ABSTRACT 16

Wastewater-based surveillance systems can track trends in multiple pathogens simultaneously by 17 leveraging efficient, streamlined laboratory processing. In Switzerland, wastewater surveillance is 18 conducted for fourteen locations representing 2.3 million people, or 26% of the national population, with 19 simultaneous surveillance of four respiratory pathogens. Trends in respiratory diseases are tracked 20 21 using a novel, six-plex digital PCR assay targeting Influenza A, Influenza B, Respiratory Syncytial Virus, and SARS-CoV-2 N1 and N2 genes, as well as Murine Hepatitis Virus for recovery efficiency control. 22 23 The multiplex assay was developed to ensure sensitivity and accurate quantification for all targets simultaneously. Wastewater data is also integrated with disease data obtained through both a 24 mandatory disease reporting system and the Swiss Sentinel System (Sentinella), a voluntary reporting 25 system for general practitioners. Comparisons between wastewater data and case data from July 2023 26 through July 2024 demonstrate a high level of agreement, specifically for Influenza A, SARS-CoV-2, 27 and Respiratory Syncytial Virus. Lower correspondence is observed for Influenza B, which highlights 28 challenges in tracking disease dynamics during seasons without pronounced outbreak periods. 29 Wastewater monitoring further revealed that targeting the N1 or N2 gene led to divergent estimates of 30 SARS-Cov-2 viral loads, highlighting the impact of mutations in the target region of the assay on tracking 31 trends. The study emphasizes the importance of an integrated wastewater monitoring program as a 32 complementary tool for public health surveillance by demonstrating clear concordance with clinical data 33 for respiratory pathogens beyond SARS-CoV-2. 34

35 INTRODUCTION

- Respiratory infections are a leading cause of morbidity and mortality worldwide particularly in children 36 and the elderly¹. Such infections are commonly caused by viral pathogens, including Influenza A (IAV) 37 and B (IBV), Respiratory Syncytial Virus (RSV), and SARS-CoV-2. Infections from respiratory viruses 38 39 typically follow a seasonal pattern, with one or two peaks annually, though in many countries influenza transmission is identified year-round². Our knowledge about respiratory virus epidemiology and infection 40 dynamics is overwhelmingly driven by clinical data reporting systems. However, such systems can be 41 subject to bias, likely underestimating the disease prevalence³, or incompletely capturing dynamics due 42 to changes in testing or reporting strategies or changes in population behavior seeking medical care. 43
- Wastewater-based surveillance (WBS) is proposed as an alternative and/or complementary option for tracking respiratory viruses^{4,5}. WBS relies on wastewater analysis for detecting genetic material of a target pathogen, often by implementing molecular-based assays, such as quantitative PCR (qPCR) and digital PCR (dPCR). The COVID-19 pandemic has highlighted the potential and advantages of WBS^{6,7},
- 48 which is now applied worldwide.
- WBS allows a broad, population-level perspective by sampling wastewater, offering insights into the trends of entire communities or regions from just one 24-hour composite wastewater sample per day. Further, WBS is useful as a complementary tool to traditional surveillance methods, providing data that can enhance the accuracy and timeliness of public health interventions⁸⁻¹⁰. Indeed, previous studies reported a strong association between wastewater viral concentrations and reported clinical cases, suggesting that when both surveillance strategies are sensitive enough, the resulting data solidly correspond.
- WBS has been applied to the detection of diverse respiratory pathogens beyond SARS-CoV-2, including RSV and influenza viruses¹¹⁻¹³. Tracking pathogen concentrations in settled solids and wastewater influent aligns with available clinical data, which often relies on metrics such as clinical positive rates (as in Hughes et al. for RSV) or influenza-like illnesses (as in Wolfe et al. and Zheng et al. for Influenza A). Moreover, simultaneous detection of multiple pathogens in wastewater offers an efficient means of monitoring distinct diseases. To achieve this multiplexing of pathogens, dPCR, compared to qPCR, offers substantial potential¹⁴.
- The wastewater monitoring program in Switzerland was initiated in July 2020 for the surveillance of 63 SARS-CoV-2, and subsequently expanded for the detection of IAV, IBV, and RSV, with the 64 implementation of a second multiplex dPCR assay¹⁵ in November 2022. To improve the workflow and 65 reduce costs of the surveillance program, we developed a novel multiplex dPCR assay for detecting 66 simultaneously the four target respiratory viral pathogens (IAV, IBV, RSV, and SARS-CoV-2) as well as 67 an additional quality control to measure recovery efficiency (Murine Hepatitis Virus, MHV). Here, we 68 report the development and application of the multiplex dPCR assay to the established wastewater 69 surveillance framework for monitoring in Switzerland. 70

RESULTS 71

Performance of the six-plex dPCR assay and guality control indicators 72

The six-plex dPCR assay, referred to as RESPV6, was designed for detecting six target genes with 73

specific fluorophores: SARS-CoV-2 N1 gene (SARS-N1, ATTO425), SARS-CoV-2 N2 gene (SARS-N2, 74

- 75 FAM), RSV N gene (RSV-N, ROX), IAV M gene (IAV-M, Cy5), IBV M gene (IBV-M, HEX), and MHV M
- gene (MHV-M, Cy5.5). All selected targets produced clusters which were separable, allowing for 76
- discrimination between positive and negative partitions, and between distinct targets (Fig. 1). 77
- 78 The assay was applied for monitoring wastewater between July 2023 and July 2024, leading to a total of 13'028 individual dPCR reactions. Of those reactions, 7'795 were performed on wastewater samples 79 collected from 14 WWTPs (Supplemental Table 1), 2'482 were run for control purposes, and 2'751 for 80 assessing PCR inhibition. Altogether, we analyzed 3'538 distinct wastewater samples. 81
- Since wastewater is a complex matrix and can contain inhibitors we determined the levels of PCR 82 inhibition present in the analyzed wastewater nucleic acid extracts, and repeated samples showing more 83
- 84 than 40% inhibition. For reactions that passed quality control (7'052/7'795), we observed a median PCR
- inhibition of 3% (interguartile range [IQR] 14%). We observed a significant variation across different 85
- locations (Kruskal-Wallis test, p < 0.001). The Dunn's multiple comparisons test displayed that samples 86
- from Basel had a significantly higher level of inhibition (median of 7%) than other WWTPs, whereas 87
- samples from Solothurn had lower level of inhibition compared to other WWTPs (median of -1%) 88 (Supplemental Table S2). 89
- 90 During this study, we observed dPCR reaction failure in a total of 743 reactions out of 7'795 (10%). Of
- these, 121 failed because of high levels of inhibition (>40% inhibition, 16%), 303 due to a failed no 91
- template control suggesting possible contamination of the sample (NTC, 40%), and 334 for insufficient 92
- number of partitions (i.e., <15'000 droplets, 44%). Reaction failure resulted in data for 281 samples (8%) 93
- being taken from a single replicate rather than the average of duplicates. 94
- Based on the recovery of MHV, the recovery efficiency control, we observed a median recovery rate of 95
- 18% (IQR 38%) and an average of 30% (± 27%), which was derived from running efficiency control in 96
- 3'951 dPCR reactions. We detected a significant difference among locations (Kruskal-Wallis test, p < 197
- 98 0.001). The Dunn's multiple comparisons test showed that samples from Basel had a significantly lower

extraction efficiency than other WWTPs (Supplemental Table S3). 99

- Among the reactions containing wastewater extracts that passed quality control, we observed a median 100 number of partitions of 22'104 (IQR 4'726). Moreover, we estimated the volume of reaction mixture that 101 did not form partitions (dead volume) which showed that the median percentage of dead volume for 102
- each reaction was 54% (IQR 10%). 103

Detection of viral pathogens in Swiss wastewater 104

- Our dPCR analysis of 3'538 samples revealed that IAV was detected in 27% of the samples (n = 941), 105
- IBV in 42% (n = 1'491), and RSV in 38% of the samples (n = 1'338). SARS-CoV-2 was detected in 99% 106
- and 98% of the samples for the N1 and N2 genes respectively (n = 3'499, n = 3'472). Despite N1 and 107
- N2 displaying a marked positive linear relationship ($R^2 = 0.97$), N2 values were generally higher than 108
- 109 N1 values (Fig. 2). Indeed, the ratio of N1 to N2 was 0.87 ± 0.33 (mean \pm standard deviation [s.d.]) (n =

medRxiv preprint doi: https://doi.org/10.1101/2024.12.06.24317241; this version posted December 10, 2024. The copyright holder for this preprint (which was not certified by peer review) is the author/funder, who has granted medRxiv a license to display the preprint in

perpetuity. It is made available under a CC-BY 4.0 International license .

3'538). Interestingly, we noted a shift in the ratio of N1 to N2 over the monitoring period. From July 2023 110 to January 2024 the ratio was constantly below one at all locations $(0.71 \pm 0.23, n = 1'648)$, but then 111

returned to one after January 2024 (1.01 \pm 0.35, n = 1'890) (Supplemental Fig. S1). 112

Viral loads of respiratory pathogens in Swiss wastewater 113

We explored the epidemiology of the target respiratory viruses by observing the viral loads in 114 115 wastewater, expressed in gene copies per person per day (gc person⁻¹ day⁻¹), over time. To better identify and interpret the trends, we calculated the median value over a centrally aligned seven-day 116 rolling period. This helped smooth fluctuations and outliers. 117

- This observational period was strongly characterized by a considerable wave of SARS-CoV-2 loads, 118 detected in all 14 catchments, from October 2023 until February 2024 (Fig. 3). Each location was 119 characterized by an outbreak peak (i.e., maximum median value) between 9th November 2023 and 21st 120 December 2023. Lucerne displayed the highest load of 9.7 \times 10⁸ gc person⁻¹ day⁻¹ on the 8th of 121 December 2023 (Fig. 3C). Importantly, a second peak of SARS-CoV-2 was identified in all catchments 122 starting in April 2024, particularly in Lausanne, where a clear second wave was visible and comparable 123 to the previous one (Fig. 3N). 124
- The surveillance period was also characterized by the presence of the other measured pathogens IAV, 125
- IBV, and RSV, though the concentrations and loads in wastewater were considerably lower than those 126
- of SARS-CoV-2, differing by more than one order of magnitude (Fig. 3, Fig. 4). Between December 127
- 2023 and mid-March 2024, we encountered a seasonal outbreak of IAV. Maximum peaks were seen 128
- within a one-month period (18th Jan 16th Feb 2024) for 13 locations. The exception was Lugano where 129
- the peak occurred earlier (Supplemental Fig. S2A). Moreover, Lugano had the highest peak value for 130
- IAV among all locations, with 5.1 \times 10⁷ gc person⁻¹ day⁻¹ on the 28th of December 2023 (**Fig. 4J**). 131
- Between November 2023 and May 2024, we observed a wave of RSV, and peak values were identified 132
- between 3rd December 2023 and 15th February 2024 for 13 locations, except for Solothurn which was 133 characterized by a peak in July 2023 (Fig. 4I and Fig. S2C). 134
- 135 Unlike SARS-CoV-2, IAV, and RSV outbreaks, which showed similar and comparable trends across
- different Swiss locations, the trends for IBV were less clear, with fewer comparable and distinguishable 136
- patterns among catchments (Supplemental Fig. S2B). As such we observe the peak values for IBV 137
- over more than eight months (13th Nov 2023 12th Jul 2024). 138

Comparison of viral loads in wastewater with clinical data from different sources 139

- At the national level, we observed consistent relationships between weekly wastewater viral loads and 140 weekly clinical cases from the Sentinella system for all four pathogens tracked (Fig. 5). We observed a 141
- strong positive correlation between IAV RNA loads in wastewater and IAV clinical cases (Pearson 142
- correlation, r = 0.95 [p < 0.0001]), between SARS-CoV-2 RNA loads and clinical cases (r = 0.87 [p < 0.001]) 143
- 144 0.0001]), and between RSV RNA loads and clinical cases (r = 0.68 [p < 0.0001]). The same analysis for
- IBV showed a rather low correlation (r = 0.28 [p = 0.04]) (Fig. 5B). 145
- Subsequently, we performed the same correlation coefficient analysis using clinical data publicly 146 available from the mandatory reporting system, which reports clinical positive cases per week for IAV, 147
- IBV, and SARS-CoV-2. As expected, we observed higher correlation coefficients (r = 0.99 for IAV [p < 100148

perpetuity. It is made available under a CC-BY 4.0 International license .

- 0.0001], r = 0.44 for IBV [p = 0.0008], and r = 0.93 for SARS-CoV-2 [p < 0.0001]), likely due to the better spatial resolution of such data which is less prone to bias (**Supplemental Fig. S3**). Additionally, we investigated the relationship between clinical data from Sentinella and from the mandatory reporting system, and we observed very strong Pearson correlation coefficients for SARS-CoV-2 and IAV (r =0.92 [p < 0.0001] and r = 0.95 [p < 0.0001]). However, the correlation for IBV was only moderate (r =0.63 [p < 0.0001]).
- From the mandatory reporting system, SARS-CoV-2 clinical data is also stratified geographically at the
- cantonal level. Therefore, we investigated the relationships between viral RNA loads from each location
- and the cases reported in the corresponding canton by computing Pearson correlation coefficients. We
- observed strong correlations with coefficients ranging from 0.55 to 0.93 (Supplemental Table S4).

159 Lag times between clinical cases and viral RNA loads in wastewater

We used time-lagged cross-correlation to estimate lag times between wastewater viral loads and clinical cases for all four pathogens. Our analysis of weekly data showed that for RSV, the maximum value was reached at one week of lag, with wastewater data preceding clinical data (Supplemental Fig. S5). However, the computed coefficient was only slightly higher compared to the value obtained without lag

164 (0.70 and 0.68, respectively) (Supplemental Table S5). In contrast, for IAV, IBV, and SARS-CoV-2, the

- highest Pearson correlation coefficient was identified with no lag.
- 166 To investigate if there was a lag within the first week, we used the clinical data obtained from the Swiss Federal Office of Public Health (FOPH) with daily resolution, which was provided for SARS-CoV-2, IAV, 167 and IBV at the cantonal level. Therefore, we examined the correlations between viral RNA loads from 168 each catchment and the reported cases in the corresponding canton. Our analysis did not reveal a 169 consistent pattern of wastewater data preceding clinical data across all locations. Indeed, lag times for 170 SARS-CoV-2 ranged from 0-5 days, for IAV from 0-7 days, and for IBV from 1-14 days, wastewater 171 always being earlier. 172 Notably, we also observed lower correlation coefficients for SARS-CoV-2, when considering cantonal 173
- data with daily resolution instead of weekly aggregation. Coefficients ranged from 0.22-0.81 compared
 to 0.55-0.92. Moreover, as the 2023/2024 season was characterized by two waves of SARS-CoV-2, we
 also computed correlation coefficients for each wave separately, and we observed that in the second
- surge, values were generally ~2.5 times lower, with coefficients ranging from 0.09-0.56.

DISCUSSION 178

In this study, we report the successful development of a multiplex digital PCR (dPCR) assay targeting 179 four common respiratory viruses – Influenza A (IAV) and B (IBV), Respiratory Syncytial Virus (RSV), 180 SARS-CoV-2 (N1 and N2 genes) – and the internal control Murine Hepatitis Virus (MHV), an RNA virus 181 182 used to monitor recovery efficiency. The six-plex dPCR assay enables absolute target quantification without the need for a standard curve for six targets simultaneously. A higher order of multiplexing can 183 be achieved through additional channels or by amplitude-based multiplexing¹⁴, broadening the panel of 184 detectable targets. Although we designed this assay for a 6-color system, it can be readily adapted to 185 meet other requirements, by modifying fluorophores or changing channels. We applied our assay to 186 Swiss wastewater samples within the scope of a previously established, national wastewater 187 surveillance program¹⁶. We obtained four or five samples per week from 14 different wastewater 188 189 treatment plants located across Switzerland, which collect the influent from more than one fourth of the Swiss residential population. Detecting viral RNA in wastewater is challenging due to low concentrations 190 and the complexity of the matrix; indicating that efficient viral concentration methods are needed¹⁷. Here, 191 we used MHV as internal control for extraction efficiency, and observed a mean recovery of 30%, which 192 was close to the lower end of the range 26.7-65.7% found in a previous study that compared different 193 concentration methods¹⁸. Notably, the extraction method used in our study which relies on direct 194 capture, was not evaluated in the study. The reduced recovery could have been influenced by the 195 contained wastewater volume employed (40 ml). Future efforts should focus on increasing sensitivity, 196 by for example, increasing the volume of samples processed or improving recovery efficiency. 197

We detected and measured RNA from all assessed respiratory viruses, suggesting that our six-plex 198 dPCR assay was specific to the selected genomic regions, and that our procedures were sufficiently 199 sensitive to capture the clinically observed outbreaks for IAV, RSV, and SARS-CoV-2. The dPCR assay 200 targeted both the SARS-CoV-2 N1 and N2 genes. Indeed, the use of various viral targets is generally 201 advised, as the selection of only one could increase the rate of false-negatives¹⁹. However, this is not 202 203 always feasible in practice, as it would greatly increase the required degree of multiplexing. Here, N1 and N2 markers showed strong agreement, despite N2 concentrations typically being higher than those 204 of N1. Specifically, the N1 to N2 ratio was constantly below one until around January 2024, before 205 returning to one. This observed discrepancy may have been triggered by mutations in the N1 probe 206 binding region, which could reduce affinity, as proposed and demonstrated by Sun and colleagues²⁰. 207 However, we identified a point mutation (T28297C), positioned in the N1 forward primer binding site, 208 which was present in 47.7% of the sequenced strains over the study period²¹. From July 2023 to January 209 2024, the percentage of strains carrying the mutation was 57.8%, which decreased to 4.3% from 210 January to July 2024, corresponding to the timing of the N1/N2 ratio shift towards one. This observation 211 suggests that T28297C lead to the decrease in N1/N2 ratio, highlighting how measured viral loads are 212 impacted by the mutation landscape. By having multiple targets for a pathogen, decreasing primer/probe 213 efficiency due to mutation can be more readily identified and primers or probes can be redesigned as 214 required to ensure continuing assay performance. 215

We report that the 2023/2024 winter season in Switzerland was characterized by a substantial outbreak 216 of SARS-CoV-2, with peak loads 10 to 100 times higher than those of other investigated respiratory 217

viruses. This observed trend is consistent with previously reported loads^{15,22}. The divergence in 218 magnitude is potentially attributed to the higher transmissibility rate of SARS-CoV-2 compared to that of 219 influenza and other seasonal respiratory viruses²³. Notably, it could also be due to higher concentrations 220 of SARS-CoV-2 RNA in feces of infected people relative to IAV, IBV, and RSV. Importantly, this winter 221 222 season was dominated by the JN.1 variant²¹, which appears to be more transmissible than its parental virus^{24,25}. In some catchments, we identified a second wave of SARS-CoV-2, which was smaller and 223 driven by the KP.2 variant²⁶. 224

Focusing on flu-season, IAV evidently prevailed over IBV, which was less abundant in wastewater and 225 less reported in clinical settings. Despite the low number of positive cases of IBV, we detected its RNA 226 in wastewater in 30% of the wastewater samples, which was not achievable by other studies^{27,28}. 227 Measurements of RSV in wastewater indicated the presence of a clear outbreak, which occurred 228 between November 2023 and May 2024. Wastewater surveillance of RSV nicely demonstrates how 229 wastewater data is valuable to get an insight into the epidemiological situation, in absence of a complete 230 reporting system, as RSV infections are not subjected to mandatory declaration requirements in 231 Switzerland. 232

For all viruses we observed occasional high measurement values. It is known that there are several 233 sources of uncertainty in wastewater-based surveillance (WBS)²⁹, and, despite attempts to control for 234 some (e.g. inhibition), there are several which cannot be controlled for and their impact on concentration 235 measurements remains to be elucidated. We therefore use a seven-day rolling median to determine a 236 smoothed trend. Further work to understand specificities of wastewater viral concentration data could 237 provide better methods for determining the average of technical replicates, generating a smooth signal 238 239 or identifying outlier data points.

WBS has been extensively proposed as a useful tool for complementing clinical data, leading to a better 240 understanding of respiratory diseases and identifying potential trends. In this study, we identified very 241 strong correlations between wastewater viral loads and clinical cases, particularly for SARS-CoV-2 and 242 IAV, as their occurrence was high during the monitoring period, and for RSV. The only exception was 243 IBV, where we did not identify a strong correlation. In this case, wastewater data did not show a seasonal 244 outbreak, whereas clinical cases collected through the mandatory reporting system indicated an 245 outbreak (Supplemental Fig. S3C). Notably, cases from Sentinella and from the mandatory reporting 246 system agreed only moderately. This might indicate that IBV was not causing a highly symptomatic 247 infection or potentially had lower levels of viral shedding. Interestingly both the mandatory reporting and 248 Sentinella systems indicate a roughly 80:20 ratio of IAV to IBV cases. The ability of the mandatory 249 reporting system to capture the IBV outbreak is likely due to the greater number of cases reported in 250 this way (n = 120'862 compared to n = 2'316). 251

Previous studies focusing on SARS-CoV-2 showed that the number of clinical cases follows viral titers 252 in wastewater by variable lag times³⁰⁻³³. Our time-lagged cross-correlation analysis on four pathogens 253 indicates that wastewater might serve as a leading indicator. However, we did not observe a uniform 254 pattern of wastewater data consistently preceding clinical data across all sites, suggesting that some 255 location-specific effects might exist. Differences might arise based on how representative the cantonal 256

clinical data is when compared to the localized catchment viral load measurements. Moreover, several factors should be considered, such as population effects, including the proportion of vaccinated individuals and mobility behavior; and sewer network characteristics, like the influence of industrial discharge, and rainfall events²⁹. Indeed, industrial wastewater might contain chemicals that could

- degrade RNA molecules; and rainfall events can introduce a dilution effect, leading to lower measured
 levels, which might fall below the limit of detection.
- In the context of SARS-CoV-2, when comparing the relationship between wastewater loads and case 263 data, we noticed that correlation coefficients were higher when clinical data were aggregated on a 264 weekly level compared to daily data. This observation might be attributable to the intra-week variability 265 in case reporting, or to a reduction of daily fluctuations of wastewater measurements when averaging 266 over seven days. Additionally, as the monitoring period was characterized by two distinct waves, we 267 observed a weaker relationship between wastewater loads and clinical cases during the spring-summer 268 surge. This observation could be attributable to a decline in testing behavior during summer months or 269 to the KP.2 variant potentially causing a less symptomatic infection. 270
- Our study possesses some limitations. Despite reporting good assay sensitivity, considerable variations in pathogen concentrations in wastewater might lead to a reduction in sensitivity for detecting lowprevalence targets. Our results strongly suggest that WBS can be particularly valuable in settings where traditional surveillance systems are limited or inaccessible, such as resource-constrained areas or regions with inadequate healthcare facilities. However, we recognize that such an implementation and surveillance framework require a robust infrastructure, which may be challenging to establish in lowand middle-income countries.
- Overall, we described a six-plex dPCR assay targeting four respiratory viruses and its application to Swiss wastewater. This allowed the identification and description of viral epidemiological trends at high temporal resolution over one entire year. The results demonstrated that tracking of priority clinical respiratory pathogens in wastewater provides data complementary to clinical-based surveillance. We believe that continued surveillance is crucial for long-term analysis and will provide insights into epidemiological trends and a more comprehensive understanding of pathogen dynamics over time, enabling more effective public health interventions.

285 MATERIALS AND METHODS

286 Experimental design

We developed a six-plex digital PCR (dPCR) assay targeting four respiratory viruses: SARS-CoV-2 N1 and N2 genes (N1 and N2), Influenza A M gene (IAV-M), Influenza B M gene (IBV-M), and Respiratory Syncytial Virus N gene (RSV-N), as well as Murine Hepatitis Virus M gene (MHV-M) which is used as an internal control for RNA extraction efficiency. The assay was applied to wastewater samples collected four or five times per week at 14 wastewater treatment plants from the 10th of July 2023 until the 22nd of July 2024.

293 Wastewater treatment plants

Fourteen wastewater treatment plants (WWTPs) were monitored across Switzerland. The treatment plants provide service to approximately 2.3 million inhabitants across different regions (Supplemental Table S1), which corresponds to 26% of the national population.

297 Wastewater sample processing and nucleic acid extraction

Raw 24-hour composite wastewater samples, routinely collected by WWTP personnel, were stored at 4°C and transported on ice to our laboratory at the Swiss Federal Institute of Aquatic Science and Technology (Eawag) in Dübendorf once a week. Samples were processed on the day of reception at Eawag which resulted in a delay between collection and processing of 2-7 days depending on the sample. Generally, five samples from each WWTP were processed weekly before 1st June 2024, then four per week afterwards.

For each sample, nucleic acids were extracted from 40 mL of wastewater using a modified version of 304 the Wizard Enviro Total Nucleic Acid Kit (Promega Corporation, USA, Cat. No. A2991), as previously 305 described¹⁵. A blank extraction control, consisting of tap water, was included in each extraction run to 306 control for contamination during extraction. Nucleic acids were eluted in 80 µL RNase-free water and 307 then purified using the OneStep PCR Inhibitor Removal Kit (Zymo Research, USA. Cat. No. D6030). 308 309 Prior to dPCR analysis, extracts were further diluted in RNase-free water to minimize PCR inhibition (generally three-fold, however five-fold for Chur, Lugano, Basel and Geneva from August 2023 to March 310 2024). Typically, extracts were analyzed using dPCR immediately following their preparation on the 311 same day. Extracts were stored for long-term preservation at -80°C. 312

313 **Positive controls**

Positive controls used in dPCR assays were prepared by combining and mixing nucleic acid templates
 to achieve approximately 500 gene copies per µL for each target. Synthetic viral RNA was used for
 SARS-CoV-2, whereas gBlocks® were used for Influenza A and B, and RSV. Positive material for MHV

317 was obtained by extracting RNA from cultured material (Supplemental Table S6).

318 Digital PCR assays

All dPCR assays were developed on the Naica® system 6-color Crystal Digital PCR Prism-6 (Stilla Technologies, France). In this study, a six-plex assay, referred to as RESPV6, was developed. RESPV6 was created by merging two previous assays used in the Swiss monitoring program: i) a duplex assay (targeting the SARS-CoV-2 nucleoprotein gene locus 1 [N1] and the MHV matrix protein [M]), and ii) a previously described four-plex assay, known as RESPV4, with some modifications¹⁵. The RESPV4 was

adapted for targeting the SARS-CoV-2 nucleoprotein gene locus 2 (N2), the Influenza A and B matrix
 protein genes (M), and the Respiratory Syncytial virus nucleoprotein gene (N). Primers and probes are
 listed and described in **Table 1** and were purchased from Microsynth AG or IDT (Switzerland).

The RESPV6 assay was prepared using a total 27 µL pre-reaction volume, which consisted of 5.4 µL of 327 template and 21.6 µL of mastermix. The mastermix was prepared as follows: qScript XLT One-Step RT-328 329 qPCR ToughMix (2x) (Quantabio, USA, Cat. No. 95132), 0.5 µM of each forward and reverse primer, 0.2 µM of each probe, SARS-N2 CDC Kit (0.125 µM of probe, 0.5 µM of primers, Integrated DNA 330 Technologies, USA, Cat. No. 10006713,), 0.05 µM of fluorescein sodium salt (VWR, Cat. No. 0681-331 100G), and RNase-free water. The reaction volume (25 µL) was loaded into Sapphire chips (Stilla 332 Technologies). Chips were loaded into a Geode (Stilla Technologies) which partitions the mastermix 333 into droplets (12 min at 40°C; droplet volume: 0.519 nL) before thermocycling using the following 334 conditions: reverse transcription (50°C for 1 h), enzyme activation (95°C for 5 min), and 40 cycles of 335 denaturation (95°C for 30 s) and annealing/extension (57.5°C for 1 min). 336

337 One Geode can run three Sapphire chips in parallel, each containing four chambers, such that 12 samples can be analyzed at once. Generally, five wastewater nucleic acid extracts were run in technical 338 duplicates, alongside a positive control and a no-template control (NTC). To pass quality control the 339 positive control must have signal and the NTC must have fewer than three positive partitions. 340 Additionally, there should be a minimum of 15'000 analyzable droplets. Reported data are the average 341 of the technical replicates, although chamber failure occasionally occurred resulting in data from a 342 singlet being taken. Reported data are the average of the technical replicates, although chamber failure 343 occasionally occurred resulting in data from a singlet being taken. Our dPCR setup follows the digital 344 MIQE (dMIQE) guidelines³⁴ as detailed in Annex 1. 345

346 PCR inhibition quality control

PCR inhibition in the RESPV6 assay was evaluated using a three-step approach as previously described²². First, the sample was analyzed to quantify the SARS-N1 target present in the wastewater matrix using the RESPV6 assay. In the second step, a known quantity of SARS-N1 RNA was spiked into the extract (approximately 750 gene copies per reaction), and the total SARS-N1 concentration was measured again with the same RESPV6 assay. Finally, inhibition was calculated using the following equation (1):

$$Inhibition (\%) = 1 - \left(\frac{Cobserved}{Coriginal + Cspike}\right)$$
(1)

where: $C_{observed}$ is the concentration of SARS-N1 measured after spiking the sample with a known quantity of SARS-N1, $C_{original}$ is the concentration of SARS-N1 in the unspiked samples, and C_{spike} is the concentration of SARS-N1 added as the spike-in.

An inhibition value of 0% indicated no inhibition, suggesting that the PCR reaction efficiency was unaffected by the sample matrix. Conversely, a value of 100% indicated complete inhibition, where the PCR amplification of the measured concentration in the spiked assay resulted in no detection of the N1 assay in the wastewater extract. Values between 0 and 100% reflected partial inhibition, with higher values indicating higher levels of inhibition. Negative inhibition values, which are observed when C_{observed}

- is higher than the sum of Coriginal and Cspike, are due to experimental variability, and are interpreted as an 362 absence of inhibition. Our internal threshold for re-running a sample was set at 40%; samples with 363 364 inhibition values above this threshold were considered inhibited and were subjected to re-analysis at a higher dilution to reduce inhibition depending on concentrations of SARS-CoV-2 in the wastewater. 365 366 SARS-N1 inhibition served as a representative for the other targets. Measured RNA concentration was
- not corrected based on the quantitative estimates of inhibition. 367

RNA extraction efficiency quality control 368

To determine the efficiency of RNA extraction, a known amount of viral control (Murine Hepatitis Virus 369 strain MHV-A59, or MHV) was spiked into wastewater prior to processing (target concentration: 10'000 370 gene copies per ml of wastewater⁸) and measured using dPCR in the resultant extract. Culturing of MHV 371 was performed in delayed brain tumor cells, at the École Polytechnique Fédérale de Lausanne (EPFL), 372 as previously described³⁵. Three out of every five samples (two out of every four samples after the 1st 373 June 2024) per week per WWTP were spiked with MHV. The recovery was determined by dividing the 374 measured concentration by the estimated spiked concentration and expressing the result as a 375 percentage. Measured RNA concentration was not corrected based on the quantitative estimates of the 376 extraction efficiency. 377

Data analysis and viral load calculation 378

All dPCR data were analyzed using the Crystal Miner Software version 4.0 (Stilla Technologies), which 379 provides RNA quantities expressed as gene copies per microliter of reaction (gc/µl of reaction). 380 Wastewater samples were defined as positive when the concentration was above the limit of detection 381 (LoD), which was set at approximately five gc per reaction, and corresponds to a threshold of at least 382 three positive partitions. Values were transformed to gene copies per liter of wastewater (gc/L_{ww}), 383 according to the following equation (2): 384

$$385 \qquad Conc. \left(\frac{gc}{Lww}\right) = PCR \ conc. \left(\frac{gc}{\mu l}rxn\right) \times dilution \ factor \ \times \ \frac{Reaction \ vol.(\mu l)}{Template \ vol.(\mu l)} \ \times \ \frac{Elution \ vol.(\mu l)}{Wastewater \ vol.(m l)} \times 1000 \tag{2}$$

386 Viral RNA concentrations were adjusted by multiplying with the flow rate on the day of sampling at the influent of the WWTP and dividing by population in the catchment area. These values are referred to as 387 viral loads and are expressed in gene copies per person per day (gc person⁻¹ day⁻¹). 388

A national median of viral loads was obtained by taking the median value over the WWTPs which have 389 data for a particular day. The centered seven-day rolling median of these data points was then taken to 390 visualize the trend. 391

Comparison with clinical data from different sources 392

The Swiss Federal Office of Public Health (FOPH) collects clinical data about respiratory viruses mainly 393 through two survey systems: the mandatory reporting system and the Swiss Sentinel System 394 (Sentinella)³⁶. The mandatory reporting system provides clinical data (i.e., clinical cases) for SARS-CoV-395 2, Influenza A and Influenza B. Publicly available data from the mandatory reporting system are grouped 396 per week for the total Swiss population (8'855'062 inhabitants in 2024, including 39'677 inhabitants from 397 Liechtenstein), and additionally the SARS-CoV-2 data is stratified by geographical location at the 398 cantonal level. For this study, we additionally obtained data from the FOPH at daily resolution and 399 stratified by canton. In contrast, the Sentinella system is a voluntary reporting system involving around 400

160 to 180 medical doctors and provides data for the four pathogens covered by our RESPV6 assay,
 including RSV³⁶. Sentinella data are only available as total number of cases reported per week with no
 geographical location information available.

- Since public case data for all the pathogens was only available at the national level, the national median of viral loads in wastewater was used for comparison. Additionally, due to the clinical data being grouped by week we computed a weekly average of our national wastewater load data by taking the mean daily value for each of the targets for each week. These national weekly averages were used for correlation analysis with case data.
- Time-lagged cross-correlation analyses were performed to detect possible lag relationships between the viral loads in wastewater and clinical cases for each of the four pathogens. Wastewater data was shifted forward by a maximum of four weeks and cross-correlation was computed using Pearson correlation. Correlation analysis and time-lagged cross-correlation were also carried out on the daily resolution clinical data made available by the FOPH. Here, there was no requirement to aggregate wastewater viral load data. Case data at the cantonal level was matched to wastewater load data based on the canton where the WWTP is located (Supplemental Table S1).

416 **DATA AVAILABILITY**

Digital PCR data are available for download from <u>wise.ethz.ch</u>. Only data which passed our described quality control processes are available here. All data is available on request. Weekly case data are available from the Federal Office of Public Health (FOPH) via a public <u>API</u>. Daily case data were specifically requested from the FOPH. All code used in the analysis is available on <u>GitHub</u>.

perpetuity. It is made available under a CC-BY 4.0 International license .

535 ACKNOLEDGEMENTS

We would like to thank present and past members of the Laboratory Monitoring Team for developing the methods, processing samples and generating and analyzing data. Additionally, we thank present and past collaborators of the WISE (Wastewater-based Infectious disease Surveillance and Epidemiology) project for their support and valuable intellectual contributions, and NEXUS for their setting up and supporting the WISE database (wisedb.ethz.ch) which facilitated our analysis. We thank the technical staff of each WWTP for promptly sending us the wastewater samples on a weekly basis, and Anna Carratala Ripolles and Tamar Kohn for providing us with MHV.

543 AUTHORS' CONTRIBUTIONS

544 CO and TRJ conceptualized, supervised, and provided funding. MP and REM designed the study, 545 performed analyses, prepared visualizations, and wrote the first draft of the manuscript. LC, JdK, CG, 546 and SK contributed invaluable scientific insights. PS provided statistical support. AD, CH, AH, GL, LS, 547 AW, and DY helped with sample processing, data generation and curation. All authors reviewed, edited, 548 and approved the final version.

549 FUNDING

550 This study was funded by the Swiss National Science Foundation (SNSF Sinergia Grant Nr. 551 CRSII5_205933) and by the Swiss Federal Office of Public Health grant to CO and TRJ.

552 CONFLICTS OF INTEREST

553 None.

554 AUTHORS' STATEMENT

555 We declare that all authors have seen and approved the manuscript and have contributed significantly

to the work. Some data and figures from the manuscript presented here have been used to create a

report to the primary funding body, the Swiss Federal Office of Public Health. The report was briefly

558 made public (September – November 2024).

SARS-CoV-2 RNA concentration according to N1 gene [gc/Lww]

Figure 2. SARS-CoV-2 RNA concentrations comparing N1 and N2 genes. Concentrations are 574 expressed in gene copies per liter of wastewater (gc/Lww) and shown on a log scale. The grey dashed 575 line indicates the identity line. The linear regression line is shown in blue. 576

Figure 3. SARS-CoV-2 N1 and N2 load in wastewater across 14 Swiss locations. SARS-CoV-2 578 RNA loads, expressed in gene copies (gc) per person per day, were calculated for N1 and N2 genes. 579 Measured RNA loads are represented with a circle (blue for SARS-N1 and teal for SARS-N2), whereas 580 the respective seven-day rolling medians are displayed with solid lines. Each panel indicates a different 581 WWTP. For visualization purposes, some very high load values are not visible in the plots and are listed 582 in Supplemental Table S7. 583

Figure 4. Influenza A, Influenza B and RSV RNA loads in wastewater across 14 Swiss locations. 585 Viral RNA loads were expressed in gene copies (gc) per person per day. Measured RNA loads are 586 represented with a circle (red for IAV, green for IBV, and yellow for RSV), whereas the respective seven-587 day rolling median is displayed with solid lines. Each panel indicates a different WWTP. For visualization 588 purposes, some very high load values are not visible in the plots and are listed in Supplemental Table 589 **S7**. 590

591

Figure 5. Comparison of viral RNA loads in wastewater and number of cases from Sentinella system. Positive cases, expressed in absolute numbers, refer to the entire Swiss territory, and were taken from the Sentinella database. Cases are shown using light grey bars. Some high load values are beyond the plotted y-max values. They are listed in Supplemental Table S7. This figure has been formatted using Inkscape.
