# Influenza A H5 in wastewater

#### 23 Abstract

- In 2024, the highly pathogenic avian influenza A H5N1 caused outbreaks in wild birds,
- 25 poultry, cows, and other mammals in the United States with 61 human cases also
- reported by the CDC. Detection of influenza A H5 RNA in wastewater has been
- 27 previously reported in sewersheds in Texas and North Carolina with nearby impacted
- dairy herds following the emergence of H5N1 in dairy cows. Here, we conduct
- retrospective testing of total influenza A and H5 hemagglutinin genes in wastewater as
- 30 well presenting and applying new assays for detection of H1 and H3 genes across a
- 31 respiratory virus season in an urban California sewershed from September 2023 May
- 32 2024. Total influenza A, H1, and H3 were regularly detected, while H5 was first detected
- in March. We developed a model that uses Monte Carlo simulations and previously
- 34 published parameters to estimate numbers of infected people, poultry, wild birds, or
- 35 liters of H5-contaminated milk required to result in measured H5 concentrations in
- 36 wastewater. Our findings demonstrate that in this California sewershed, contaminated
- 37 milk or infected poultry were the most likely sources of H5 to wastewater. We created a
- publicly available tool to apply the H5 input model in other sewersheds estimaterequired inputs.

## 41 Synopsis

42 We developed a model to understand potential sources of influenza A H5 RNA in

43 wastewater, enabling interpretation of H5 RNA wastewater detections.

44

## 45 Introduction

46 Approximately 3-11% of the population in the United States is infected with influenza

47 virus each year, and Influenza A virus (IAV) is responsible for the majority of these

48 infections.<sup>1</sup> In recent years, wastewater monitoring of infectious diseases has emerged

- 49 as a powerful tool for tracking trends in disease incidence in the community. Previous
- 50 research has found that concentrations of total IAV genomic RNA in wastewater track
- 51 closely with occurrence of infections in the contributing community.<sup>2–5</sup> IAV has subtypes
- that are classified by both hemagglutinin (H) and neuraminidase (N) proteins.<sup>6</sup> The H1
- and H3 subtypes are most common in humans and swine, while many subtypes,
- <sup>54</sup> including H1, H3, H5, H7, H9, and H10, are common in avian populations.<sup>7</sup> Given that
- 55 levels of total IAV (measurements that include all H subtypes) in wastewater have been
- 56 closely correlated with human disease, and municipal wastewater primarily consists of
- anthropogenic inputs, the predominant source of IAV RNA in wastewater has thus far
   been considered to be human.
- 58 59
- 60 The highly pathogenic avian influenza (HPAI) A (H5N1) outbreak in birds began in the
- 61 United States in February 2022 and has resulted in the deaths of millions of poultry and
- 62 wild fowls.<sup>8</sup> This outbreak in poultry has prompted concerns about increased spillover

into humans and the possibility of future human to human transmission, as humans 63 sporadically infected with H5N1 have experienced severe symptoms and high mortality 64 in the past.<sup>9</sup> Other animal influenza strains have jumped from animal populations to 65 humans through mutations, adaptation, or reassortment events with human influenzas, 66 resulting in epidemics and pandemics.<sup>10,11</sup> This concern has grown as outbreaks of 67 unknown illness in cattle in March 2024 were identified as infections caused by H5N1 68 later that month. Between March 1 and December 19, 2024, 865 infected dairy cow 69 herds and 61 human cases were reported in 16 states.<sup>12</sup> Human cases of H5N1 were 70 reported mostly among those who worked in close proximity to dairy cows and poultry; 71 72 human-to-human transmission has not been reported or suspected in any of the known cases.13-15

73 74

Beginning in March 2024 and concurrent with cattle outbreaks, we detected the H5 IAV 75 76 subtype genomic RNA (hereafter, H5 RNA) in wastewater in multiple sites across the United States.<sup>16</sup> Prior to the H5N1 outbreaks in cattle, contributions to wastewater from 77 animals infected with H5N1 (such as poultry) were expected to be minimal. However, 78 cows infected with H5N1 shed the virus in milk, and IAV RNA has been detected both in 79 raw milk and in pasteurized milk available on store shelves.<sup>17,18</sup> Because of the food 80 chain, a substantial amount of milk products enter sewers; it is estimated that 12% of 81 milk available for sale is wasted at retailers and 20% by consumers after purchase.<sup>19</sup> 82 Milk is commonly provided with breakfast and lunch to students at schools, and much of 83 this milk is wasted as well. Studies report that 45% of milk was wasted at kindergarten 84 and pre-kindergarten lunches,<sup>20</sup> and 13% by high school students.<sup>21</sup> This wasted milk 85 may be disposed of down the drain, entering sewer systems and contributing detectable 86 viral RNA to wastewater. Food industries are also often permitted to dispose of waste 87 generated while processing dairy products into sewer systems. Contributions to 88 89 wastewater from birds are less likely because of the lack of connection between wild bird habitats and domestic flocks to municipal sewer systems. However, wastewater 90 sewer systems that accept stormflow ("combined sewers") are less common but may 91 receive fecal waste from wildfowl and other wild birds that mixes with runoff and enters 92 sewer systems. Both poultry and wildfowl can shed IAV in their feces when infected.<sup>22,23</sup> 93 94 Wastewater treatment plants with open-air settling tanks, or that accept waste from industries that generate standing water, may be susceptible to inputs of bird feces. 95 Therefore, we conclude that any one of cow's milk, poultry feces, wildfowl feces, or 96 97 human contributions are the most likely sources of H5 in wastewater. 98 99 In this study, we present findings from retrospective testing of wastewater solids for total IAV and H1, H3, and H5 IAV subtype RNA from September 2023 - May 2024 in a 100

101 publicly owned treatment work (POTW) in California. We also present findings from a

102 model developed to estimate the theoretical contributions of humans, cow milk, wildfowl

- 103 feces, and poultry feces to the wastewater system necessary to result in the observed
- 104 H5 RNA concentrations. Our objectives were to 1) identify the timing of the first H5
- 105 detection in the sewershed during a period with circulating human influenza and 2)
- develop and implement a model of theoretical sources of H5 into the wastewater system
- 107 to contextualize our findings.
- 108

### 109 Methods

## 110 H1 and H3 Assay Design

- 111 IAV H1 and H3 subtype genome sequences were downloaded from the National Center
- 112 for Biotechnology Information (NCBI) in January 2023 (H1 genomes) and December
- 113 2022 (H3 genomes) and supplemented with additional newer sequences available from
- 114 NCBI and GISAID in April 2024. Sequences were aligned, and primers and probes were
- designed to target the hemagglutinin (HA) gene using Primer3Plus. Parameters used in
- 116 assay development (e.g., sequence length and GC content) are provided elsewhere.<sup>24</sup>
- The primers and probes (Table S1) were confirmed to be specific and sensitive for influenza A containing the H1 and H3 subtypes of the HA gene *in silico* using NCBI
- 119 BLAST.
- 120
- 121 The H1 and H3 assays were tested *in vitro* against nucleic acids from a large collection 122 of respiratory pathogens including different influenza subtypes (Table S2). Nucleic acids
- from these panels were extracted and purified as described below for wastewater solids
- samples, then used as template in droplet digital RT-PCR assays. The panels were run
- in a single well using the same ddPCR methods described below and elsewhere.<sup>16,24</sup>
- 126

## 127 IAV M gene and H5 assays

- 128 The H5 assay used has been described in detail elsewhere,<sup>16</sup> as has the M gene
- assay.<sup>24</sup> See the Supporting Information for information on primers, probes, and positive
- 130 control material. The influenza M gene assay detects all IAV subtypes and hereafter,
- 131 measurements made using the M gene assay will be interpreted as "total IAV RNA".
- 132

# 133 *Retrospective analysis of samples*

- 134 Biobanked nucleic-acid extracts obtained from wastewater solids samples collected
- between September 1, 2023 and May 13, 2024 from a POTW (Southeast San
- 136 Francisco) were retrospectively analyzed for total IAV (M gene), H1, H3, and H5 (n=110
- 137 samples). Nucleic-acids were stored between 1 and 10 months at -80°C before
- analysis. Samples consisted of grab samples of settled solids from the primary clarifier.
- 139 Samples were collected using sterile methods and stored at 4°C prior to nucleic-acid
- 140 extraction. The POTW is located in an urban area and serves 750,000 people, and
- services a geographic area with combined stormwater and sanitary sewer systems

142 meaning that stormwater and urban dry weather runoff (generated via irrigation or car washing, for example) may enter the POTW. 143

144

Sample processing methods are described in detail elsewhere.<sup>24–26</sup> Briefly, nucleic acids 145 were extracted from the solid fraction of each sample using the Chemagic Viral 146 DNA/RNA 300 Kit H96 (PerkinElmer, Shelton, CT) followed by inhibition removal (Zymo 147 OneStep PCR Inhibitor Removal Kit, Irvine, CA).<sup>25</sup> Nucleic-acid extraction occurred 148 immediately within 24 h of sample collection. Between 0.5-1g of the dewatered solids 149 150 were dried at 110°C for 19-24 h to determine the dry weight. Concentrations of total IAV 151 (M gene), H1, H3, and H5 RNA were measured in multiplex using droplet digital 1-step RT-PCR (dd-RT-PCR) run on an AutoDG Automated Droplet Generator (Bio-Rad, 152 Hercules, CA), Mastercycler Pro (Eppendorf, Enfield, CT) thermocycler, and a QX600 153 154 Droplet Reader (Bio-Rad). Ten ddPCR replicates were run for each sample. Only wells 155 with over 10,000 droplets were included; all wells met this criterion. Extraction and PCR 156 positive and negative controls were run on each 96-well plate. Positive controls consisted of Twist synthetic controls (M gene, H1, H3) and custom gene blocks (H5; 157 IDT); see the SI for full details. Negative controls consisted of no template controls 158 159 (NTC) containing nuclease free water. Bovine coronavirus (BCoV) was spiked into samples and measured as an internal control, and pepper mild mottle virus (PMMoV) 160 was measured using ddPCR as an endogenous internal control. We used the 161 QuantaSoft Analysis Pro software (Bio-Rad) to threshold droplets, and a sample had to 162 have 3 or more positive droplets to be considered positive. Three positive droplets 163 164 corresponds to a concentration between 500-1000 copies/g. Values were converted to gene copies/dry g using dimensional analysis. See the SI for reaction chemistry and 165 cycling parameters. 166

167

#### 168 Model of theoretical inputs

We developed a model to estimate the H5 RNA inputs into the system that would be 169

required to result in the measured H5 RNA concentrations in wastewater solids. We 170

considered inputs from humans, cow milk, poultry feces, and waterfowl feces, as each 171

172 input type had a plausible mechanism for entering wastewater. We note that these

173 inputs may enter wastewater in a number of ways, including from household uses,

174 businesses, industrial discharges, and, in some cases, environmental sources.

176

- 177 **Figure 1.** Conceptual image of sources of H5N1 to the POTW.
- 178
- 179 Mass Balance
- 180 We assume that the concentrations measured in wastewater relate to inputs from
- 181 humans, birds, and cow's milk according to the following equation:

- 183whereindicates the daily flux of H5 RNA (gene copies/day) through the POTW184and,,and,,and,,
- 185 copies/day) of humans, poultry, wild birds, and milk, respectively, to the POTW.
- 186
- 187 Calculations of daily H5 wastewater fluxes,
- 188 We assume that both the liquid and solid portions of wastewater contain H5 RNA when
- detected in solids and calculate total H5 RNA content across both phases. The
- 190 concentration in liquids is calculated using the Freundlich isotherm:<sup>27</sup>
- where indicates the H5 RNA concentration in liquids (gene copies/mL), indicates
  the H5 RNA concentration in solids (gene copies/dry gram), and indicates the
  Freundlich partitioning coefficient (mL/dry gram).
- Total daily H5 RNA flux through the POTW (gene copies/day) is calculated as the sum of H5 RNA in solids (gene copies/day) and in liquids (gene copies/day). We obtain the daily flow rate (in millions of gallons per day) and total suspended solids (TSS; mg/L)

198 from the POTW for each day. The total daily flux of solids through the POTW is

199 calculated as:

$$M_s = \frac{F_{L_{day}} \times TSS}{10^3} \#3$$

where  $F_{L_day}$  is the daily flow rate in terms of L/day, TSS is the total suspended solids (mg/L), and the 10<sup>3</sup> factor is to convert from mg/day to g/day. The daily flux of H5 RNA

202 in the solids (gene copies/day) is calculated by:

$$H5_s = M_s \times C_s #4$$

203

204 The daily flux of H5 RNA in the liquids (gene copies/day) is calculated by:

$$H5_l = F_{L_{dav}} \times C_l \#$$

205

206 The total daily flux of H5 RNA through the POTW (gene copies/day) is calculated by:  $F_{wwtp,d} = H5_s + H5_l #6$ 

207 Human inputs

We consider human contributions to the POTW from saliva, sputum, and feces, such that:

 $F_{human,d} = N_{human,d} \times (C_f \times V_f \times FS_f + C_{sp} \times V_{sp} \times FS_{sp} + C_{sal} \times V_{sal} \times FS_{sal}) \#7$ where *N* indicates the number of infected people contributing to wastewater, *C* indicates
concentration in that excretion type (gene copies per mL or per g), *V* indicates volume
of that excretion type entering the wastewater system per day per person (mL or g), and *FS* indicates the fraction of infected persons shedding influenza by that route (unitless). *F* refers to feces, *sp* refers to sputum, and *sal* refers to saliva.  $F = F_{wwtp,d} = F_{human,d} \#8$ 

217

and, plugging in Eq. 7:

$$F_{wwtp,d} = N_{human,d} \times (C_f \times V_f \times FS_f + C_{sp} \times V_{sp} \times FS_{sp} + C_{sal} \times V_{sal} \times FS_{sal}) \#9$$

219

220 Rearranging to solve for the number of infected individuals (*N*):

$$N_{human,d} = \frac{F_{wwtp,d}}{C_f \times V_f \times FS_f + C_{sp} \times V_{sp} \times FS_{sp} + C_{sal} \times V_{sal} \times FS_{sal}} \#10$$

221

222 Poultry inputs

223 We consider inputs from poultry to the POTW through feces:

$$F_{poultry,d} = N_{poultry,d} \times (C_{CS} \times CF_{SG} \times V_f) \# 11$$

224

225 Where  $C_{cs}$  indicates the concentration of influenza reported in cloacal swabs collected

from domestic poultry (gene copies/swab),  $CF_{SG}$  indicates a conversion factor from

concentration/swab to concentration/g (swab/gram), and  $V_f$  indicates the volume of 227 feces produced by birds per day (grams). 228 229 230 Assuming no contribution to the POTW from humans or milk, we can simplify Eq. 1 to:  $F_{wwtp.d} = F_{poultrv.d} #12$ 231 and, plugging in Eq. 11:  $F_{wwtp,d} = N_{poultry,d} \times (C_{CS} \times CF_{SG} \times V_f) \# 13$ 232 233 Rearranging to solve for the number of infected birds (*N*): 234  $N_{poultry,d} = \frac{F_{wwtp,d}}{C_{CS} \times CF_{SG} \times V_f} \# 14$ 235 236 237 Wild bird inputs We consider inputs from wild birds to the POTW through feces: 238  $F_{bird.d} = N_{bird.d} \times (C_{CS} \times CF_{SG} \times V_f) \# 15$ 239 Where  $C_{cs}$  indicates the concentration of influenza reported in cloacal swabs collected 240 from domestic poultry (gene copies/swab), CF<sub>SG</sub> indicates a conversion factor from 241 concentration/swab to concentration/g (swab/gram), and  $V_f$  indicates the volume of 242 243 feces produced by birds per day (grams). 244 Assuming no contribution to the POTW from humans or milk, we can simplify Eq. 1 to: 245  $F_{wwtp,d} = F_{bird,d} #16$ 246 and, plugging in Eq. 15:  $F_{wwtp\,d} = N_{bird\,d} \times (C_{CS} \times CF_{SG} \times V_f) \# 17$ 247 248 Rearranging to solve for the number of infected birds (*M*): 249  $N_{bird,d} = \frac{F_{wwtp,d}}{C_{CS} \times CF_{SC} \times V_f} \#18$ 250 251 Cow milk inputs 252 We estimate the daily flux of H5 RNA from cow milk (gene copies/day) by: 253  $F_{milk d} = C_{MILK} \times V_{MILK} \times CF_{milk} # 19$ 254 255 where  $C_{MILK}$  refers to the H5 concentration in cow's milk,  $V_{MILK}$  indicates the volume of

milk entering the wastewater system per day, and  $CF_{milk}$  is a conversion factor from the EID50/mL units  $C_{MILK}$  is reported in to gene copies/mL units.

258

- Assuming no contribution to the POTW from humans or birds, we can simplify Eq. 1 to:  $F_{wwtp,d} = F_{milk,d} # 20$
- and, plugging in Eq. 19:

$$F_{wwtp.d} = C_{MILK} \times V_{MILK} \times CF_{milk}$$
#21

261 Rearranging to solve for the daily volume of infected milk entering the POTW:

$$V_{MILK} = \frac{F_{wwtp,d}}{C_{MILK} \times CF_{milk}} \#22$$

262

- 263 Data Sources
- 264 Using previously published systematic reviews and parameters on daily human waste
- input into the system, we identified a distribution of human IAV shedding into
- wastewater per day per infected individual (**Table 1**).<sup>28,29</sup> For cow milk, we identified a
- 267 distribution of H5N1 RNA per gallon of pasteurized milk using published reports on
- 268 H5N1 EID50 content in pasteurized cow milk<sup>17,18</sup> and a conversion from EID50 to RNA
- 269 gene copies.<sup>30</sup> Distributions of daily H5 RNA shedding in the feces of poultry and
- 270 waterfowl were separately estimated from studies reporting IAV shedding in each bird
- type (**Table S4**).<sup>22,23</sup> Blue-winged teal were used as the model species for wild birds,
- per Humphreys *et al.*<sup>31</sup> Raw data for empirical distributions are provided in the Stanford
- 273 Digital Repository (<u>https://purl.stanford.edu/ks454rq5640</u>).
- 274

276

To estimate the total daily H5 RNA for the POTW, we calculated total solids and total

278 liquids at the POTW per day using the flow rate and total suspended solids (TSS)

reported by the POTW. We assumed homogeneity in both solids and liquids, meaning

that the quantity of H5 RNA measured in the solids sample is the same throughout all

solids passing through the system. The H5 RNA concentration in liquids was estimated
 from the solids using the partitioning coefficient of IAV RNA in wastewater and the

adsorption intensity (**Table 2**).<sup>27</sup> We summed the total H5 RNA in solids and total H5 RNA in liquids to calculate the total H5 RNA at the POTW per day.

285

#### 286 **Table 2.** Wastewater model input parameters

| Category   | Parameter                                   | Unit     | Distribution | Parameters           | Reference |
|------------|---|----------|--------------|----------------------|-----------|
| wastewater | solid-liquid<br>partitioning<br>coefficient | mL/g     | Empirical    |                      | 27        |
| wastewater | Adsorption intensity                        | unitless | Uniform      | min = 0.7, max = 1.9 | 27        |

287

Raw data were fit to distributions using the *fitdistr* package in R. For each parameter, 288 289 we first used the *descdist* function to create a Cullen and Fray graph, which plots the 290 square of skewness against kurtosis. The value from the observed data is plotted, as 291 are the locations of theoretical distributions. Whichever theoretical distribution the 292 observation is plotted nearest is selected as the distribution type, with the beta 293 distribution being the lowest priority (meaning if the observation is near normal, uniform, 294 exponential, or logistic, while still being located within the beta region, the other non-295 beta distribution is selected). After selecting a distribution type, data were fitted to the 296 distribution using the *fitdist* package and distribution parameters were extracted.

297

### 298 Model Approach

299 In the models, we assumed that the measured H5 RNA in wastewater originated

300 entirely from one of the four input types and then independently calculated (1) the

number of infected humans in the sewershed, (2) the liters of milk input into the sewer,

302 (3) the number of poultry contributing feces to the sewer, and (4) the number of waterfowl contributing feces to the sewer that would be required to result in the 303 measured H5 concentration. By looking at each source independently, we can estimate 304 an upper bound on the number of infected individuals or IAV-impacted liters of milk that 305 306 could be contributing to the system. To assess variability in our parameter estimates, we conducted Monte Carlo simulations using n=10,000 iterations. For each iteration, we 307 randomly selected a value from each parameter's distribution and conducted the 308 calculations. Presented throughout are the median and interguartile range (25th - 75th 309

- 310 percentile) from these simulations. Due to the limited data available for our
- 311 assumptions, we are reporting order of magnitude results.
- 312

#### 313 Sensitivity Analysis

We use a previously-published method to conduct a sensitivity analysis to determine

- which parameters the model is most sensitive to.<sup>38,39</sup> The model is run with the
- parameter first set to its 25th percentile (p25) then set to the 75th percentile (p75) while
- 317 all other parameters are set to their median value. We calculate the ratio between the
- 318 model output for p75/p25. A p75:p25 ratio of 1 indicates that the model is not sensitive
- to the parameter, while a ratio above or below indicates the model is sensitive to that
   parameter. For ratios below 1, we calculated the inverse (1/p75:p25) so that all ratios
   are presented on a comparable scale.
- 322

### 323 Shiny Application

We developed an application using the R Shiny package to make the model available for public use. Users can input the H5 wastewater concentration in solids (gene copies/dry g) and the flow rate (in millions of gallons [MGD] per day) and total suspended solids (TSS; mg/L) at the treatment plant. The model will conduct n=50,000 iterations and provide estimates of the required inputs. The Shiny app is available at <u>https://abharv52.shinyapps.io/h5\_input\_estimates/</u>.

330

## 331 Identifying food and/or agricultural industries within the sewershed

We used multiple online sources to search for potential industrial contributors of dairy products to the sewershed wastewater. We searched google maps for dairy, cheese, or butter processing facilities and cross-checked locations with the sewershed boundaries to see if they fell within the sewershed. The boundary shapefile was provided by the POTW. We also searched the Enforcement and Compliance History Online (ECHO) database for facilities with Clean Water Act permits with a Standardized Industry Code (SIC) indicating dairy processing (**Table S5**).

- 339
- 340

#### 341 Results

### 342 H1 and H3 assay performance and QA/QC

Both *in silico* and *in vitro* testing indicated the H1 and H3 assays are 100% specific. *In vitro* tests returned non-detects for all non-target pathogens, including other influenza subtypes.

346

347 The Environmental Microbiology Minimal Information (EMMI)<sup>40</sup> and McClary-Gutierrez

348 et al. guidelines<sup>41</sup> were used for reporting results (both checklists available at

349 <u>https://purl.stanford.edu/ks454rq5640</u>). Positive and negative controls performed as

- 350 expected. Nucleic acid extraction efficiency in samples exceeded the quality control
- 351 threshold of 0.1 for bovine coronavirus (median = 1.8, interquartile range (IQR) = 1.2 -
- 2.4); recoveries greater than one are likely a result of errors associated with the
- 353 measurement of bovine coronavirus seeded into the sample. PMMoV was detected at
- high concentrations in all samples (median of  $6.1 \times 10^8$ , IQR =  $4.8 \times 10^8$ - $7.9 \times 10^8$  cp/g)
- 355 providing further support of efficient nucleic-acid extraction
- 356

## 357 H5 RNA detection in wastewater samples

H5 RNA was first detected at the POTW on March 18, 2024 (**Fig 2**). Between March 18

and May 13 (the final sample of this study), 13 of 25 (52%) samples tested positive for

H5 RNA. The median concentration detected was 2410 gc/dry g, with the peak

- 361 concentration detected on May 3 (19,000 gc/dry g). H5 RNA detections were not related
- to rainfall patterns in the region (**Fig S1**).

364

Figure 2. Concentrations of influenza A M gene (all IAV), H5, H1, and H3 RNA in
wastewater solids. Concentrations measured are indicated by filled circles with the 68%
confidence interval represented by bars. Samples with no detection are indicated by
open circles. The lines represent the 5-adjacent sample trimmed average.

369

Both total IAV (M gene) and H1 RNA were regularly detected throughout the sampling
period, and concentrations of both peaked in late December 2023 (Fig 2). H3 RNA was
regularly detected from December 2023 onwards. H1 and H3 RNA concentrations
remained low during H5 RNA detections from March through May. Of clinical influenza
cases reported in CA during the 2023-2024 season, over 70% of cases were H1N1 (Fig
S2)<sup>42</sup>.

#### 378 Modeled sources of H5 RNA

We calculated the total gene copies of H5 theoretically contributed to wastewater per

infected human, liter of milk, and in daily fecal production in poultry and wild birds

381 (**Table 3**). The estimated required inputs per source varied with measured H5 RNA

concentrations (**Figure 3**). Overall, the lower bound (25th percentile) of contributions

required to result in the median measured H5 RNA concentration were  $10^4$  liters of milk,

 $10^4$  infected humans,  $10^2$  infected poultry, or  $10^5$  infected wild birds.

385

**Table 3**. Median gene copies of H5 RNA contributed to wastewater per day per infected individual (person, poultry, waterfowl) or per liter (IAV RNA containing milk).

| Source        | 25                | 50 (median)       | 75                |  |
|---------------|-------------------|-------------------|-------------------|--|
| Person        | 2x10 <sup>6</sup> | 9x10 <sup>6</sup> | 3x10 <sup>7</sup> |  |
| Liter of Milk | 7x10 <sup>4</sup> | 4x10 <sup>5</sup> | 2x10 <sup>6</sup> |  |
| Poultry       | 5x10 <sup>6</sup> | 6x10 <sup>7</sup> | 6x10 <sup>8</sup> |  |
| Waterfowl     | 9x10 <sup>4</sup> | 3x10 <sup>5</sup> | 1x10 <sup>6</sup> |  |

386

388

Figure 3. Median and IQR (25th - 75th quantile) of number of infected individuals
 required (humans, poultry, waterfowl) or liters of milk required to result in the lowest
 non-zero, median, and maximum H5 concentration measured at the POTW.

392

The peak H5 RNA concentration was detected on May 3, 2024; for this concentration (19,000 gc/dry g), the lower bound (25th percentile) required contributions were  $10^4$ liters of milk,  $10^4$  infected humans,  $10^3$  infected poultry, or  $10^6$  infected waterfowl.

396

397 Sensitivity Analysis

398 The H5 input model is very sensitive to the concentrations of IAV in poultry and

399 waterfowl cloacal swabs, the concentration of influenza RNA in cow milk, and the

400 concentration of influenza in human saliva (**Fig 4**).

401

Figure 4. Sensitivity analysis results. Presented are the ratios of model output between
 the 75th and 25th percentiles for each parameter while all other parameters are set to
 their median value.

405

#### 406 **Possible sources of animal inputs into the wastewater system**

407 We identified two dairy processing facilities in the sewershed: a cheese making

408 business and a butter creamery. We were not able to determine the volume of waste

409 output from these businesses or whether their waste entered the sewer system.

410 Given that an estimated 20% of milk is wasted in residential settings,<sup>19</sup> an estimated

411 daily milk consumption per capita of 118 mL,<sup>43</sup> and a sewershed population of 750,000,

412 we estimate that approximately 22,000 liters of milk are wasted per day in households in

413 the sewershed. This is a conservative estimate, not accounting for waste in

414 pasteurization, dairy products, food service, or at retail stores (of which an estimated
415 15% is wasted<sup>19</sup>).

416

417 We also located one live bird market in the sewershed where poultry are kept alive and

418 where poultry feces enter the sewershed via drains in the establishment. The market

419 operates on select dates and birds are typically housed at the market for a maximum of

420 24 hours before being sold; thousands of birds can be present at any one time.

#### 421

#### 422 Discussion

423 We first detected H5 RNA in San Francisco wastewater in mid-March 2024 after H5N1 424 outbreaks in cows had been identified in the United States but before any outbreaks 425 had been reported in California. Samples from September 2023 to mid-March 2024 were all non-detect for H5 RNA, despite regular detection of the influenza A M gene and 426 known outbreaks of H5N1 in domestic poultry and wild birds in the region.<sup>8</sup> The timing of 427 the initial H5 RNA detections generally aligned with detections of H5 RNA in wastewater 428 from Amarillo, TX (with detections late February to late April in the South plant and 429 430 detections from mid-March to late April in the North plant) and Dallas, TX (detections mid-March to mid-April).<sup>16</sup> However, while dairy cow herds were identified with H5N1 431 illness in Texas during this time, none were identified in California until late August 432 433 2024.<sup>44</sup> High concentrations of H5 RNA were detected in wastewater from dairy industries discharging to the wastewater system in Amarillo, TX,<sup>16</sup> while no major dairy 434 435 operations of similar scale were identified in the San Francisco sewershed. H5N1 436 outbreaks in poultry flocks were reported in San Francisco (May 9, 2024) within the time period of wastewater H5 RNA detections. As such, the source of H5 RNA in wastewater 437 438 in San Francisco is unclear based on circumstantial evidence and we implemented a modeling approach to determine the feasibility of different H5 influenza sources to the 439 sewer system producing these results. We found the model helpful to estimate the order 440 441 of magnitude contributions that may be required from different pathways; however, data 442 on shedding and other assumptions means that the ability of the model to make precise 443 estimates is limited.

444

445 Waterfowl. Based on the model results, waterfowl are unlikely to be a major source of H5 RNA to wastewater from the SF sewershed. Feces from at least ten thousand of 446 447 these infected birds would be required to result in the minimum H5 RNA concentration measured, and there is unlikely to be a feasible way for the required mass of bird feces 448 to enter the system despite it being a combined system in which some contribution is 449 likely. This analysis was limited by a lack of data on wild bird fecal shedding of 450 451 influenza. In California in 2024, waterfowl such as geese as well as owls, gull, falcons, and other types of wild birds have all tested positive for H5N1.<sup>45</sup> Our shedding data was 452 based on a study in blue-winged teals,<sup>22</sup> which are considered representative of 453 waterfowl.<sup>31</sup> Influenza shedding in other types of birds with confirmed H5N1 in California 454 are sparse.<sup>23</sup> It is possible that other species of wildfowl could shed greater quantities of 455 456 IAV in feces or produce much greater quantities of feces. However, the mechanisms 457 through which wild bird feces enter the wastewater system are limited, and the model assumes all feces produced are entering the system. Stormwater or urban runoff 458 entering the combined system could wash bird feces into the system, yet there were no 459 460 precipitation events recorded in San Francisco during the period of H5 RNA detections.

461 Bird feces could enter the system through bodies of standing water that drain to the 462 system, yet none were identified within the sewershed.

463

464 **Poultry.** Poultry are a feasible contributor of H5 to the SF sewer system, especially 465 given the live bird market located within the sewershed where chicken feces can be washed into the sanitary sewer system. Notably, poultry at the live bird market infected 466 with H5N1 were identified on May 9, 2024,<sup>8</sup> during the study period and coinciding with 467 an H5 RNA wastewater detection. The USDA describes that the outbreak involved 700 468 birds;<sup>8</sup> this number is within the IQR of the modeled number of poultry required for both 469 470 the minimum and median H5 RNA concentrations measured in wastewater. Based on the author's observation, we estimate that the bird market may house as many as 3,000 471 472 birds at one time, which is within the lower IQR (25th percentile) for the number of 473 infected poultry required to result in the maximum H5 concentration measured. 474 However, there were additional H5 detections after the May 2024 outbreak and it is 475 unlikely that such a large number of H5N1-infected birds could go undetected. Outbreaks of highly pathogenic avian influenza (HPAI), which includes H5N1, result in 476 477 severe morbidity and mortality in affected flocks. An early sign of HPAI is often 478 unexpected chicken deaths, and common symptoms in chickens are severe and would be difficult to miss.<sup>46</sup> On Dutch poultry farms, the time between virus introduction and 479 final mortality within individual chicken flocks ranged from 5 - 12 days,<sup>47</sup> signifying rapid 480 spread through flocks. We saw sustained detection of H5 RNA in wastewater across 5 481 weeks in the POTW, which would require that chickens at the live bird market be 482 483 consistently infected with H5N1 during this time period if the market were the sole or primary H5 RNA wastewater source. 484 485

The poultry model is very sensitive to poultry fecal shedding. Our model uses fecal shedding estimates for HPAI from a meta-analysis that incorporates data from 71 studies, including 25 studies specific to H5N1.<sup>23</sup> The presentation of H5N1 in poultry in the U.S. since the beginning of the outbreak in 2022 has been similar to H5N1 outbreaks in poultry in other regions;<sup>46</sup> as such, we feel that we are using the best available estimates of poultry fecal shedding.

492

493 Milk. We find that milk is feasible as a primary or sole H5 RNA source to the POTW, but only if the milk supply is widely contaminated. Pasteurization of milk inactivates IAV, but 494 does not reduce the IAV RNA concentration in milk which is still detectable by PCR.<sup>48–50</sup> 495 496 Residential milk waste could drive H5 RNA detections; even for the maximum H5 RNA 497 wastewater concentration, the lower bound model output (25th percentile) requires 10,000 liters of contaminated milk to enter the sewer system. This is within our 498 499 conservative estimate of the amount of milk wasted residentially each day in the 500 sewershed (22,000 liters) not including the contribution of small dairies, retailers, and

food service, and so it is possible that dumping of contaminated milk could result in the
 detected H5 RNA if there was widespread contamination of milk at retailers within SF.

504 This analysis was limited by the availability of data on H5 and IAV concentrations in milk. No H5 or IAV containing milk was reported in milk processed in California during 505 the time of this study,<sup>17,51</sup> although testing was limited (Tarbuck et al.: n=3, Suarez et al., 506 n=6), and no infected dairy cows were reported in California during the time period of 507 this study.<sup>44</sup> However, it is possible that contaminated milk may enter the supply chain in 508 San Francisco through either unidentified local cattle outbreaks or through milk 509 510 processed in other locations with H5N1 outbreaks in dairy cattle. The model is sensitive to the H5 concentration in milk, and thus our input estimates would be affected by an 511 512 over- or underestimation of the H5 concentration in milk.

513

514 Humans. Infected humans are unlikely to be a major contributor of H5 RNA to the San Francisco wastewater. As of December 19, 2024, only 61 people in the United States 515 have been identified with H5N1 infections, and these cases were mostly in people who 516 worked closely with infected cows or poultry.<sup>12</sup> Human-to-human transmission of H5N1 517 is not suspected at this time. While it is possible that asymptomatic or undiagnosed 518 cases exist and the true number of infections is higher,<sup>52</sup> there is no evidence to support 519 the likelihood of widespread infection in humans at this time - especially 10<sup>3</sup> cases as 520 the model estimates would be required to produce the minimum H5 concentration.<sup>13</sup> 521 522

523 Our estimates of the required H5 human cases are constrained by available human IAV shedding data, and do not necessarily align with previous observations of influenza A in 524 525 wastewater during outbreaks in humans. The shedding data are based on human shedding of influenza A overall (no subtyping conducted), H1N1, H3N2, or H7N9,<sup>28</sup> and 526 527 data on H5N1 shedding in humans are not available. No information is available on human IAV shedding of any subtype in urine.<sup>28</sup> Recent H5N1 infections have presented 528 differently than seasonally influenza,<sup>13,53</sup> and shedding profiles of H5N1 may differ from 529 those of other influenza types. We also noted that our estimate that 10<sup>3</sup> to 10<sup>4</sup> infected 530 531 humans would be required to result in the minimum H5 concentration observed is 3-4 orders of magnitude larger than the number of infected individuals that were empirically 532 observed to produce a similar concentration of total IAV in Ann Arbor, Michigan and at 533 Stanford University, as determined through case reporting and in depth outbreak 534 investigation.<sup>2</sup> Future work is needed to better quantify human shedding of influenza in 535 536 wastewater-relevant excretions.

537

Research is also needed into the possibility of human dietary shedding of H5 following
consumption of H5N1-containing dairy products. Other single-stranded RNA viruses,
such as PMMoV, brown rugose tomato virus, and porcine circoviruses, have been

541 detected in human stool following consumption of foods containing these viruses.<sup>54–57</sup> If

542 H5 IAV present in milk or other dairy products is able to be shed in human stool,

uninfected humans who consume dairy products could contribute to H5 wastewaterdetections.

545

546 **Limitations.** We note that a major limitation of the study is the uncertainty in the data underlying many parameters, especially because the model was found to be sensitive to 547 several of these related to shedding. These shedding parameters are particularly 548 influential in the model, and in many cases are poorly understood. Concerns about this 549 550 limitation are exacerbated by the observation that modeled estimates for human 551 infections are substantially higher than would be expected based on observations from 552 previous influenza A outbreaks of other subtypes. Despite these limitations, we feel that 553 the model provides a helpful framework for discussing the order of magnitude estimated 554 contributions from different sources to wastewater. More data on shedding in animals 555 and humans will continue to improve estimates in the future.

556

557 Another limitation of this study is that inputs from humans, poultry, wild birds, and milk 558 were estimated separately. Multiple sources could contribute to H5 RNA wastewater detections, yet there is no information available to constrain the fraction of input that 559 may come from each source, and thus each source was modeled separately. If multiple 560 sources contribute H5 to the wastewater system, the number of required infected 561 individuals or liters of milk could be lower than the lower bounds estimated by our 562 563 models. Our H5 assay will detect all IAV in the H5 subtype, and this could include strains other than the currently circulating H5N1 (e.g., H5N8); however, no other H5 564 strains are currently expected to be circulating in wastewater-relevant species. It should 565 also be noted that the IAV genome, particularly the HA gene, has a high rate of 566 567 mutation. Although the H1, H3, and H5 assays used herein are highly sensitive and specific for the dominate IAV H1, H3, and H5 subtypes circulating at the time of the 568 study, they may not be highly sensitive and specific in different time periods during 569 which different clades of each subtype are in circulation. For example, we have 570 571 confirmed that the H1 assay is no longer sensitive for the H1N1 clade circulating in the 572 2024-2025 flu season.

573

574 The model developed could be applied to other sites with H5 detections in wastewater 575 to help constrain potential sources, and we developed a Shiny app tool to allow the 576 model to be easily deployed at other sites. For other sites using the model, however, the 577 feasibility and appropriateness of each pathway included in the model would need to be 578 determined based on the specifics of the wastewater system.

- 580 In this study, we show that H5 was detected in an urban California watershed months
- 581 before H5N1 cases in California dairy cattle were reported. Given a lack of dairy
- industry in the sewershed or surrounding area, the source of H5 RNA in the wastewater
- 583 system was unclear. Here, we employ modeling to estimate the theoretical H5
- contributions from infected humans, poultry, and wildfowl, and from H5-contaminated
- 585 milk. We demonstrate that humans and waterfowl are unlikely to be major contributors
- of H5 to the system, while poultry and milk are both feasible sources in this system.
