8 Abstract

3

4 5

6 7

Extracting and detecting viral RNA in wastewater has proven to be a rapid and cost-effective approach for 9 community-level monitoring during the recent global Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-10 CoV-2) pandemic. Various sample concentrating methods, such as centrifugal ultrafiltration, have been utilized in 11 wastewater SARS-CoV-2 detection studies. However, freeze drying, a promising technique commonly used for 12 concentrating and preserving various biological samples, has yet to be explored in this field. This study compared 13 the performance of freeze-drying and the widely used centrifugal ultrafiltration method in terms of recovery rate, 14 detection limit, and other key parameters for concentrating 72 wastewater samples collected from four facilities in El 15 Paso, TX. Statistical analyses revealed that the freeze-drying method demonstrated higher overall recovery 16 efficiency (20.33% vs 13.00%), a superior detection ratio (68.4% vs. 31.6%), and lower detection limits 17 18 (0.06copies/mL vs 0.35copis/mL) than centrifugal ultrafiltration, particularly during the early stages of the pandemic. Despite its longer processing time than centrifugal ultrafiltration, freeze-drying offers several notable 19 20 advantages, including eliminating pretreatment steps, providing flexible sample storage options, preventing signal 21 loss and sample degradation, and reducing labor and exposure risks. Freeze-drying also does not require intensive 22 training for concentrating sewage water. These benefits, combined with its efficient capture of viral RNA, position 23 freeze-drying as a promising alternative for wastewater virus detection, especially in resource-constrained lab 24 settings at local wastewater treatment plants. The protocol and findings reported here provide a baseline for further development of freeze-drying-based methods for enabling community-level early warning and surveillance against 25 emerging viral threats in the future. 26

31 1. Introduction

27

Coronavirus disease 2019 (COVID-19) is caused by the Severe Acute Respiratory Syndrome Coronavirus 2 32 (SARS-CoV-2), a single-stranded RNA virus. The World Health Organization has classified COVID-19 as a global 33 pandemic. As of December 15, 2024, the total number of deaths attributed to the disease worldwide is 7,079,142 34 35 (CDC, 2020b; World Health Organization, 2020). To proactively monitor and mitigate the further dissemination of 36 the virus at the early stage of a pandemic, the surveillance of viral presence in wastewater has emerged as a 37 significant strategy. Notably, in March 2020, Medema et. al., conducted the first-ever successful research in the Netherlands, highlighting the feasibility of wastewater-based surveillance for COVID-19 (Medema et al., 2020). 38 39 Subsequently, Wurtzerthe et. al. detected viral genetic material in wastewater samples before the epidemic reached a massive scale around March 8th (Wurtzer et al., 2020). Furthermore, Fontenele et. al. screened SARS-CoV-2 viral 40 signals from 91 wastewater samples among 11 states (Fontenele et al., 2021). Quantifying of SARS-CoV-2 viral 41 RNA in sewage offers the possibility to develop an early alarm system, providing valuable insights into disease 42 prevalence and potential virus transmission within populations. A similar system can provide early alarm for future 43 pandemics, allowing public health authorities more time to respond. Thus, a sensitive and cost-effective method will 44

45 be desirable for such applications.

Nevertheless, assessing viral load within wastewater presents challenges due to the variable composition of 46 sewage. Wastewater comprises both liquid and solid phases, each containing a variety of substances (Wakefield, 47 48 2015). The liquid phase primarily consists of water with dissolved substances, including organic and inorganic compounds, nutrients, and pathogens (Friedler et al., 2013; Henze, 2008; Prot et al., 2022; Shi et al., 2021; Zhang et 49 al., 2021). The solid phase includes suspended solids, colloidal particles, and settleable materials based on their size 50 and behavior in water (Otterpohl and Buzie, 2013; Rashid et al., 2021; Sahu et al., 2014). Moreover, the composition 51 of wastewater is influenced by numerous factors, including local precipitation, drought conditions, temperature 52 53 fluctuations, and water usage patterns (Hughes et al., 2021). Therefore, the concentration of viruses in wastewater 54 can fluctuate widely. In addition, nuclease in the environment can potentially degrade viral nucleic acids, particularly RNA, representing another significant factor impacting RNA viral concentration in wastewater (Farkas 55 et al., 2020). Considering all these variables, detecting minute quantities of specific pathogens in the complex matrix 56 of wastewater represents a substantial challenge, necessitating proper sample handling to ensure the collection and 57 preservation of viruses for subsequent detection. 58

To tackle these challenges, the detection method should be developed specifically to address the properties 59 of wastewater. Such a method should efficiently collect viruses from both phases of wastewater while safeguarding 60 61 the viral genomic materials from degradation. It is crucial to maintain appropriate temperatures during sample 62 handling and minimize the processing time to prevent RNA degradation due to the ubiquitous existence of RNase in 63 the environment (Farkas et al., 2020). Given the expected low viral load during the early stages of a pandemic and 64 the fluctuation of viral concentration in wastewater, a substantial volume of samples is required to achieve 65 detectable results. In addition, sampling at multiple sites and time points is required for such an early warning system to work. Thus, an efficient concentrating method that is safe and minimizes labor-intensive processes is 66 highly desirable for long term surveillance. The U.S. Centers for Disease Control and Prevention (CDC) have 67 outlined five distinct methodologies for concentrating viral particles from wastewater: ultrafiltration, electronegative 68 membrane filtration with sample pre-treatment, polyethylene glycol (PEG) precipitation, skim milk flocculation, and 69 centrifugal ultrafiltration. While each of these methods employs different principles to address the challenge of low 70 viral RNA content in wastewater, none fully meets all the criteria for effectively concentrating and detecting viruses. 71 Filtration-based methods are limited to collecting viruses in the liquid phase, potentially missing those associated 72 with solid particles. The use of additional chemicals in electronegative membrane filtration, precipitation, and 73 flocculation potentially inhibits subsequence viral detection. Ultracentrifugation cannot handle large-volume 74 samples, limiting its practicality for widespread usage. In summary, achieving sensitive viral RNA detection in 75 wastewater samples, especially during the onset or decline of COVID-19 peaks with sporadic infections, 76 necessitates the development of more strategic sample concentrating methods. 77

78 A promising yet unexplored approach in concentrating wastewater is freeze-drying. Traditionally, this 79 technique has been widely used to preserve various biological products in laboratory and industry circumstances (Liu and Zhou, 2015). It has also been utilized for environmental samples, such as soil, to preserve and concentrate 80 nucleic acids for next-generation sequencing (Weißbecker et al., 2017). Recently, freeze-drying was used to 81 concentrate wastewater samples to evaluate the deactivating effect of Fe³⁺ treatment on bacteria (Qin et al., 2018). 82 However, freeze-drying has not been explored for virus detection in wastewater. During freeze drying, ice within 83 samples is sublimated into vapor under vacuum and frozen temperature conditions, effectively removing water from 84 85 wastewater matrices. This method uniquely retains viral entities from both the liquid and solid components of wastewater, potentially enhancing detection sensitivity. Additionally, freeze-drying does not rely on reagent-86 dependent sample pre-treatment, thus preserving sample integrity from chemical interventions. The cryogenic 87 environment during freeze-drying prevents the degradation of viral RNA, thereby increasing the detection limit in 88 the subsequent steps. Although the overall processing time for large-volume samples is lengthy, freeze drying offers 89 operational convenience by requiring minimal human oversight after initial setup. In summary, freeze drying is an 90 ideal choice for sensitive, reliable, and less labor-intensive virus detection methodologies, as it minimizes viral loss 91

92 and optimizes the protection of viral RNA.

This study will be the first to apply freeze drying to measure SARS-CoV-2 levels in wastewater. A 93 comparative analysis was conducted between freeze drying and centrifugal ultrafiltration as concentrating methods 94 95 for wastewater samples. Throughout the subsequent sections, "ultrafiltration" will be used in lieu of the more descriptive term "centrifugal ultrafiltration" to improve conciseness. Ultrafiltration was chosen for comparison 96 because it is the widely used method, having been employed in the first and several early publications on detecting 97 of SARS-CoV-2 in wastewater. In this study, factors such as recovery efficiency and detection limit were compared 98 and evaluated between these two methods using Reverse Transcription Quantitative Polymerase Chain Reaction 99 100 (RT-qPCR). The resulting data is pivotal for developing a sensitive, precise, reproducible, and practical system to detect viruses in wastewater, ultimately enhancing community-level early warning and surveillance capabilities. 101

102

103 **2. Material and Methods**

104 2.1. Sample collection and pasteurization

On the designated sample collection dates, 500 mL 24-hour composite wastewater samples were obtained 105 from four wastewater treatment plants (WWTPs) in El Paso, Texas, USA. These WWTPs include Haskell Street 106 Wastewater Plant (HS), John T. Hickerson Water Reclamation Facility (JH), Fred Hervey Water Reclamation (FH), 107 and Roberto Bustamante Wastewater Plant (BU). For safety concerns during the pandemic before the person-to-108 person transmission pathway of the SARS-CoV-2 was elucidated (March 2020 to July 2020), a sample collecting 109 protocol was developed and approved by the Institutional Biosafety Committee of the University of Texas at El 110 Paso. Individuals collecting samples wore disposable single-use nitrile gloves (double layer), splash goggles, N95 111 or surgical masks, and disposable lab coats. 112

Samples were collected in the pre-cleaned wide-mouth leak-proof bottles (FisherbrandTM, Cat# 05719709), which were then capped and sealed with parafilm, and the exterior was disinfected with Cavicide using absorbent pads. Both the bottle and the absorbent pads were placed into one zip-lock bag, and then in a second zip-lock bag. The double zip-lock bagged samples were transferred to the non-porous hard-plastic transport cooler with coolant blocks and spill-absorbing materials inside until arrival at the biosafety level 2 (BSL-2) lab. Upon sample retrieval, the surface of the Ziploc bags was wiped with disinfectant one more time.

119 Samples collected in the early days of the pandemic, before the analysis protocol was fully developed, were 120 immediately frozen and stored at -80°C until further analyses. Before analyses, these early pandemic samples were 121 thawed and pasteurized in a water bath at 65°C for 90min to inactivate any remaining virus as recommended by the 122 CDC guidelines (CDC, 2020a). After the protocol was fully developed during the later period of the pandemic, the 123 collected armsles meet an externing the fore heir stored at 200°C

123 collected samples were pasteurized before being stored at -80°C.

124 *2.2. Sample concentrating via freeze-drying*

Although samples were pasteurized and thus considered to be biosafety level 1 (BSL-1) based on the CDC 125 guidelines (CDC, 2020a), a fully sealed freeze-drying set-up was overcautiously designed and implemented using 126 127 FreeZone 2.5 Liter -84°C Benchtop Freeze Dryer (LabconcoTM, Cat# 710201000), this design is illustrated in Fig. 1. The biosafety set-up incorporated multiple safeguards: (1) The freeze dryer vacuum chamber contained PTFE 128 coated coil, which is resistant to erosive disinfectants that are used after each freeze-drving cycle; (2) Three layers of 129 Filter papers (LabconcoTM, Cat# 7544810) and aseptic valve (LabconcoTM, Cat# 7543900) were added between the 130 fast-freeze flask and manifold to prevent any potential accidental pathogen from passing through; (3) A HEPE filter 131 was added before vacuum pump as the secondary filter to capture any potential accidental pathogen leakage and 132 spillage; (4) Wastewater samples were placed inside plastic Erlenmeyer flasks which were wrapped with absorbent 133 pads in 600ml Complete Fast-Freeze Flasks (Labconco™, Cat# 7540800). The absorbent pads were intended to 134 capture any accidental spill; and (5) The exhausting pipe was connected to the chemical fume hood, to exhaust the 135 odorous volatile organic compound from the wastewater. Even with these safety designs, as an extra precaution, all 136 potentially contaminated containers and the flow path before the HEPA filter were disinfected after each freeze-137 138 drying run.

Prior to the freeze-drying procedure, 200ml of each pasteurized wastewater sample was weighed and aliquoted to a 250ml plastic Erlenmeyer flask, wrapped with absorbent pads, placed into a zip-lock bag, and frozen at -80° C at least overnight. On the day of concentrating, the frozen samples in Erlenmeyer flasks wrapped with absorbent pads were then placed in Fast-Freeze Flasks with plastic Erlenmeyer flask caps loosened. Freeze-drying was conducted with temperature set to -86° C and vacuum to 0.040mbar. After approximately three days of freeze-

144 drying, sample masses were reduced to about 3g. Volume reduction factors were estimated by sample weight before

and after freeze drying. The freeze-dried samples were dissolved in three volumes (v/w), approximately 9mL, of

146 TRIzol[™] LS reagent (Thermo Fisher Scientific, Cat # 10296-028). Samples were vortexed to ensure thorough

mixing before storing at -20° C until viral RNA extractions. It has been proven that TRIzol will deactivate all viral

pathogens such as SARS-CoV-2 in the sample (Patterson et al., 2020). Therefore, the following steps will be

- 149 considered as BSL-1.
- 150

151
 152 Fig. 1. Schematic diagram of freeze-drying set-up. Key biosafety safeguard features are highlighted and labeled with numbers
 153 within the diagram.

154 2.3. Sample concentrating via ultrafiltration

In parallel to concentrating samples via freeze-drying, another 200ml of pasteurized wastewater sample 155 was aliquoted into four 50ml conical tubes and loaded into swinging buckets (Thermo Fisher Scientific, Cat# 156 75003655) with adaptors (Thermo Fisher Scientific, Cat# 75003683) for the TX-400 rotor (Thermo Fisher 157 Scientific, Cat# 75003181). The swinging buckets are sealed with ClickSeal Biocontainment Lids (Thermo Fisher 158 Scientific, Cat# 75003656) and wiped with disinfectant on the outside before centrifuging at $3000 \times g$ for 15min 159 using Multifuge X1R Refrigerated Centrifuge (Thermo Fisher Scientific, Cat# 75004251). After centrifugation, the 160 supernatant was filtered using a 0.22µm PES bottle filter (CorningTM, Cat# 431096) while the pellets were collected 161 and weighed. Three volumes of (v/w) TRIzolTM LS reagent was added to the weighed pellet. All these procedures 162 were carried out in a biosafety cabinet (BSC) to ensure safety. Fig. 2 illustrates the filter system with multiple, 163 164 overcautiously designed safeguards: (1) A trap bottle with disinfectant on the bottom was connected to the filter bottle to capture any potential accidental pathogen leakage and spillage; (2) An in-line 0.22µm filter was added 165 before the vacuum valve further to capture any potential accidental pathogen leakage and spillage. 166

Inside the BSC, the filtered supernatants from the previous step were aliquoted (approximately 70ml) into 167 Centricon Plus-70 with 10kDa MW cut-off membrane (MilliporeSigma, Cat# UFC701008) and placed into 168 disinfected swinging buckets (Thermo Fisher Scientific, Cat# 75003655, with seal cap Cat# 75003656). The buckets 169 were completely sealed with ClickSeal Biocontainment Lids (Thermo Fisher Scientific, Cat# 75003656) and wiped 170 with disinfectant on the outside before being taken out from BSC to be loaded onto TX-400 rotor (Thermo Fisher 171 172 Scientific, Cat# 75003181). The samples were centrifuged at 3500×g for about 15min using Multifuge X1R 173 Refrigerated Centrifuge (Thermo Fisher Scientific, Cat# 75004251). After centrifugation, the swinging buckets were moved back into the BSC, and the passthrough liquid was disinfected and discarded. Following the same 174

- centrifugation protocol, the remaining filtered supernatants were added to Centricon Plus-70 units for the next roundof concentrating via ultrafiltration.
- 177After three to four rounds of centrifugation, the sample volume was reduced from 200ml to approximately1780.5mL. Following the manufacturer's instructions, the filters were inverted and centrifuged at $1,000 \times g$ to collect the
- 179 concentrates. The concentrated samples were subsequently transferred to new tubes and mixed with three volumes,
- approximately 1.5mL, of TRIzol[™] LS reagent. TRIzol treated samples were vortexed to ensure thorough mixing
- before being stored at -20° C until viral RNA extractions. Volume reduction factors for ultrafiltration were
- determined by comparing the weights of the samples before and after concentrating. All the filters and liquid
- transfer pipettes were soaked in $\sim 1\%$ bleach for at least 15min before being safely discarded.

188 2.4. Viral RNA extraction and quantification

SARS-CoV-2 RNA was extracted and purified using the PureLinkTM RNA Extraction Kit (Thermo Fisher 189 Scientific, Cat# 12183018A). Prior to RNA extraction, the frozen samples mixed with TRIzol were thawed at room 190 191 temperature. For every milliliter of sample mixed with TRIzol, 0.2ml of Chloroform was added. The mixture was then centrifuged at 12,000×g at 4°C for 30mins using ST16 Centrifuge (Thermo Fisher Scientific, Cat# 75004381). 192 Following centrifugation, the colorless upper aqueous phase, which contains the RNA, was carefully extracted and 193 collected. Ethanol was then added to the collected sample to reach a final concentration of 35%. The samples were 194 aliquoted (600μ L each) into spin cartridge provided in the kit and then spun at $6,800\times$ g for 30s. The process of 195 aliquoting and spinning was repeated until the entire sample was passed through the spin cartridge. The bound RNA 196 197 was eluted from the spin cartridge in 30µL of ribonuclease-free water and collected by centrifugation. To maximize RNA recovery, second and third elutions were performed by adding 100µL of ribonuclease-free water and 198 centrifuging. The purified viral RNA was immediately analyzed by one-step RT-qPCR or stored at -20°C to 199 minimize RNA degradation. 200

SARS-CoV-2 RNA was quantified by one-step RT-qPCR using N1 and N2 primers sets suggested by the 201 202 CDC (Dare et al., 2007; Lu et al., 2020) (Table 1). Samples were analyzed using the TaqPath[™] 1-Step RT-qPCR (Thermo Fisher Scientific, Cat# A15299) in 20-µL reactions. The PCR reactions were run at 50°C for 15min and 203 95 °C for 2min, followed by 45 cycles of 95°C for 5s and 55°C for 30s per manufacturer's recommendations. The 204 performance and efficiency of N1 and N2 primers in the RT-qPCR assay were first evaluated by generating standard 205 curves using ten-fold series dilution (100 to 10^5 copies per reaction) of templates: (1) a DNA plasmid containing 206 complete nucleocapsid gene from SARS-CoV-2 (IDT, Cat# 10006625), and (2) Twist synthetic SARS-CoV-2 RNA 207 (Twist Bioscience, Cat# MT0075s44). The standard curve was plotted as RT-qPCR Ct value (v-axis) against the log 208 of copy number (x-axis) estimated from the dilution of the original standards (Fig.4). Linear least square fitting was 209

performed for each set of plotted data using the equation $y = a \times x + b$. The quality of these fittings was accessed 210 using the coefficient of determination R² values. To evaluate the stabilities of DNA and RNA standards, RT-qPCR 211 212 standard curves were generated the day when they were prepared and again after three or four months of storage at -20°C. Small-scale RT-qPCR was performed using a Magnetic Induction Cycler (Bio Molecular System, Cat# 71-213 101). Later, the StepOnePlus[™] Real-Time PCR System (Thermo Fisher Scientific, Cat#4376600) was used for 214 large-scale RT-qPCR. 215 The original DNA and RNA stock had concentrations of 2.0×10^5 copies/µL and 1.0×10^6 copies/mL, 216 217 respectively. According to the literature, the Ct value from RT-qPCR is linear to the logarithm of sample concentration (Bustin et al., 2009). Therefore, using the 10-fold diluted standard curves, Ct values from specific RT-218 qPCR can be converted into virus concentration in units of copies/mL using a fitted function of the standard curve as 219 shown in Fig.4. Then, for each elution, the amount of virus detected can be calculated using the equation:

220 221

222 *Virus detected = Virus concentration* × *elution volumn* ($30\mu L$ *for* 1^{st} *elution and* $100\mu L$ *for* 2^{nd} *elution*) Eq. 2.1

Total copies of the virus detected (column Total copies in Supplementary Table 1) will be the summation of the virus detected from both elutions. The detecting viral concentration in the original unconcentrated sample (column D.c. in Supplementary Table 1) can be determined using the equation:

226

227 Detected concentration = Total copies / original sample volume

Eq. 2.2

These calculations for detected concentration in the original unconcentrated sample also enable the comparison of analytical sensitivity between the two concentrating approaches. Method-specific detection limits were determined by the minimum detected concentration from all the wastewater samples using the same method (Supplementary Table 1 last row).

232 (Supplementally Factor)

	Probe	5'-6FAM-TCCGCCTGGCACGGTACTCCCT-BHQ-3'

234 2.5. Recovery efficiency calculations using OC43

235 OC43 was chosen as the surrogate virus in this study to calculate recovery efficiency for both concentrating 236 methods: freeze-drying and ultrafiltration. To estimate the amount of virus to be spiked to wastewater for recovery efficiency calculation, a standard curve of heat-inactivated OC43 virus was generated. The virus infectivity of the 237 original stock of heat-inactivated OC43 culture fluid (ZeptoMetrix, Cat# 0810024CFHI) is defined by the median 238 tissue culture infectious dose (TCID₅₀), the dilution of virus required to infect 50% of the given cell monolayers (Lei 239 et al. 2020). An exact 100 μ L aliquot of this inactivated OC43 at 5.0 ×10⁸TCID₅₀/ μ L was used to prepare a10-fold 240 serial dilutions with water. The concentration of inactivated OC43 in each dilution was determined based on the 241 dilution factor. These serially diluted samples were then subjected to the same procedures aforementioned for 242 TRIzol treatment, RNA extraction, and RT-qPCR, but with different primer/probe sets for OC43 (Sigma Custom 243 DNA Oligos Cat# 41105327) (Table 1). Following a similar approach mentioned in Section 2.4 for DNA and RNA 244 standards, a standard curve was established by plotting the RT-qPCR Ct value (y-axis) against the logarithm of heat-245 246 inactivated OC43 concentration, expressed in the units of TCID₅₀.

To calculate the recovery efficiency of the virus from the wastewater sample, an exact 20uL aliquot of Zeptometrix heat-inactivated OC43 was spiked into 400ml wastewater sample. To demonstrate that RT-qPCR

cannot detect the virus without concentrating the wastewater sample, 1mL of spiked sample was collected and

treated with 3 mL of TRIzol[™] LS reagent. The remaining spiked sample was divided into two parts (approximately 200mL each) and concentrated via either freeze drying or ultrafiltration, following the same procedure described in

251 Sections 2.2 and 2.3 on sample concentrating. Viral RNA was then extracted and analyzed by RT-qPCR using the

same procedure described previously in Section 2.4, but with a different primer/probe set for OC43 as listed in

254 Table 1.

Using the initial concentration $(5.0 \times 10^8 \text{TCID}_{50}/\mu\text{L})$ and volume $(20\mu\text{L})$ of heat-inactivated virus spiked 255 256 into wastewater, the total amount of virus added was estimated to be $2.67 \times 10^4 \text{TCID}_{50}/\mu\text{L}$. After concentrating the spiked wastewater sample using freeze-drying and ultrafiltration, RT-qPCR was performed on the extracted and 257 purified RNA sample using the same conditions as used for the heat-inactivated OC43 standard curve. The Ct value 258 from the RT-PCR and the standard curve allowed the estimation of the amount of virus recovered by the two 259 methods, expressed in the unit of $TCID_{50}/\mu L$. Recovery efficiency was then calculated as the ratio of the recovered 260 virus amount to the amount initially spiked, with both values expressed in units of $TCID_{50}$. The recovery efficiency 261 estimations were performed in triplicate, allowing for the calculating the mean and standard deviation for each 262 method. A Wilcoxon test, a nonparametric statical hypothesis test without assuming a normal distribution of the data 263 264 (Damian Riina et al., 2023), was subsequently conducted to determine whether there was a significant difference 265 between the two methods.

266 2.6. Creatinine measurement

267 Creatinine concentration was measured to evaluate human contribution to wastewater. Frozen pasteurized
 268 samples were thawed at 4°C, and 100μL was aliquoted for creatinine analyses using a creatinine colorimetric
 269 detection assay (Enzo Life Sciences, Cat# ADI-907-030).

270 2.7. Epidemiological data and statistical analysis

271 Daily COVID-19 record from April 14, 2020, to May 28, 2021 in El Paso, TX, was collected from https://www.epstrong.org/results.php and https://elpasocovid19tracker.com/index.html. Sampling dates with 272 associated viral load calculations from all four wastewater plant sites are listed in Supplementary Table 1. The 273 correlation between the total COVID-19 cases and SARS-CoV-2 viral load in wastewater was evaluated using the 274 Pearson correlation coefficient (Lee Rodgers and Nicewander 1988). This correlation coefficient, ranging from -1 to 275 1, provided a quantitative measure of the observed relationship between the two variables: COVID-19 case numbers 276 and SARS-CoV-2 viral load in wastewater. A correlation coefficient close to zero means no correlation, while close 277 to 1 and -1 indicate strong positive or negative correlation, respectively. All data processing and statistical analyses 278 279 were conducted using R Studio (Rstudio Team, 2020).

280 **3. Results and Discussion**

Our study underscores the importance of strict safety procedures when handling wastewater samples 281 containing emerging pathogens, particularly in adhering to the stringent biosafety standards set by institutions such 282 as the CDC and NIH. The designs of our wastewater sample collection and processing protocols reflect a strong 283 commitment to these high safety standards. A multilayer safety setup was implemented during sample collection and 284 pasteurization, including the use of disposable protective gear, rigorous disinfection protocols, and an approved 285 safety protocol developed early in the SARS-CoV-2 pandemic. This proactive approach to biosafety was crucial 286 during uncertain times. Combining sample collection with immediate pasteurization, a swift transition to BSL-1 287 became possible, offering a versatile solution for handling unknown emerging pathogens. This approach is 288 particularly beneficial for laboratories with limited resources, such as those affiliated with wastewater treatment 289 plants. 290

3.1. Number of Samples

A total of 83 wastewater samples were collected from four wastewater treatment plants (WWTPs) in El Paso, Texas, USA, from April 14, 2020, to May 28, 2021. However, some samples from certain WWTPs were unavailable due to technical and personnel challenges encountered during the pandemic. During the initial small peak between April 2020 and May 2020, 71 samples were collected and stored in a -80°C freezer using sample collection protocol approved by the Institutional Biosafety Committee (IBC) at the University of Texas at El Paso

297 (UTEP) before the analytic protocol was fully developed and approved by IBC. Due to the limited lab accessibility

²⁹⁸ during the pandemic, human resources constraints, and the restricted storage space in -80°C freezers, sample

collection was paused between August 2020 and April 2021. Once the samples were processed using the fully developed and approved protocol and storage space was freed up in -80°C freezers, sample collection was resumed

developed and approved protocol and storage space was freed up in -80°C freezers, sample collection was resumed in May 2021. The collection frequency during this period was more sporadic, depending on the processing speed of

stored samples. For the second period, a total of 12 samples were collected. Following pasteurization to inactivate

wastewater pathogens, 71 samples were concentrated using freeze-drying and 70 using ultrafiltration respectively.

Additionally, 56 pellets were collected from 70 ultrafiltration samples (Fig.3). Unfortunately, RT-qPCR date for

about 10 samples were lost due to an unexpected crash of the computer that controls the StepOnePlus[™] Real-Time

306 PCR System. At the end, data from a total of 72 samples were obtained (Fig. 3, Supplementary Table 1).

307

308

Fig. 3. Flowchart of sample processing with sample numbers. Samples collected from four different WWTPs were inactivated through

310 pasteurization, and then concentrated using two methods. The number of samples processed at each pre-process step is indicated in parentheses

after "n =". Viral RNA of all the samples was extracted from concentrated samples and subjected to RT-qPCR for quantification. FH, Fred

314 *3.2. RT-qPCR primer selection and template stabilities*

Fig. 4 (original data in Supplementary Table 2) shows standard curves and their least-squares regression equations $y = a \times x + b$, with coefficients *a* and *b*. The slope *a* should be negative, with an absolute value between 3.3 and 3.4, as the literature suggests that each 10-fold drop of the template is expected to increase approximately 3 PCR cycles to reach the same fluorescent signal value (Svec et al., 2015). Any value out of this range indicates potential issues with the dilution of standard templates or suboptimal RT-qPCR conditions. The y-intercept b represents the Ct value when there is no template, where the fluorescence may arise from one or more of the following: non-specific amplification, primer-dimer formation, and background signal (Taylor et al., 2017).

322 The standard curve analysis provides valuable insights into the performance and suitability of the N1 and N2 primers for quantifying RNA and DNA targets from SARS-CoV-2 samples. Across all time points of RNA and 323 DNA standards, the N1 primer consistently exhibited higher R² values than the N2 primer, indicating a stronger 324 linear correlation between the measured and expected quantities. Additionally, the fitted lines of N1 for both RNA 325 and DNA are lower than those of N2, reflecting overall lower Ct values for the N1 primer. These higher R² values 326 327 and lower overall Ct values highlight the superior quantification accuracy and reliability of the N1 primer, making it 328 the preferred choice. However, the impact of standards degradation over time cannot be overlooked, as evidenced by the progressive increase in the heights (Ct values) of fitting lines observed for both RNA and DNA standards. 329 Obviously, RNA exhibited more significant degradation than DNA underscoring its higher susceptibility to 330

degradation. The crossing observed in the RNA and DNA standard curves using N2 primers after storage in Fig. 4B
 and Fig. 4D suggests that the N2 primer region may be more susceptible to degradation, resulting in deviations from
 the expected slope (approximately -3) of the standard curve. Consequently, while the N1 primer is the optimal
 choice for fresh samples due to its stronger linear correlation, DNA standards are more suitable for long-term studies
 or situations requiring extended sample storage, owing to its greater stability. Therefore, for the subsequent studies,
 we used DNA standards to estimate the total number of detected viruses.

337

Fig. 4. RNA and DNA standard curves. Panels A and B display the fitted lines of qPCR Ct values plotted against gene copies of serially diluted
 RNA standards, using the N1 and N2 primers, respectively. Panels C and D present similar fitted lines for DNA standards. As the legend
 indicates, the different line colors represent standard curves generated from fresh samples or samples stored at -20°C for 3 or 4 months. The fitted

341 equations and corresponding R² values are shown in the same colors as their respective lines.

342 3.3. Comparison of recovery efficiency of two concentrating methods

To compare the recovery efficiency of the two concentrating methods, OC43 was spiked into a wastewater sample. Both OC43 and SARS-CoV-2 are beta-coronaviruses that cause respiratory infections in humans and are transmitted via droplets and/or aerosols. However, unlike SARS-CoV-2, OC43 does not cause severe disease in humans, making it an ideal surrogate for laboratory recovery tests without biosafety concerns.

347

348

Fig. 5. OC43 standard curve. qPCR Ct values are plotted against gene copies in units of $TCID_{50}/\mu L$, derived from serial dilutions of OC43 RNA standards. The fitted line illustrates the relationship using specific primers targeting OC43, with the corresponding equation and R² value shown on the graph.

352 Table 2. Recovery rate of freeze-drying and ultrafiltrati

Method	Ct			Average Ct (±SD)	Recovered virus (TCID ₅₀ /µL)	Recovery rate
Freeze drying	27.93	27.38	27.70	27.67 (±0.34)	5.42 x 10 ³	20.33%
Ultrafiltration	28.61	28.22	28.18	28.34 (±0.66)	3.47 x 10 ³	13.00%

353

Based on the standard curve using heat-inactivated OC43 virus (Fig.5, original data in Supplementary 354 Table 3), approximately 10.0×10^9 TCID₅₀ of the virus was spiked into 400mL of wastewater. This sample was 355 divided into two equal volumes and concentrated using either freeze-drying or ultrafiltration methods. A control 356 sample without concentrating had an undetermined Ct value, indicating that RT-qPCR could not detect the OC43 357 358 signal prior to concentrating. Recovery rates were calculated based on the Ct values from the first RNA extraction 359 elution and were found to be 20.33% for the freeze-drying method and 13.00% for the ultrafiltration method. The 360 freeze-drying method demonstrated a recovery efficiency that was superior to or at least comparable with the widely 361 used ultrafiltration technique.

Notably, the second elution from the freeze-dried sample exhibited a lower Ct value than the first elution 362 (Supplementary Table 1). This phenomenon was also observed in other freeze-dry concentrated wastewater samples 363 during SARS-CoV-2 detection but not in the sample concentrated via ultrafiltration or RNA extracted from heat-364 inactivated OC43 serial dilution when establishing the standard curve. Since the freeze-drying process concentrates 365 all small molecules, it is possible that inhibitory substances affecting RT-qPCR may also be enriched. When 366 combining the recovery rates from both the first and second elutions, the overall recovery rates remained at 22.37% 367 for freeze-drying and 13.93% for ultrafiltration, demonstrating the potential advantage of the freeze-drying 368 approach. 369

370 *3.4. Comparison of early detection of two concentrating methods*

To evaluate the detection sensitivities of the freeze-drying and ultrafiltration methods, wastewater viral 371 load data from the early stages of the COVID-19 pandemic (April 2020 to May 2020) were analyzed. A total of 38 372 samples were collected from various wastewater treatment plants in El Paso, Texas. The freeze-drying method 373 identified 26 positive samples (68.4%) (Table 3). As previously discussed, the freeze-drying method yielded lower 374 Ct values (indicating more sensitive detection) in the second elution. When the second elution was included, the 375 detection ratio increased to 28 positive samples (73.7%). In contrast, the ultrafiltration detected only 12 positive 376 samples (31.6%), which increased slightly to 13 positive samples (34.2%) when including the second elution (Table 377 3). The higher detection ratio observed with the freeze-drying method highlights its superior ability to concentrate 378 viral material compared to ultrafiltration. 379

380

381 Table 3 Positive ratio and Ct value range for samples collected from four WWTPs between April 2020 to May 2020

C:4-	Sample	Positive numbers		Positive Ratio %		Range of Ct Value	
Sile	Number	Freeze dry	Ultrafiltration	Freeze dry	Ultrafiltration	Freeze Dry	Ultrafiltration
HS	18	12 (14)	5 (6)	66.7 (77.8)	27.8 (33.3)	31 (32) – 42 (42)	33 (33) - 38 (38)
ЛН	1	1 (1)	1 (1)	100.0 (100.0)	100.0 (100.0)	33 (33) - 33 (35)	35 (35) - 36 (36)
FH	8	6 (6)	5 (5)	75.0 (75.0)	62.5 (62.5)	32 (32) - 39 (39)	32 (32) – 41 (41)
BU	11	7 (7)	1 (1)	63.6 (63.6)	9.1 (9.1)	33 (33) - 37(37)	33 (33) - 34 (34)
Total	38	26 (28)	12 (13)	68.4 (73.7)	31.6 (34.2)		

* Numbers in the parentheses are values obtained from the second elution

382 383

The superior detection sensitivity of the freeze-drying method was further supported by the lower average 384 Ct values obtained during RT-qPCR analyses. Across all four wastewater treatment plants, the freeze-drying method 385 consistently exhibited lower Ct values compared to ultrafiltration (Table 3), indicating a higher amount of viral RNA 386 in the concentrated samples. Furthermore, a paired T-test analysis was conducted to compare virus copies in the 387 original wastewater samples across all four facilities. As described in the Section 2., the total virus copies were 388 estimated using the DNA standard curve and the Ct values. For both freeze dry and ultrafiltration methods, both first 389 and second elutions were combined to calculate the total RNA copies in the original wastewater samples. Where a 390 method or elution did not detect the virus, it was recorded as zero copies. A total of 11 data pairs showed that freeze-391 drying method detected significantly higher virus concentration than ultrafiltration with a p-value smaller than 392 0.0068 from the Wilcoxon test. As described in Section 2.4, method-specific detection limits can be determined 393 using the highest Ct value for each method and the standard curves. The freeze-drying method demonstrated a lower 394 limit of detection (0.06 copies/mL) compared to ultrafiltration (0.35 copies/mL) (Supplementary Table 1). 395

396 3.5. Correlated virus load and case number in epidemic

Due to the substantial variation in wastewater flow rate caused by weather conditions (rainfall, drought, and 397 temperature-dependent evaporation) and fluctuations in water usage throughout the day, estimating the proportion of 398 human contribution to wastewater is challenging (Katukiza et al., 2012). To address this issue, the concentration of 399 creatinine, a metabolic product from humans, has been proposed as an internal control for assessing human 400 contribution to wastewater (Chen et al., 1977; Daughton, 2012). However, many of the reported creatinine levels in 401 wastewater, as low as 0.01 mg/dL (Rusiñol et al., 2021), are close to or outside the limit of the detection kit (0.042 402 mg/dL) (Enzo Life Sciences Cat# ADI-907-030), raising concerns about the reliability of using creatinine as the 403 404 internal standard for human contribution. This discrepancy may be attributed to the dilution effect of non-human wastewater components, such as industrial and agricultural effluents, which can significantly impact creatinine 405 concentrations (Choi et al., 2018). In this study, the creatinine levels detected were listed in Supplementary Table 1. 406 When using pure water as blank, as recommended by the manufacturer, some of our measurements yield negative 407 values, suggesting the presence of certain interfering substances in wastewater that require further investigation 408 (Xagoraraki and O'Brien, 2020). As a result, we decided not to use creatinine concentrations to normalize our viral 409 load data, as the low levels of creatinine detected in our samples might not accurately reflect the human contribution 410 to the wastewater. 411

To investigate the correlation between the measured viral load in wastewater and the reported COVID-19 412 cases in El Paso, TX, available viral load data from Haskell Street Wastewater Plant which serves the central and 413 east area of El Paso were collated with the corresponding daily COVID-19 case counts on the wastewater sample 414 collection dates in the city covering zip codes 79901, 79902, 79903, 79904, 79905, 79907, 79912, 79915, 79922, 415 416 79925, 79928, 79930, 79935, 79936, and 79938. The data was tested for normality using the Shapiro-Wilk test. Since p<0.05, it was concluded that the data was not normally distributed. Given the small sample size, a non-417 parametric test was chosen instead of a parametric test (de Souza et al., 2023; King and Eckersley, 2019). The 418 Spearman rank correlation test was applied to evaluate the association between the total viral load and the total 419 number of reported cases on each date across the studied areas. The Spearman rank test is a non-parametric method 420 that uses the correlation coefficient rho (ρ) to measure the strength and direction of a monotonic relationship 421 between two variables, with values ranging from -1 (perfect negative correlation) to 1 (perfect positive correlation). 422 The Spearman correlation coefficient was calculated to assess the relationship between mean virus concentrations 423

and total COVID-19 case counts in the datasets. Due to the unavailability of active case numbers during the early

stages of the pandemic (April 2020 to May 2020), the analysis was conducted using cumulative case numbers.
 During this period, the difference between active and cumulative cases was likely minimal. Additionally, prior

427 studies have indicated that recovered patients may continue shedding the virus (Kampen et al., 2021). During the

early period, the analysis revealed a moderate negative correlation of -0.072 between the freeze-dried viral load and

the cumulative case numbers. However, this correlation was not statistically significant (p=0.808). Similarly, for the

430 ultrafiltration method, using data from the same period, the analysis showed a moderate negative correlation of -

431 0.316 between the viral load and the cumulative COVID-19 case numbers, which was also not statistically

432 significant (p=0.270).

433 4. Discussion

434 Specific precautions must be followed to mitigate RNA degradation in concentrated wastewater and preserve its integrity for potential future analyses. Immediate sample processing post-collection is ideal for 435 maximizing RNA extraction yield and maintaining its integrity. However, logistical constraints often necessitate 436 sample storage, for which TRIzol or similar denaturing reagents are highly recommended. TRIzol effectively 437 inhibits RNase activity, thereby preventing RNA degradation (Chomczynski and Sacchi, 2006). Concentrated 438 samples in TRIzol demonstrate superior stability for long-term storage, particularly when stored at -80°C freezer 439 (Fabre et al., 2014). Thus, maintaining samples in TRIzol without RNA extraction until imminent RT-qPCR analysis 440 is considered the optimal storage strategy. Moreover, minimizing freeze-thaw cycles of samples, regardless of the 441 storage method, is critical to prevent RNA degradation. RNases are prevalent and can regain enzymatic activity after 442 removing denaturing conditions (Thatcher, 2015). Consequently, after RNA is extracted from the TRIzol storage 443 solution, downstream procedures should be performed promptly to minimize RNA degradation and ensure the 444 reliability and accuracy of the subsequent RT-qPCR analyses. 445

The two concentrating methods demonstrated contrasting advantages and disadvantages. For the 446 pretreatment step, ultrafiltration requires centrifugation and filtration to remove larger solid particles (sewage 447 448 sludge) that may clog the concentrator. Both steps may result in the loss of viral signals, as evidenced by the signal 449 detection in the pellet collected during the pretreatment steps (Supplementary Table 4). Other studies have also 450 observed a reduction in viral detection after removing solids from wastewater (Ahmed et al., 2020). Accordingly, 451 some studies recommend retaining solids in the wastewater for analysis. In contrast, the freeze-drying method does 452 not involve pretreatment steps to remove solids. All solids are retained in the final concentrate, allowing RNA from these solids to be extracted. However, the freeze-drying method does require an initial overnight low-temperature 453 freezing step (-80°C), which can be time-consuming. Considering that most wastewater samples are pasteurized and 454 stored at -80°C rather than being processed on the same day of collection, this freezing step could also provide 455 456 flexibility for both sample storage and processing time.

For the concentrating process, ultrafiltration involves using expensive filters and multiple centrifugation 457 and liquid handling steps. These steps prolong operator exposure to wastewater, increasing the potential risk of 458 459 pathogen transmission. Consequently, ultrafiltration requires rigorous personal protective equipment (PPE) and 460 extensive decontamination procedures for centrifuges, rotors, and buckets. This makes the process labor-intensive, thus limiting the throughput to approximately eight samples per day. Contrariwise, the freeze-drying method only 461 uses inexpensive sample bottles. It minimizes operator exposure to wastewater, with only brief handling required for 462 cap loosening of the bottles and mounting the Fast-Freeze Flask (Fig. 1). Decontamination was only needed at the 463 end of the freeze-drying process. Although the freeze-drying method does require three days to concentrate eight 464 465 samples to the desired volume, it demands minimal labor and reduces exposure to wastewater. Furthermore, the whole process for freeze drying does not require extensive training such as aliquoting and transferring wastewater 466 safely in BSC in ultrafiltration technique (Section 2.3) 467

Detection sensitivity is a critical factor in evaluating concentrating methods. The higher detection 468 sensitivity of the freeze-drying method can be attributed to several potential factors. Firstly, as literature 469 demonstrated, many viruses can be associated with sewage sludge (Kitajima et al., 2020; Ye et al., 2016). By 470 471 retaining all components of the wastewater, freeze-drying maximizes the capture of viruses present in wastewater. In contrast, ultrafiltration may exclude viral particles bound to sewage sludge, potentially resulting in signal loss. 472 Secondly, the freeze-drying process involves fewer liquid handling steps and minimizes sample loss during 473 processing, further contributing to its higher detection efficiency. Additionally, the cryogenic environment 474 maintained during freeze-drying helps prevent RNA degradation, preserving the integrity of viral genetic material 475 for downstream detection. The freeze-drying method's higher detection ratio and lower detection limit highlight its 476 advantages for early detection of viral pathogens during the onset of a pandemic. By effectively capturing and 477

concentrating viral material from wastewater samples, freeze-drying facilitates the identification of emerging viral
 threats at lower prevalence levels, enabling the timely implementation of public health interventions and
 surveillance strategies.

The relationship between wastewater viral load and community COVID-19 cases is a key consideration in 481 evaluating the utility of wastewater surveillance. Our finding is consistent with the literature, which has reported 482 varying degrees of correlation between wastewater viral loads and community-level COVID-19 cases. Several 483 studies have demonstrated a positive correlation, with higher viral loads in wastewater preceding or coinciding with 484 485 increased case counts in the corresponding communities (Medema et al. 2020; Randazzo et al. 2020). However, other studies have reported weaker or inconsistent correlations, potentially due to factors such as varying viral 486 shedding patterns, differences in testing rates, and the influence of local conditions on viral transport and persistence 487 in wastewater systems (Gonzalez et al. 2020). It is important to note that the correlation observed in this study is 488 based on minimal data from the early stages of the pandemic and lacks reliable normalization of human contribution 489 to wastewater. Although this study's primary focus is the evaluation and comparison of the freeze-drying and 490 ultrafiltration methods for concentrating viral particles from wastewater samples, the correlation analysis still 491 offered some insights into the relationship between wastewater viral loads and community-level case counts. 492

493 In summary, this study demonstrated that the freeze-drying method outperforms the widely used 494 ultrafiltration technique for concentrating viral particles from wastewater samples. The freeze-drying approach 495 exhibited higher overall recovery rates for the surrogate virus OC43, a higher detection ratio for SARS-CoV-2 viral RNA, and lower detection limits, particularly during the early stages of the COVID-19 pandemic. These findings 496 497 highlight the superior ability of freeze-drying to capture and retain viral material from complex wastewater matrices. While freeze-drying is more time-consuming, it offers several advantages over ultrafiltration. It eliminates the need 498 for pretreatment steps that might exclude viral signals associated with sewage sludge. Additionally, freeze-drying 499 provides flexibility in sample storage, reduces labor demands and exposure risks, and requires minimum training. 500

501 These advantages make freeze-drying a favorable option for wastewater virus detection, especially in resource-

502 constrained settings such as wastewater treatment facilities with limited personnel and training resources.

Combining efficient viral particle capture and operational practicality, positions freeze-drying as a promising
 approach for enhancing community-level early warning and surveillance capabilities against emerging viral threats.
