# 18 ABSTRACT

19	Carotenoids are dietary bioactive compounds with health effects that are biomarkers of fruit and
20	vegetable intake. Here, we examine genetic associations with plasma and skin carotenoid
21	concentrations in two rigorously phenotyped human cohorts (n=317). Analysis of genome-wide
22	SNPs revealed heritability to vary by genetic ancestry (h <sup>2</sup> =0.08–0.44) with ten SNPs at four loci
23	reaching genome-wide significance (P<5E-08) in multivariate models, including at RAPGEF1
24	(rs3765544, P=8.86E-10, beta=0.75) with α-carotene, and near <i>IGSF11</i> (rs80316816, P=6.25E-
25	10, beta=0.74), with cryptoxanthin; these were replicated in the second cohort (n=110). Multiple
26	SNPs near IGSF11 demonstrated genotype-dependent dietary effects on plasma cryptoxanthin.
27	Deep sequencing of 35 candidate genes revealed associations between the PKD1L2-BCO1 locus
28	and plasma $\beta$ -carotene (Padj=0.04, beta=-1.3 to -0.3), and rare, ancestry-restricted, damaging
29	variants in CETP (rs2303790) and APOA1 (rs756535387) in individuals with high skin
30	carotenoids. Our findings implicate novel loci in carotenoid disposition and indicate the
31	importance of including cohorts of diverse genetic ancestry.

# 33 INTRODUCTION

34	Carotenoids are a diverse group of natural pigments produced by plants, fungi, algae, and
35	photosynthetic bacteria. While there are over 1000 identified carotenoid species in nature <sup>1</sup> , six
36	species ( $\alpha$ -carotene, $\beta$ -carotene, cryptoxanthin, lycopene, lutein, and zeaxanthin) constitute more
37	than 95% of total human blood carotenoids <sup>2</sup> . Humans cannot synthesize carotenoids
38	endogenously, thus primarily acquire carotenoids from dietary fruits and vegetables (FV), mostly
39	in the form of $\beta$ -carotene, lycopene, and lutein/zeaxanthin <sup>3,4</sup> . Carotenoids are absorbed,
40	metabolized, and distributed throughout the blood, skin, and other tissues in a manner similar to
41	dietary lipids <sup>4</sup> . Carotenoid activities depend on their chemical properties, which can be pro-
42	vitamin A, nuclear receptor signaling, light filtering, or antioxidant/anti-inflammatory <sup>3,4</sup> .
43	Because carotenoids are absorbed, retained in the body for a moderate amount of time, and are
44	detectable by spectroscopy, carotenoid concentrations, measured in plasma and more recently
45	non-invasively measured in the skin, have been proffered as biomarkers for dietary fruit and
46	vegetable intake assessment in adults and children <sup>5,6</sup> .
47	Epidemiologic, clinical, and preclinical studies also indicate that carotenoids are
48	associated with protection from many chronic diseases, including cancers, cardiovascular
49	disease, and macular degeneration <sup>4</sup> . Their importance lies in their ability to modulate
50	intracellular signaling, offering antioxidant, antiapoptotic, and anti-inflammatory properties that
51	protect cells from oxidative stress, UV damage, and support functions like vision and immune
52	response <sup>3</sup> .
53	While carotenoid plasma and tissue concentrations are primarily a function of dietary
54	intake, there is still substantive inter-individual variation in plasma and tissue carotenoid

55 concentrations. Age, body mass index (BMI), and smoking have all been implicated as

It is made available under a CC-BY-NC-ND 4.0 International license .

56	environmental contributors to this inter-individual variation. Genetic variation is known to also
57	contribute to this variation <sup>4,7-10</sup> . For instance, in Mexican American children, the heritability of
58	plasma carotenoid concentrations has been quantified, with $\alpha$ -carotene demonstrating a
59	heritability (h <sup>2</sup> ) of 0.81 (P = $6.7 \times 10E-11$ ) and $\beta$ -carotene exhibiting an even higher heritability
60	of 0.90 (P = $3.5 \times 10E-15$ ) <sup>8</sup> . However, a detailed understanding of how genetic variation
61	influences interindividual remains unclear. A handful of early epidemiologic and clinical studies
62	found associations between common SNPs in select lipid and carotenoid metabolism genes and
63	blood concentrations of specific carotenoid species <sup>11-15</sup> . An early genome-wide association study
64	(GWAS) in European populations identified an association with genetic variation near $\beta$ -
65	carotene 15,15-dioxygenase $(BCO1)^{12}$ , the key enzyme responsible for central cleavage of
66	provitamin A carotenoids to yield vitamin A <sup>16</sup> . At the tissue-specific level even less is known
67	about the impact of genetic variation on carotenoid levels; carotenoids in the macula of the eye
68	have been associated with SNPs in BCO1, BCO2, NPC1L1, ABCG8, and FADS2 <sup>17-19</sup> , and in
69	small studies, carotenoids in prostate and skin have been associated with SNPs in the same
70	genes <sup>9,20</sup> , albeit without subsequent replication of results.
71	To date, a broadly comprehensive understanding of how human genetic variation
72	influences plasma and tissue carotenoid concentrations, particularly bioactive carotenoid species,
73	remains elusive. This knowledge gap is strikingly evident for populations with non-European
74	ancestral backgrounds, as most prior studies have focused on individuals of European descent.
75	For example, early studies linking variants in <i>BCMO1</i> (aka <i>BCO1</i> ) to plasma $\beta$ -carotene levels <sup>12</sup>

and variants in *RBP4* (retinol-binding protein 4) to circulating retinol (a carotenoid metabolite)

<sup>77</sup> levels<sup>21</sup> were both conducted in homogenous Eurocentric cohorts. Additionally, *SCARB1* (a key

receptor for carotenoid uptake) has been associated with plasma lycopene levels in multiethnic

It is made available under a CC-BY-NC-ND 4.0 International license .

populations under certain conditions such as in postmenopausal women, though the effect sizes vary across groups<sup>22</sup>. The lack of unbiased genome-wide analyses, particularly in ancestrally diverse cohorts, restricts the generalizability of carotenoid genetics findings, limiting their applicability in both population and precision nutrition strategies<sup>23-25</sup>. Conducting comprehensive studies in diverse populations is thus essential going forward, as efforts to implement precision medicine and nutrigenomic initiatives, and identify biomarkers that can be used across population groups, intensify.

86 Here, we leverage detailed phenotypic data (including age, sex, BMI, self-reported 87 race/ethnicity, and food intake), and rigorous plasma and skin carotenoid assessments from two 88 ancestrally and geographically diverse US cohorts to conduct both genome-wide and targeted 89 (sequence-based) association studies of plasma carotenoid species and skin carotenoid levels. We 90 identify novel population common- and rare- genetic variants associated with steady-state and 91 diet-responsive carotenoid levels. Further, we reveal ancestry-specific differences in heritability 92 and genetic association. Using data derived from a controlled dietary intake study, we also 93 uncover gene-by-dosage interactions at associated loci. Collectively, our findings highlight 94 previously unrecognized genetic heterogeneity in human carotenoid metabolism, providing a 95 foundation for advancing precision nutrition and understanding global health and nutrigenetics. 96

# 97 **RESULTS**

Genetic studies were conducted in two extensively characterized, previously described
cohorts<sup>26,27</sup> (Methods). The primary discovery cohort comprised 213 individuals (207 after QC
and familial relatedness check) from four self-reported United States (US) racial and ethnic
groups (Asian, Hispanic, Non-Hispanic Black, and Non-Hispanic White) (Supplementary

It is made available under a CC-BY-NC-ND 4.0 International license .

102	<b>Table S1</b> ). Participants were recruited from two sites in the US, and had extensive clinical,
103	lifestyle, and demographic phenotype data documented alongside cross-sectional plasma
104	carotenoid species concentrations (measured by HPLC-photodiode array detection) and
105	aggregate skin carotenoids (skin carotenoid score - measured by non-invasive pressure mediated
106	reflection spectroscopy). These individuals were genotyped using the H3Africa genotyping
107	microarray (Illumina, CA, USA), designed to be used in genetically diverse populations. To
108	cover candidate loci that were not well-represented on the genotyping array, short-read capture-
109	based sequencing was performed across 35 genomic loci, which are reported to influence
110	carotenoid concentrations (Methods, Supplementary Table S7).
111	The secondary (intervention) cohort consisted of 162 individuals (Supplementary Table
112	S2), of whom 110 unique participants were not included in the primary cohort. Participants were
113	recruited from three sites, two of which were the same as the primary cohort, as part of a dietary
114	carotenoid intervention study. This study collected identical phenotypic data within a
115	longitudinal, randomized carotenoid-rich juice dose-response study. Data were collected at
116	baseline, 3-, and 6-weeks post-intervention for three mixed carotenoid doses (low/control (0
117	mg/d), moderate (4 mg/d), and high (8 mg/d)). This cohort underwent the same genomic
118	interrogation using the same platform and panel as the discovery cohort (Figure 1) (Methods
119	and Supplementary Methods). For genetic analyses, self-reported race/ethnicity was refined
120	through Multidimensional Scaling (MDS) of genomic information, aligning participants with
121	human ancestral populations based on the 1000 Genomes Project data (Figure 2A).
122	

# 123 Ancestral background influences carotenoid phenotype variability

It is made available under a CC-BY-NC-ND 4.0 International license .

124	Carotenoid concentrations in plasma and skin are influenced by a variety of factors,
125	including indistinct biological factors proxied by self-reported racial-ethnic background <sup>27,28</sup> .
126	Overall, we did not observe significant variation in the plasma carotenoid concentrations and
127	skin carotenoid levels among the four race/ethnicity groups in the Primary Study Cohort
128	(ANOVA); however, several significant differences in total plasma carotenoid levels were
129	observed among pairwise comparisons between the four primary cohort groups. Self-identified
130	non-Hispanic black and Asian individuals showed the most significant differences, including in
131	total plasma carotenoid (Welch's Two-Sample <i>t</i> -tests P = 0.021), plasma $\beta$ -carotene (P = 0.003),
132	and plasma lutein/zeaxanthin ( $P = 0.037$ ) (Figure 2B; Supplementary Figure S2). Additionally,
133	levels of $\alpha$ -carotene, lycopene, cryptoxanthin, and skin carotenoids differed significantly
134	between all four groups, with t-test p-values ranging from 8.67E-5 (non-Hispanic black vs. Asian
135	for $\alpha$ -carotene) to 0.031(non-Hispanic black vs. non-Hispanic white for lycopene) (Figure 2 and
136	Supplementary Figure S2), while without significant differencs between the EAS and SAS
137	(Supplementary Figure S3). Correlations between skin and plasma carotenoids were not
138	different between self-reported race and ethnicity <sup>27</sup> ; however, significant pair-wise differences in
139	skin carotenoid levels between self-reported groups mirrored observations in plasma carotenoids,
140	although the variance in the distributions of carotenoid species in groups was broader (Figure
141	2C).
142	The Primary Study Cohort included self-identified racial and ethnic groups consistent

with historical US census race and ethnicity categories; to appropriately contextualize these
groups for genetic studies, we aligned recruited individuals to genetic ancestry superpopulation
clusters from the 1000 Genomes Phase III dataset<sup>29</sup> using multi-dimensional scaling (MDS).
Most individuals identifying as 'white' and 'non-Hispanic black' clustered closely with 'European'

It is made available under a CC-BY-NC-ND 4.0 International license .

147	and 'African' genetic ancestry superpopulations, respectively. The reported 'Asian' race and
148	ethnic group, however, separated into two distinct clusters on the first two dimensions of the
149	MDS, with some individuals clustering with Indian/South Asian individuals (GIH) and others
150	aligning with East Asian ancestral groups (JPT, CHB) (Figure 2A). Individuals self-identifying
151	as 'Hispanic' clustered with mixed American and Hispanic ancestral groups (AMR). A small
152	group of individuals displayed notable discrepancies between their self-reported race/ethnicity
153	and genetic clustering (Figure 2A), including four individuals reported as 'white' and two
154	reported as 'Asian' whose genetic ancestry aligned more closely with 'South Asian' or 'Hispanic'
155	and 'AFR' super populations, respectively. (Figure 2A). For individuals discordant between self-
156	reported and genetically clustered ancestry, their genetic ancestry was used in downstream
157	analyses.

158

#### 159 The heritability of carotenoid concentration varies by carotenoid species and genetic ancestry

160 To evaluate heritability in our cohort and facilitate downstream genetic analyses, we 161 derived a curated, quality-controlled (QC) dataset of 1,917,156 genotyped single nucleotide 162 polymorphisms (SNPs) from 207 healthy, unrelated individuals (Supplementary Methods). 163 This dataset was used to impute a total of 26,084,710 SNPs utilizing the Michigan Imputation 164 Server<sup>30</sup>; with the 1000 Genomes Phase III v5 (GRCh37/hg19) reference panel serving as the 165 primary reference for this cohort of diverse US individuals. Further filtering for SNPs with a 166 correlation coefficient  $(r^2)$  of 0.3 or greater, and a minor allele frequency (MAF) greater than 167 0.05 resulted in a final dataset of 7,467,403 SNPs. Relative and absolute heritability of total and 168 sub-speciated plasma carotenoids, as well as skin carotenoid levels, was then calculated in 169 GCTA<sup>31</sup>(Methods) using QCed autosomal SNPs.

It is made available under a CC-BY-NC-ND 4.0 International license .

170 In our primary cohort, the overall estimated heritability of plasma carotenoids was low 171  $(h^2=0.08)$  albeit with a wide standard error (se= 0.157); perhaps unsurprising given the 172 substantial dietary contribution to the variance in carotenoid levels. Plasma lutein/zeaxanthin had 173 the lowest heritability estimate ( $h^2=0.09$ , se= 0.172) among carotenoid species, also reflecting a 174 heavy dietary influence. There was, however, notable variation in heritability estimates between 175 carotenoid species; for instance, plasma cryptoxanthin ( $h^2=0.44$ , se= 0.322) and  $\alpha$ -carotene ( $h^2=$ 176 (0.35, se= 0.338) had higher heritability estimates compared to other species, which were 177 generally <0.17 (Figure 3A, Supplementary Table S4). By contrast, the heritability of skin 178 carotenoids was considerably higher than that of total plasma carotenoids ( $h^2=0.08$  for plasma carotenoids versus  $h^2 = 0.30$  for skin carotenoids) and more consistent with estimates for  $\alpha$ -179 180 carotene (Figure 3A, Supplementary Table S4). 181 To better understand the contribution of genetic ancestry to interindividual variation in 182 carotenoid phenotypes, we also estimated heritability across each genetic ancestry group. Given 183 the modest size of the resulting sub-samples, which resulted in large standard errors, we focused 184 on heritability estimates relative to the entire Primary Study Cohort. The heritability of total 185 plasma carotenoids was found to be relatively consistent across groups, except among

186 participants genetically clustering with Hispanic individuals (Figure 3B), in whom it was 9x

187 higher. A similar trend was observed for plasma  $\alpha$ -carotene,  $\beta$ -carotene, and total lycopene,

188 which all exhibited higher relative heritability among Hispanic (AMR) clustering participants

189 (Figure 3B). By contrast, plasma cryptoxanthin had a relatively higher heritability (2.3x) among

190 African American clustering individuals (AFR), while the heritability of plasma lycopene was

191 notably higher among South Asian (SAS) clustering individuals (2.4x). The heritability of skin

192 carotenoids was highest among East Asian (EAS) clustering individuals (3.3x) (Figure 3B).

It is made available under a CC-BY-NC-ND 4.0 International license .

- 193 Generally, ancestry-specific relative heritability for skin carotenoids was higher among groups194 outside of the European genetic cluster (Figure 3B).
- 195

# 196 Common variants at novel loci are associated with plasma, but not skin, carotenoid

197 concentrations

198 Given the relatively high heritability of some of the carotenoid species, we next sought to 199 identify genetic loci with significant effects on carotenoid concentrations across our diverse 200 cohort. Carotenoid measurements were log<sub>2</sub>-transformed to provide a better approximation of a 201 normal distribution to be used in our statistical models (Supplementary Table S3). For most 202 measurements, such as plasma and food carotenoids, the log2-transformed values showed 203 improved normality (e.g., for food carotenoids, W = 0.794; P = 9.691E-16 in the original data, W 204 = 0.993 and P = 0.422 after log<sub>2</sub> transformation) (Supplementary Table S3). However, for skin 205 carotenoid measurements, the original values had a better fit to normality. Using the transformed 206 plasma values, we first conducted a genome-wide association study (GWAS) of total carotenoids 207 and carotenoid species concentrations in plasma using linear regression models as implemented 208 in GEMMA and incorporating covariates of age, sex, BMI, log<sub>2</sub>-transformed carotenoid intake, 209 and the first two MDS dimensions (Supplementary Figure S1).

In our analysis of plasma carotenoids, we identified six SNPs at three loci that reached genome-wide significance (P = 5E-08) for either total- or plasma carotenoid species (**Table 1**, **Figure 4**). A total of 37 SNPs at 12 loci surpassed a more permissive suggestive association threshold (P < 5E-06). The strongest association was observed between plasma  $\alpha$ -carotene concentrations and rs3765544 (chr9:134458148:G>A) on chromosome 9q34 (P = 8.86E-10, beta = 0.750; **Table 1, Figures 4B & 4G**), located in the intronic 24 region of the *RAPGEF1* gene.

It is made available under a CC-BY-NC-ND 4.0 International license .

216	This SNP had an effect size translating to an increase of 68% more $\alpha$ -carotene concentration per
217	allele. RAPGEF1 encodes a guanine nucleotide exchange factor involved in the activation of Ras
218	family GTPases <sup>32,33</sup> that plays a role in several cellular signaling pathways <sup>34,35,36</sup> , and it is widely
219	expressed in tissues such as skeletal muscle and adipose tissue. Notably, the same SNP allele (G)
220	at this locus also showed marginal association (P = 6.43E-08, beta = 0.789) with $\beta$ -carotene
221	levels (Table 1, Figure 4C & 4F Supplementary Table S5), suggesting shared activity.
222	Consistent with the high heritability seen for plasma cryptoxanthin, we observed two
223	genome-wide significant loci associated with plasma cryptoxanthin concentrations: 1) multiple
224	SNPs downstream of IGSF11 on chromosome 3q13 (Figure 4A & 4D; top SNPs:
225	chr3:118521532:T>C (rs80316816), P=6.25E-10, beta=0.08; chr3:118494728:C>G
226	(rs76613159) P=4.95E-09, beta=0.08; chr3:118446886:T>C (rs76087842) P=8.32E-09, beta =
227	0.08) and 2) an intergenic locus on chromosome 19p13, comprising multiple SNPs (Figure 4E;
228	top SNPs: chr19:893793:C>A (rs28468554), P=6.26E-09, beta=-0.462). Collectively, these two
229	loci account for approximately 32.95% of the variance in cryptoxanthin concentration. The 3q13
230	locus includes (within 50kb) genome-wide significant SNPs associated with education
231	attainment in two large studies <sup>37,38</sup> and may not be regulatorily related to the closest gene
232	(IGSF11). In the Genotype-Tissue Expression (GTEx) database <sup>39</sup> the top SNP on 19p13
233	(rs28468554) is an expression quantitative trait locus (eQTL) SNP for MED16 in multiple
234	tissues. MED16 encodes a protein of the same name that is a component of the mediator
235	complex <sup>40</sup> , which enables thyroid hormone and vitamin D3 receptor binding <sup>41,42</sup> .
236	We used the same GWAS model to evaluate SNPs associated with skin carotenoids, but
237	for this analysis, we also included measurements of melanin and hemoglobin - both of which are

thought to influence skin carotenoid measurements<sup>27</sup> - as covariates. No variants surpassed either

It is made available under a CC-BY-NC-ND 4.0 International license .

239 the genome-wide or suggestive association threshold. We considered that by including skin tone 240 measurements and accounting for ancestry (as modeled in GEMMA), we may have 241 overcorrected for the ancestry effect; that is, if melanin and hemoglobin are collinear with some 242 genetic ancestries, also incorporating components reflecting genetic ancestry could be redundant. Therefore, we reran the association using only clinical covariates (i.e. without MDS coordinates 243 244 or race/ethnicity) (Supplementary Figure S4A). This yielded 107 SNPs surpassing our genome-245 wide significance threshold (**Supplementary Figure S4B**, genomic inflation factor = 2.06); this 246 suggested a strong effect of ancestry (population stratification) and was reflected in disparities in 247 minor allele frequencies at 'associated' loci between different genetic ancestry groups 248 (Supplementary Figure S4D). This disparity in association with and without ancestry 249 adjustments was not observed in the plasma carotenoid association analyses (Supplementary 250 Figure S4C). 251 252 Replication and gene-by-dosage effects of carotenoid candidate SNPs 253 To replicate our primary cohort findings, we conducted genome-wide genotyping in a 254 secondary cohort derived from a dietary carotenoid intervention study with a similar study 255 design<sup>26</sup> (Methods). This secondary cohort was smaller in size (n=162) and had a larger 256 proportion of Hispanic clustering (AMR, 23% vs. 14%), and a smaller proportion of European 257 clustering (EUR, 27% vs. 33%), individuals relative to our initial cohort (Figure 1). The 258 distribution of sex in the second cohort (male: n=79, 49%; female: n=83, 51%) is nearly equal, 259 contrasting with the predominantly female first cohort (male: n=62, 29%; female: n=151, 71%).

- 260 while age (median age = 29 years) was not different between the two cohorts (**Supplementary**
- 261 **Table S1 & S2**). Secondary cohort samples were genotyped on the same platform and underwent

It is made available under a CC-BY-NC-ND 4.0 International license .

identical quality control procedures as the primary cohort. We used baseline (pre-intervention)
plasma carotenoid and species measures as the outcome phenotype, applying the same GWAS
covariates and linear regression models in GEMMA with the 110 non-overlapping individuals
(i.e. only unrelated individuals who did not participate in the primary cohort were included in
analyses).

Meta-analysis between the two cohorts was then conducted in METAL<sup>43</sup> for the 37
 suggestive threshold SNPs (representing 12 loci). We found nominal evidence for replication of

269 the same carotenoid species (cryptoxanthin) at the same two loci noted in our primary analysis

270 (*IGSF11* at 3q13 and *RNF111/MED16* at 19p13). Meta-analysis of rs1088589 at *IGSF11* 

surpassed genome-wide significance, with a similar direction and magnitude of effect in both

cohorts (p = 9.69E-08, beta = 0.532) (**Table 1**). Additionally, several other SNPs in this region (8

out of 12) surpassed the suggestive meta-analysis threshold (P < 1E-06) and exhibited the same

direction of effect. Two imputed SNPs, including our top SNP in *RAPGEF1*, were not observed(imputed) in the secondary cohort and thus could not be replicated.

276 The interventional study design in our secondary cohort involved randomizing 277 participants to receive low, moderate, or high doses of dietary carotenoids via a daily, 278 carotenoid-enriched, fruit and vegetable juice, with skin and plasma carotenoid concentrations 279 measured at baseline (time 0) as well as 3- and 6-weeks post-intervention. This study design 280 allowed us to investigate whether SNPs at candidate loci identified in our primary cohort might 281 also influence the accumulation of carotenoids over time. We applied linear regression models 282 (Methods), incorporating the same covariates as in our initial study, along with additional terms 283 for intervention time points and a gene-by-dosage interaction effect (Methods). Of the 37 284 candidate SNPs identified in the discovery cohort and evaluated in the Intervention Cohort

It is made available under a CC-BY-NC-ND 4.0 International license .

(Supplementary Table S5 and S6), 32 (86.5%) had significant F-statistic p-values (<0.05),</li>
indicating a statistically significant relationship with the outcome variable (plasma carotenoid
concentration). Additionally, six (16.2%) SNPs – upstream of *IGSF11* (n=5) associated with
cryptoxanthin exhibited gene-by-dosage effects, where the effect of genotype on plasma
carotenoid concentrations differed by intervention dosage (Figure 5A-F, Supplementary
Figure S5).

291

#### 292 Target sequencing captures association between PKD1L2 and $\beta$ -carotene concentrations

293 Previous genome-wide studies have demonstrated an association between  $\beta$ -carotene and common variants upstream of  $\beta$ -carotene oxygenase 1 (*BCO1*)<sup>12</sup>. However, our primary GWAS 294 295 dataset lacked strong evidence for this. Whilst population differences (Eurocentric vs diverse 296 cohort) and sample size undoubtedly underlie part of this observation, we also noted low 297 coverage (few polymorphic SNPs) in this region on the genotyping array used; this is a known 298 limitation of array-based studies in genetically diverse populations<sup>44,45</sup>. To address this, we 299 performed targeted sequencing of a subset of candidate genes (Supplementary Table S7) 300 identified from the literature<sup>4,46,47</sup> and not adequately covered by the array. This sequencing provided consistent median coverage across targeted loci (chr16:81101012-81220480), with 301 302 *PKD1L2*, upstream of *BCO1*, exhibiting a higher number of variants than other genes 303 (Supplementary Figure S7). 304 *PKD1L2* single nucleotide variants (SNVs) were the only SNVs from our targeted

305 sequencing cohort that were consistently associated with plasma or skin carotenoid levels in our 306 linear regression models, specifically with  $\beta$ -carotene concentrations. This association remained 307 significant when comparing the top third versus the bottom third of  $\beta$ -carotene concentrations

It is made available under a CC-BY-NC-ND 4.0 International license .

308 (Supplementary Figure S7). *PKD1L2* variants also showed the strongest associations in the 309 replication cohort, with a similar direction (positive association) and effect sizes across the two 310 cohorts, though the specific variants differed (Supplementary Figure S7). The *PKD1L2* locus is 311 found upstream of *BCO1*, in a region consistently associated with  $\beta$ -carotene concentrations. 312 Although our targeted capture did not directly sequence previously reported SNPs upstream of 313 BCO1<sup>11</sup>, linkage disequilibrium (LD) patterns suggest that PKD1L2 variants are likely to be in 314 the same LD block. As the *BCO1-PKD1L2* association was initially observed among the 315 European genetic ancestry group, we evaluated genotypes and  $\beta$ -carotene levels across our four 316 genetic ancestry groups. The top two SNPs (rs4148211 and rs7194871) were analyzed for 317 associations with  $\beta$ -carotene concentrations across four ancestry groups. A nominally significant 318 association was observed for rs4148211 in the Asian group (P=0.012, n=51), while no significant 319 associations were found for rs7194871 (p>0.5). 320 321 Rare, protein-damaging variants are observed in individuals with outlier carotenoid 322 concentrations 323 Rare, protein-damaging variants in coding regions of genes can have large effects on 324 physiologic traits<sup>48</sup>. We, therefore, looked for rare, putatively protein-damaging variants 325 (Supplementary Methods) among individuals with extreme values (>2SD or <2SD) for either 326 plasma or skin carotenoids across Primary Study Cohort (Supplementary Table S8). 327 In the Intervention Cohort, we identified an individual carrying a rare, predicted-328 damaging, missense coding variant (Supplementary Table S9) (rs142824860, 329 NC\_000016.9:g.81272554A>G; p.Glu14Gly; gnomAD MAF = 9.7E-05; CADD score 25.0) 330 (Supplementary Methods) in the *BCO1* gene who also had the lowest plasma  $\beta$ -carotene

It is made available under a CC-BY-NC-ND 4.0 International license .

331	concentrations in the cohort. For skin carotenoid concentrations, three notable outliers were
332	observed: two of these individuals clustered with the 1000 Genomes EAS population, and both
333	individuals carried a missense coding variant in CETP (rs2303790, NM_000078.3:c.1376A>G;
334	p.Asp459Gly; gnomAD MAF = 0.002) that is seen in 3% of East Asian (EAS) clustering
335	individuals but <1% in all other populations. The third outlier, clustering with other European
336	(EUR)-identifying individuals, possessed an ultra-rare (MAF=9.9E-06) variant in APOA1
337	(rs756535387; p.Arg201Ser; CADD score 24.0), predicted to be deleterious with an
338	AlphaMissense score of 0.701 (likely pathogenic) (Supplementary Methods). All three outliers
339	also had elevated plasma cryptoxanthin concentrations, which were strongly correlated with skin
340	carotenoid levels ( $r = 0.57$ ; Figure 6).
341	
342	DISCUSSION
343	Through GWAS and targeted sequencing analyses in two ancestrally diverse cohorts, we
344	provide comprehensive estimates of heritability and the genetic architecture underlying plasma
345	and skin carotenoid concentrations. We find that heritability varies across plasma carotenoid
346	species and is influenced by genetic ancestry, with estimates being generally lower for plasma
347	carotenoids compared to skin carotenoids. Notably, we identify and replicate an association
348	between genetic variation at chromosomes 3q13 (upstream of IGSF11) and 19p13 (MED16) and
349	plasma cryptoxanthin concentrations and find evidence of gene-by-dosage effects at the 3q13
350	locus. We confirm the association between $\beta$ -carotene at the <i>PKD1L2-BCO1</i> locus and identify
351	putatively protein-damaging rare variants with large effects on skin and plasma carotene

352 concentrations.

It is made available under a CC-BY-NC-ND 4.0 International license .

353 We observed substantial heritability for plasma carotenoid species  $\alpha$ -carotene and 354 cryptoxanthin, as well as skin carotenoids, with estimates comparable to those observed for serum lipids such as cholesterol (ranging from 0.30 to 0.70)<sup>49,50</sup>; this is consistent with the shared 355 356 biochemistry and metabolism of serum lipids and carotenoids. We also noted significant 357 variation in heritability estimates across different genetic ancestry groups, with individuals 358 clustering with admixed Amerindians (AMR; self-identified 'Hispanic') exhibiting high 359 heritability for nearly all plasma carotenoid sub-species, including replication of the high 360 heritability of  $\alpha$ -carotene in previous studies among Mexican Americans (h<sup>2</sup> = 0.85 in this study; 361 0.81 in the previous study)<sup>8</sup>. Given that heritability represents the genetic contribution to total 362 variance, these results likely reflect the balance between genetic variation and differences in 363 typical dietary and environmental factors across groups. That some carotenoid species have 364 higher heritability estimates suggests that the metabolic events preceding their plasma 365 accumulation, such as intestinal absorption, are more sensitive to genetic variation. The public 366 health implication thereof is that dietary recommendations (or interventions) for certain 367 carotenoids (e.g. cryptoxanthin) aimed at achieving a specific plasma concentration range may 368 be more challenging to develop than for those carotenoid species with lower heritability. Larger 369 sample sizes will be important in further elucidating these differences and their public health 370 implications.

The distinct contributions of diet and genetics were further illustrated in our analyses of skin carotenoid heritability. Non-invasive measurements of the tissue accumulation of carotenoids in the skin present unique considerations. Principally, the efficiency of detecting colorimetric changes due to carotenoid accumulation in the skin depends partially on skin reflectivity, which may be influenced by skin melanin content and hemoglobin levels.

It is made available under a CC-BY-NC-ND 4.0 International license .

376 Previously, we demonstrated that, after adjusting for melanin, hemoglobin, and dietary intake, a 377 robust correlation remains between skin and plasma total carotenoid concentrations<sup>27</sup>, though we 378 subsequently did not find skin melanin and hemoglobin to be significant modulators of skin carotenoid responses to changes in dietary carotenoid intake<sup>10</sup>. Consequently, the apparent 379 380 heterogeneity in heritability estimates across ancestry groups could be a combination of 381 variability in confounding skin parameters and ancestral variability in factors influencing tissue 382 accumulation. The latter contention is worthy of consideration given the importance of 383 carotenoids to vitamin A metabolism, as carotenoids serve as precursors to retinoids, which are critical for maintaining skin health<sup>46</sup>. This highlights the potential influence of ancestral 384 385 variability on vitamin A-related physiological processes and the tissue accumulation of 386 carotenoids. Despite this, our understanding of the factors influencing tissue carotenoid 387 accumulation remains limited and warrants further investigation. 388 The relatively higher heritability for plasma cryptoxanthin was reflected in the number of 389 genome-wide- and suggestive associations compared to concentrations of other carotenoid

391 considered cryptoxanthin concentrations, and to the best of our knowledge, a role for genetic

species, especially at the 3q13 and 19p13 loci. Few if any previous genetic studies have

390

392 variation at these two loci has not previously been described. At 3q13, the closest gene, *IGSF11*,

393 encodes a member of an immunoglobulin superfamily<sup>51</sup> whose primary function is as a cell

394 adhesion molecule that stimulates cell growth<sup>52,53</sup>; however, in addition to neurocognition,

395 genetic variation at 3q13 has been implicated in gut microbiota diversity<sup>54,55</sup> and body mass

index<sup>56-58</sup>, suggesting that the full functional regulatory impact of this locus may not yet be well

understood. The 3q13 locus also provided five of the six SNPs (all in strong linkage

398 disequilibrium (LD) with each other) with evidence for gene-by-dosage effects, with the mutant

It is made available under a CC-BY-NC-ND 4.0 International license .

399	(non-reference) minor allele being negatively correlated with cryptoxanthin concentrations at
400	high FV doses but being positively correlated or neutral at low or intermediate FV doses. We
401	documented the gene-by-dosage effect for dietary carotenoid intervention and further highlighted
402	the complexity of making personalized nutrition recommendations for specific carotenoid
403	species. Cryptoxanthin, while a relatively small component of total plasma carotenoids, serves as
404	a highly bioavailable vitamin A precursor, and confers reduced inflammation, improves immune
405	function, and antioxidant activity <sup>59-61</sup> . A recent longitudinal population study found a strong
406	positive association between maternal cryptoxanthin concentrations at delivery and offspring
407	cognitive development at age two <sup><math>62</math></sup> .
408	Targeted sequencing further enhanced our ability to capture the full spectrum of genomic

409 variation, particularly given the diverse ancestries included in our study. This approach 410 facilitated the interrogation of loci that are not well captured or imputed in diverse cohorts using 411 genotyping microarrays, and the identification of rarer and novel variants that would not be 412 detectable from fixed-content arrays. This was most evident at the *PKD1L2-BCO1* locus; these 413 two genes are arranged in reverse tandem (head to tail) within an ~18 kb stretch on chromosome 414 16q. Common variants in this region – ranging from the 5'upstream of BCO1 to CETP have been consistently associated with  $\beta$ -carotene metabolism<sup>11,12,63</sup>; however, narrowing down putatively 415 416 causal variants in this region has been elusive. Our findings underscore this uncertainty -the top 417 associated variants were in the fifth exon of *PKD1L2*, but the top associated variant was much 418 further downstream of *PKD1L2* in our Intervention Cohort (Supplementary Figure S7). The 419 challenge of replicating individual variants at this locus across studies likely stems from 420 differences in population ancestry, environmental factors (such as adequately accounting for 421 dietary carotenoid intake), and study design, all of which may distort the association of variants,

It is made available under a CC-BY-NC-ND 4.0 International license .

422 particularly if multiple associated alleles each have small effect sizes. Regardless, the gene-level 423 association is sufficiently consistent that the *PKD1L2* may harbor multiple common variants, 424 each contributing modestly to  $\beta$ -carotene levels, collectively exerting a significant effect. In line 425 with this, we identified a rare, damaging variant (rs142824860) in the BCO1 gene in our 426 Intervention Cohort in an individual with the lowest  $\beta$ -carotene levels, further highlighting the 427 potential for multiple variants with varying effects to contribute to population levels of β-428 carotene<sup>10</sup>. 429 Our results also suggest a strong putative overlap between lipid metabolism and 430 physiological carotenoid regulation. Six genes (ALDH7A1, ATF6, MED16, SALL1, SORBS1, 431 SORBS2) near our plasma carotenoid suggestive candidate loci, as well as both genes (CETP

432 and APOA1) harboring high-impact rare variants in individuals with outlier carotenoid

433 concentrations, are either known or suspected modulators of lipid metabolism<sup>64-69</sup>. Among these,

the *ATF6* locus on chromosome 1had the strongest statistical association, with the rs11579627

435 SNP (chr1:161930954:G>A) nearing genome-wide significance (P = 8.23E-08, beta = 0.32),

436 **Supplementary Table S5**). Notably, ATF6, a key transcription factor in the endoplasmic

437 reticulum (ER) stress response and the unfolded protein response (UPR) pathway<sup>70</sup>, is implicated

438 in lipid biosynthetics<sup>65</sup>. These associations highlight allelic variation in genes predominantly

439 involved in cell signaling and lipid metabolism.

The missense coding variant in *CETP* has been previously linked to exudative age-related macular degeneration<sup>71,72</sup> (a condition related to carotenoid nutrition) and elevated high-density lipoprotein cholesterol levels (a determinant of plasma carotenoid concentrations)<sup>73</sup>. Whilst the overlap between lipid and carotenoid loci is not entirely surprising, given similarities in the biochemistry of both, it does suggest that identifying genetic contributors to carotenoid

It is made available under a CC-BY-NC-ND 4.0 International license .

445 concentrations in larger studies could benefit from overlapping a comprehensive compendium of
446 lipid metabolism genes and that genetic studies of lipid variation, particularly in diverse
447 populations, would benefit from including carotenoid assessments and using colocalization to
448 identify strong biological candidates.

449 The modest sample sizes and relatively balanced distribution of ancestry groups in our 450 study means that our study was necessarily aimed at identifying loci with large trans-ancestry 451 effects that are likely to be relevant across ancestries. Conducting our analysis in a diverse multi-452 ancestry cohort, however, still provided unique insights that would not have been evident using a 453 more ancestrally homogenous study group, particularly as it pertains to the allelic spectrum 454 underlying carotenoid variability. For instance, most of the carotenoid heritability estimates were 455 relatively higher among non-European populations, and all of the suggestive and genome-wide 456 significant candidate variants observed had higher minor allele frequencies in non-European 457 populations; this was particularly true for skin carotenoid concentrations. The inclusion of 458 diverse genetic ancestry in our rare variant studies further emphasized the utility of ancestrally 459 diverse cohorts – the coding missense variant in CETP (rs2303790) associated with very high 460 skin and cryptoxanthin levels is predominantly common among individuals with East Asian 461 ancestry.

Despite the insights gained from our analysis, there are limitations to our study. Our sample size is small in comparison to modern GWAS; whilst this undoubtedly limited our power to detect variants/loci with smaller effect sizes, our sample size is comparable to that used to discover major effect loci for more commonly measured physiologic proteins (e.g. fetal hemoglobin levels and cholesterol), and replicating our results in a second independent cohort mean that the reported associations are unlikely to be false positives. Despite the well-

It is made available under a CC-BY-NC-ND 4.0 International license .

468 documented health effects of carotenoids, carotenoid concentrations are not routinely measured 469 clinically or included in large-scale biobanks and databases; as a result, these resources are not 470 available to further replicate our findings. Additionally, although supplemented by imputation 471 and, for some loci, targeted sequencing, our reliance on genotyping arrays, particularly in a 472 cohort with diverse ancestries, may have missed rare or novel variants that could either be 473 independently associated with carotenoid concentrations or augment findings at suggestive loci. 474 Potential differences in population structure (e.g. linkage disequilibrium) and/or nutritional 475 factors between the discovery and replication cohorts may have contributed to a lack of 476 replication of some discovery associations, especially if multiple associated alleles each have 477 small effect sizes.

478 Going forward, there are several lessons for future carotenoid and nutrigenetic research. 479 Principally, from a genetic standpoint, larger and more diverse cohort studies of carotenoids are 480 necessary to replicate our findings and enhance the robustness and generalizability of the 481 identified associations. Methods of incorporating local genetic ancestry<sup>74</sup> and deconvoluting 482 ancestry effects in trans-ancestry GWAS continue to improve and are likely to be particularly 483 important for exploring and refining carotenoid associations, given the variability noted across ancestry groups. Additionally, incorporating detailed phenotyping of potential covariates, 484 485 controlled interventions, and measurements of lipids and related physiological compounds is 486 likely to be fruitful in understanding the complex underlying physiology. The rare variant 487 candidates identified here provide strong starting points for *in vitro* and *in vivo* functional 488 validation studies, particularly at the CETP (rs2303790) and BCO1 genes. Finally, large 489 population-based studies would provide the necessary data to consider developing personalized 490 risk profiles that incorporate carotenoid (and related compound) measurements, genetic factors,

It is made available under a CC-BY-NC-ND 4.0 International license .

- 491 and independent demographic and dietary interactions. Such studies have the potential to provide
- 492 the level of detail needed to tailor public health recommendations for FV intake and
- 493 interventions across different population groups.
- 494 The comprehensive, agnostic view of the genetics of carotenoid metabolism presented
- 495 here provides a robust starting point for future studies of this important class of natural dietary
- 496 compounds and underscores the necessity of including diverse ancestry groups and deep
- 497 phenotyping in precision nutrigenetic research going forward.
- 498

#### 499 **METHODS**

# 500 Study design and carotenoid species measurement.

501 We utilized the samples and phenotypic data collected from individuals who participated in two

502 previous studies<sup>26,27</sup>. In the first study, participants were healthy adults aged 18-65 years,

503 recruited from two sites in North Carolina and Minnesota. They self-identified as Non-Hispanic

504 Black or African American (hereafter referred to as Non-Hispanic Black), Asian, Non-Hispanic

505 White, or Hispanic. The demographics of the Primary Study Cohort are detailed in

506 Supplementary Table S1. Skin carotenoids were measured using pressure-mediated reflection

507 spectroscopy (Veggie Meter, Longevity Link, Utah), which returns and aggregates skin

508 carotenoid score measurements that correspond with multiple skin carotenoids<sup>75,76</sup>. Total plasma

509 carotenoid concentrations were determined via an HPLC-photodiode array<sup>26</sup>. The resulting

- 510 dataset comprised SNPs from a cohort with the following self-identified racial and ethnic
- 511 distribution: non-Hispanic black (61, 29%), Asian (53, 25%), non-Hispanic white (70, 33%), or
- 512 Hispanic (29, 14%). Participants were predominantly female (N=151 (71%)), with fewer males

513 (N=62 (29%)), and a median age of 30 years.

It is made available under a CC-BY-NC-ND 4.0 International license .

514	The second cohort was also drawn from a previous intervention study <sup>26</sup> , recruited from three
515	sites in North Carolina, Minnesota, and Texas. The racial and ethnic distribution of the
516	Intervention Cohort slightly differed from the primary cohort, consisting of non-Hispanic black
517	(41, 25%), Asian (40, 25%), non-Hispanic White (44, 27%), and Hispanic (37, 23%)
518	participants, with a near-equal sex distribution (49% male and 51% female) (Supplementary
519	Table S2). Plasma and skin carotenoid concentrations were collected at three time points
520	(baseline/week 0, week 3, and week 6) using the same methods. Participants were randomized to
521	receive negligible, medium-dose (4 mg total carotenoids/day), or high-dose (8 mg total
522	carotenoids/day) of dietary carotenoids for the intervention. Daily intervention adherence was
523	recorded by participants and non-intervention carotenoid intake was assessed with repeated 24-
524	hour dietary recalls prior to each visit.
525	Multidimensional Scaling (MDS)
526	Next, we combined our dataset with the 1000 Genomes phase III data to estimate the genetic
527	ancestry of the cohort. The 1000 Genomes phase III data were acquired from
528	https://ftp.1000genomes.ebi.ac.uk/vol1/ftp/release/20130502/ following the instructions at
529	https://www.cog-genomics.org/plink/2.0/resources#1kg_phase3. After downloading, the data
530	was converted to PLINK binary format, removing ambiguous SNPs (i.e. A>T/T>A and
531	C>G/G>C SNPs that are indistinguishable at the strand level), non-AT, and non-GC SNPs. The
532	data was pruned to remove SNPs with R <sup>2</sup> >0.1 in windows of 50 SNPs advancing 10 SNPs at a
533	time across the chromosome (indep-pairwise 50 10 0.1), after which SNP nucleotide
534	mismatches were corrected and merged with our cohort data using similar QC filters.
535	Subsequently, Multidimensional Scaling (MDS) was performed using thecluster andmds-
536	plot options in PLINK, generating eigenvalues and eigenvectors that encapsulate the MDS

It is made available under a CC-BY-NC-ND 4.0 International license .

537 dimensions and their respective scores for each individual. R version 4.3 was then used for

538 plotting the MDS and scree plot.

# 539 Genome-wide heritability analysis

540 Heritability estimates were calculated using Genome-wide Complex Trait Analysis (GCTA)<sup>31</sup>

541 version 1.94.1. The input data for the analysis comprised quality-controlled, genotyped, genome-

542 wide SNPs with minor allele frequency (MAF) thresholds of 0.01(--autosome --maf 0.01). Total

543 plasma carotenoids, plasma species, and skin carotenoid measurements for each individual

544 included in the filtered genotyping dataset served as the phenotypic data for the heritability

545 assessment. Genetic ancestry was used for downstream genomic analyses. Relative heritability is

546 calculated as the heritability estimate in each subgroup divided by the heritability estimate in the

547 entire cohort.

#### 548 Genome-Wide Association Studies (GWAS)

549 Genome-wide association studies (GWAS) were conducted to explore the relationship between

550 imputed genotyping variants and carotenoid species levels, employing GEMMA<sup>77</sup> version

551 0.98.5. As an orthogonal assessment, we also conducted association using PLINK 1.9; all

552 primary results reported relate to tests done in GEMMA. For analyses of plasma carotenoid and

553 species covariates of age, sex, BMI, race/ethnicity (self-reported or MDS-defined), and food

554 carotenoid were used. Additionally, for the skin carotenoids association study, the melanin index

and hemoglobin index were included, consistent with previous findings<sup>28</sup>.

556 Before association testing, the normality of raw data, log2-transformed phenotypes, and

557 covariates was assessed using the Shapiro-Wilk Test (**Supplementary Table S3**). Measurements

approximating a Gaussian distribution were included in the association analysis. Log<sub>2</sub>-

transformed values generally improved normality for plasma and food carotenoids, while

It is made available under a CC-BY-NC-ND 4.0 International license .

560 original values better fit skin carotenoid data. GWAS was then conducted on both the study and

561 intervention cohorts.

## 562 Replication and transferability of significant SNPs

- 563 Suggestively associated variants (P = 5E-04) with plasma carotenoid species and skin
- 564 carotenoids, identified from the GWAS in the Primary Study Cohort, were further evaluated in
- the Intervention Cohort. We conducted an association analysis on individuals who participated
- 566 exclusively in the Intervention Cohort (n=110) using GEMMA, applying models similar to those
- 567 used in the Primary Study Cohort. Baseline carotenoid measurements served as the phenotypic
- 568 data. METALysis<sup>43</sup> was used with significantly associated SNPs in this Intervention Cohort.
- 569 For the second replication analysis, changes in plasma carotenoid species and skin carotenoid
- 570 levels from baseline (week 0) to the intervention endpoint (week 6) were used as phenotypes,
- 571 following the approach of a previous study<sup>27</sup>. Covariates including age, sex, BMI, baseline
- 572 carotenoid concentrations, treatment assignment (0, 1, 2), study sites, and the first and second
- 573 dimensions of MDS together with SNPs and SNPs \* treatment assignment (0, 1, 2) were fitted
- 574 into a linear regression model. For skin carotenoids, we also incorporated the melanin and
- 575 hemoglobin index in the linear regression model.
- 576 Linear regression model
- 577

- *Y* = Change in plasma carotenoid species or skin carotenoid levels
- 578  $\beta_0 = \text{Intercept}$
- 579  $\beta_1, \beta_2, \beta_3, ..., \beta_n = \text{Coefficients for each covariate}$
- 580  $X_1 = Age$
- $X_2 = \text{Sex} (\text{coded as a binary variable})$
- 582  $X_3 = BMI$
- 583  $X_4$  = Baseline carotenoid levels

584	• $X_5$ = Treatment assignment (0, 1, 2)
585	• $X_6$ = Study site (coded as necessary)
586	• $X_7 =$ First MDS coordinate
587	• $X_{\delta}$ = Second MDS coordinate
588	• $X_9$ = Melanin index (for skin carotenoids)
589	• $X_{10}$ = Hemoglobin index (for skin carotenoids)
590	• $SNP_i$ = Genotypic data for the i-th SNP (coded as necessary)
591	• $SNP_i \times Treatment =$ Interaction term between SNP and treatment assignment
592	The linear regression model can be expressed as:
593	$Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \beta_3 X_3 + \beta_4 X_4 + \beta_5 X_5 + \beta_6 X_6 + \beta_7 X_7 + \beta_8 X_8 + \beta_9 X_9 + \beta_{10} X_{10}$
594	$+ i \sum \beta_{SNPi} SNP_i + j \sum \beta_{SNPj  imes Treatment} (SNP_j  imes Treatment) + \epsilon$
595	Where:
596	• $\epsilon =$ Error term representing the variability not explained by the model.
597	
598	Targeted sequencing and bioinformatics analysis
599	Thirty-five (35) genes (Supplementary Table S7) identified as important for carotenoid
600	metabolism were sequenced using the Ampliseq Custom Panel from Illumina. FASTQ files
601	were aligned to the GRCH38/hg38 reference genome using BWA78 MEM with the following
602	parameters: -M -O 30 -E 4 -T 20 -v 3. Data from multiple lanes were then merged and indexed
603	using SAMtools <sup>79</sup> v1.5. Per-base coverage was computed with bedtools <sup>80</sup> coverage
604	(Supplementary Table S7, Supplementary Figure S6). Subsequently, the Genome Analysis
605	Toolkit (GATK) <sup>81-83</sup> v4 was utilized for variants calling following the steps of
606	MarkDuplicatesSpark, BaseRecalibrator, Apply BQSR, Haplotype Caller, GenomicsDBImport
607	and GenotypeGVCFs. SNP annotation was performed using ANNOVAR <sup>84</sup> (version 2020-06-08).

It is made available under a CC-BY-NC-ND 4.0 International license .

#### 608

#### 609 Targeted sequencing association study

610 The Variants Association Tool<sup>85</sup> and VCFTools<sup>86</sup> (v0.1.15) were employed to filter the variants 611 within the Ampliseq target regions. Quality control filters were applied to exclude variants with a 612 minor allele frequency (MAF) below 0.01 and a call rate below 95%. Variants significantly 613 deviating from Hardy-Weinberg equilibrium (p < 0.001) were also excluded. We focused on 614 non-synonymous variants by filtering out synonymous substitutions, thereby retaining only those 615 variants with potential impacts on protein function for downstream analysis. 616 617 **Gene-by-dosage effect analysis** 618 To evaluate the interaction between genetic variants and intervention dosage on plasma

619 carotenoid levels, we performed a Gene-by-dosage analysis using the linear regression model 620 above. For each locus, genotype-by-treatment interactions were assessed by fitting a model 621 where the log<sub>2</sub>-transformed plasma carotenoid levels at the intervention endpoint (week 6) were 622 the dependent variable. The independent variables included the genotype of the specific locus, 623 intervention dosage group (control, moderate, or high), baseline plasma carotenoid levels, and a 624 range of covariates: age, sex, BMI, study site, and race. We also included the interaction term 625 between genotype and treatment dosage. This model was applied across loci, allowing for locus-626 specific examination of the gene-by-dosage effect. The significance of the gene-by-dosage effect 627 was determined by the p-value, with a significance threshold of p < 0.1. Results were visualized 628 using boxplots with fitted regression lines for each dosage group, illustrating the differential 629 effects of intervention dosage across genotypes.

640 The authors would like to thank all the persons who participated in data acquisition and sharing

641 during the two cohorts' establishment. This research was supported by the NIH NHLBI (SJP,

MNL, NEM, QW: 1R01HL142544-01A1), by funding from NIH NHGRI (HG-200412 to

N.A.H.), and the USDA/ARS (cooperative agreement 3092-51000-059-002S to NEM). The

644 work and views expressed do not reflect the views of the NIH or the USDA. This work utilized

645 the computational resources of the NIH HPC Biowulf cluster (<u>http://hpc.nih.gov</u>).

646

#### 647 AUTHOR CONTRIBUTIONS

648 N.E.M. and N.A.H. designed the study. M.N.L., N.E.M., and S.B.J.P. led the teams that recruited

649 participants, obtained informed consent, and collected samples. S.M. performed the rare variant

- association analysis. Y.H. conducted all other data analyses, including ancestry assessment,
- heritability estimation, GWAS, statistical genetics, and bioinformatics processing of the target
- 652 sequencing data. Q.W. provided support for statistical analysis. Y.H. wrote the initial first draft,

It is made available under a CC-BY-NC-ND 4.0 International license .

- with intellectual content added by S.M., N.A.H., and N.E.M. All authors reviewed and approved
- 654 the final manuscript.
- 655

## 656 DECLARATION OF INTERESTS

- 657 The authors do not have any conflicts or relevant interests to declare.
- 658

# 659 SUPPLEMENTARY INFORMATION

#### 660 Supplementary Tables

- 661 Supplementary Table S1. Demographics of the Primary Study Cohort.
- 662 Supplementary Table S2. Demographics of the Intervention Cohort.
- 663 Supplementary Table S3. Normality test of the phenotypic measurements.
- 664 Supplementary Table S4. Estimated heritability for carotenoid species.
- 665 Supplementary Table S5. SNPs that are significantly associated with carotenoid metabolism.
- 666 Supplementary Table S6. Results of the linear regression test for gene-by-dosage interactions
- across 37 SNPs.
- 668 Supplementary Table S7. Per-base coverage of 35 genes from target sequencing.
- 669 Supplementary Table S8. *PKD1L2* variants associated with plasma  $\beta$ -carotene.
- 670 Supplementary Table S9. Variants associated with plasma cryptoxanthin, skin carotenoid levels,
- 671 and  $\beta$ -carotene identified in outlier analysis.

#### 672 Supplementary Figures

- 673 Supplementary Figure S1. Scree plot of the MDS eigenvalues for the Primary Study Cohort.
- 674 Supplementary Figure S2. Density plots of plasma carotenoid subspecies concentrations.

It is made available under a CC-BY-NC-ND 4.0 International license .

- 675 Supplementary Figure S3. Density plots of plasma carotenoid and subspecies concentrations (and
- skin carotenoids in the East Asian (EAS) and South Asian (SAS) groups.
- 677 Supplementary Figure S4. Genome-wide association analysis of skin carotenoid level.
- 678 Supplementary Figure S5. Gene-by-dosage plots of plasma carotenoids, genotype, and
- 679 intervention dosage at week 6.
- 680 Supplementary Figure S6. Distribution and effects of genetic variants across selected genes.
- 681 Supplementary Figure S7. LocusZoom plot of variants in the *PKD1L2* gene on chromosome 16.

## 682 Supplementary Methods

- 683 DNA processing and genotyping
- 684 Genotyping data imputation
- 685 SNP and individual quality control
- 686 Rare Variants Annotation

It is made available under a CC-BY-NC-ND 4.0 International license .

884	Common and rare genetic variation intersects with ancestry to
885	influence human skin and plasma carotenoid concentrations
886	(Han et. al)

It is made available under a CC-BY-NC-ND 4.0 International license .

- 895 were performed for all participants. For the Intervention Cohort, additional measurements were
- 896 collected at weeks 3 and 6 post-intervention. Data were collected from previous studies (see
- 897 Reference 6 and 8). Array Genotyping data from the Study Cohort was used for genetic ancestry
- 898 assessment and heritability estimation, stratified by race/ethnicity. Both common and rare
- 899 variants identified in the Study Cohort were further analyzed for interaction effects in the
- 900 Intervention Cohort.

It is made available under a CC-BY-NC-ND 4.0 International license .

902

903

#### 904 Figure 2. Self-reported and genetically defined race/ethnicity and total carotenoid

905 concentrations in primary cohort. Self-identified race/ethnicity groups include Asian (n=53),

- 906 Hispanic (n=29), Non-Hispanic Black (n=61), and Non-Hispanic White (n=70). 2A -
- 907 Multidimensional Scaling (MDS) of genomic data alongside 'superpopulations' from 1000
- 908 Genomes Project: AFR (African), AMR (Admixed American), EAS (East Asian), EUR
- 909 (European), SAS (South Asian). '\*' indicates individuals whose self-reported ancestry differs
- 910 from genomic alignment. 2B Plasma carotenoid concentrations (mcg/dL, log2-transformed); 2C

- 911 skin carotenoid scores. Group number is indicated in parentheses, and differences were
- 912 assessed via Welch's Two-Sample *t*-tests.

913

922 concentrations. Manhattan and Q-Q plots from GEMMA linear regression analysis of log2-

923 transformed plasma cryptoxanthin (4A),  $\alpha$ -carotene (4B), and  $\beta$ -carotene (4C). Genome-wide

significance is indicated by red line  $(-\log P = 7.3)$  and suggestive association by the blue line (-

- $\log P = 6$ ). LocusZoom plots of SNP associations with carotenoid levels at significant loci: 3q13
- 926 (*IGSF11*) (**4D**), 19p13 (*R3HDM4/MED16*) (**4E**), and intragenic to *RAPGEF1* (**4F**).
- 927 Recombination rates and linkage disequilibrium  $(r^2)$  are relative to the AFR superpopulation in

928 1000 Genomes.

It is made available under a CC-BY-NC-ND 4.0 International license .

- 932 plasma carotenoid distributions within each genotype and dosage. Smoothed regression lines
- 933 show genotype effects within treatments. P-values indicate the significance of genotype
- 934 (P(genotype)), treatment (P(treatment)), and genotype-by-treatment interaction (P(genotype ×
- 935 treatment)). Treatment p-values < 0.1 indicate significant dosage effects.

936

947 **Table 1. SNPs significantly associated with carotenoid concentration phenotypes.** SNPs in

bold were directly genotyped on the Infinium<sup>™</sup> H3Africa Consortium Array v2; the remaining

949 SNPs were imputed. SNP ID includes chromosome: chromosome position: reference allele:

950 alternate allele. Phenotypes are log<sub>2</sub>-transformed carotenoid concentrations in plasma. AF-Minor

951 Allele Frequency; Beta–logistic regression slope (effect size); P - p-value from the GEMMA

952 analysis; **P**<sub>Meta</sub> - p-value from the METALysis. Dir – direction of effect (positive or negative).
