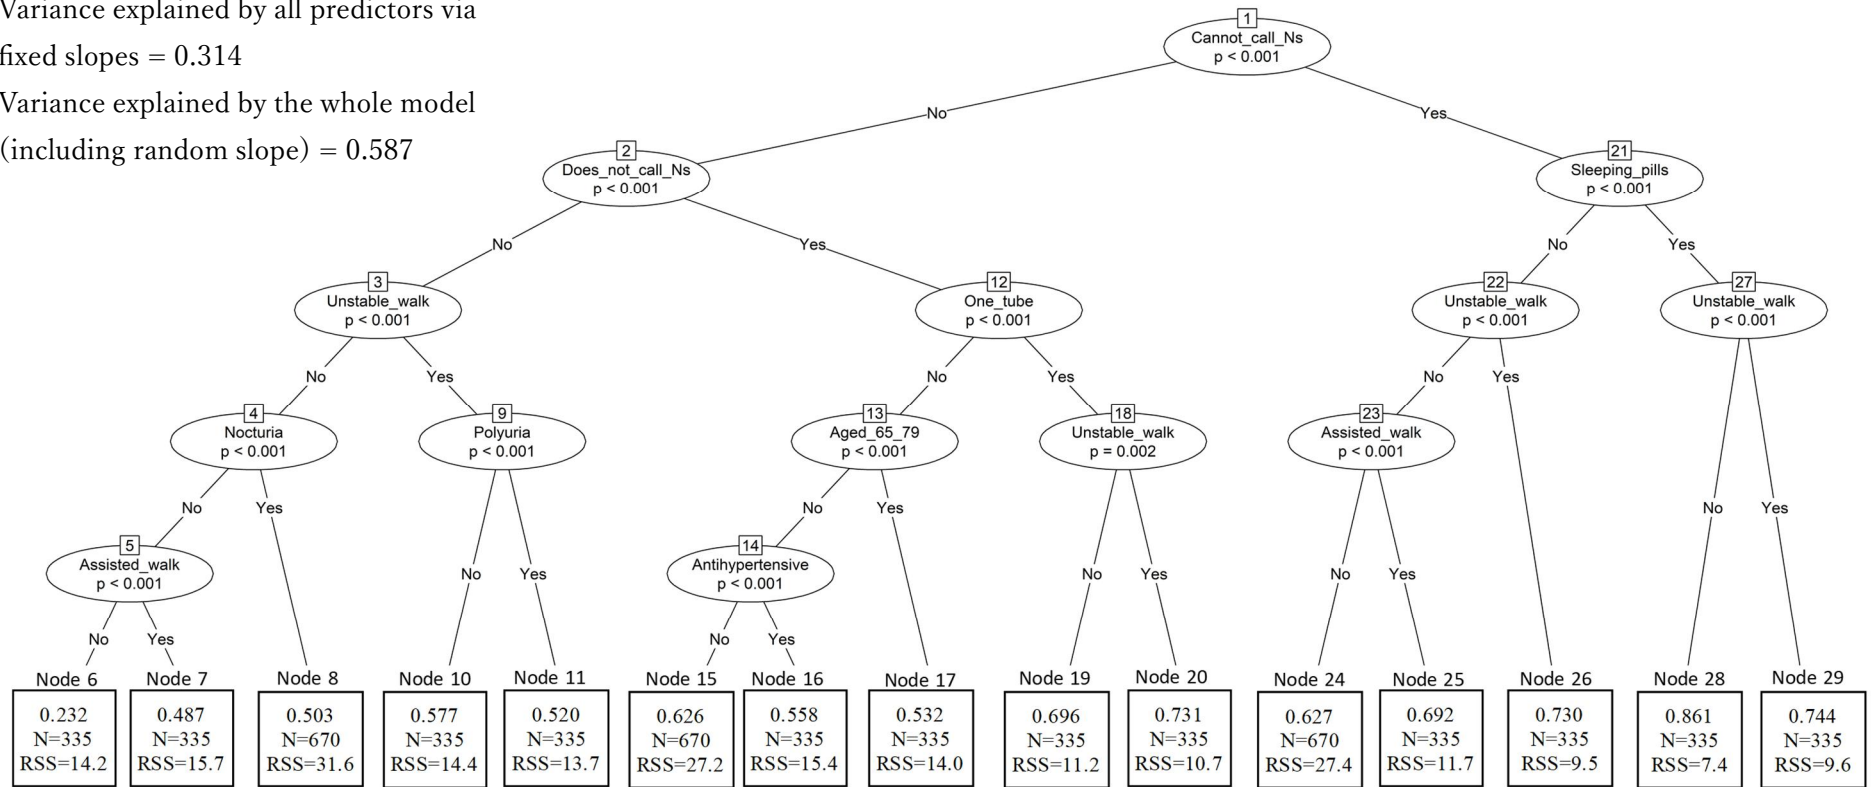

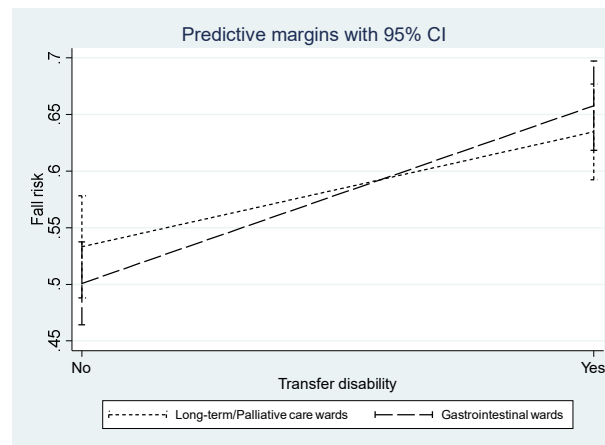

Figure 2. Regression tree illustrating nurses' judgement in the risk of falling

Note: The numeric values in the boxes indicate the mean probability of falling estimated by nurses, and 'RSS' indicates the residual sum of squares. N indicates the number of observations (335×18=6030 observations in total). In this analysis, patient conditions (see Table 1) were dummy-coded, with the risk level 1 variable serving as the reference category for each condition.
