21

22 **ABSTRACT**

23 **Background:** Prior candidate gene studies have shown tumor suppressor DNA methylation in
24 breast milk related with history of breast biopsy, an established risk factor for breast cancer. To
25 further establish the utility of breast milk as a tissue-specific biospecimen for investigations of
26 breast carcinogenesis we measured genome-wide DNA methylation in breast milk from women
27 with and without a diagnosis of breast cancer in two independent cohorts.

28 **Methods:** DNA methylation was assessed using Illumina HumanMethylation450k in 87 breast
29 milk samples. After quality control, 368,171 autosomal CpG loci were analyzed. Cell type
30 proportion estimates from RefFreeCellMix were calculated and adjusted for in this Epigenome
31 Wide Association Study using linear mixed effects models adjusted for history of breast biopsy,
32 age, time of delivery, cell type proportion estimates, array chip, and subject as random effect.

33 **Results:** Epigenome-wide analyses identified 58 differentially methylated CpG sites associated
34 with a breast cancer diagnosis in the prospectively collected milk samples from the breast that
35 would develop cancer compared with women without a diagnosis of breast cancer (q -value <
36 0.05). Nearly all CpG sites associated with a breast cancer diagnosis were hypomethylated in
37 cases compared with controls, and were enriched for CpG islands. In addition, inferred repeat
38 element methylation was lower in breast milk DNA from cases compared to controls, and cases
39 exhibited increased estimated epigenetic mitotic tick rate as well as DNA methylation age
40 compared with controls.

41 **Conclusion:** Breast milk has utility as a biospecimen for prospective assessment of disease
42 risk, for understanding the underlying molecular basis of breast cancer risk factors, and
43 improving primary and secondary prevention of breast cancer.

44

45 **BACKGROUND**

46 Breast cancer is the most common non-keratinocyte cancer in women in the USA, with over
47 270,000 new cases each year [1]. Established risk factors for breast cancer include age,
48 reproductive history, and family history of disease and can be used to estimate disease risk
49 [2,3]. Additionally, and beyond the recognized role of inherited *BRCA* mutation, individual
50 germline genetic variants, and even polygenic risk scores from genome-wide association
51 studies have also contributed to breast cancer risk assessment [4–6]. Nonetheless, a large gap
52 in the capacity to predict breast cancer risk remains, and the molecular basis of breast cancer
53 risk and carcinogenesis has largely not been studied using target-organ biospecimens from
54 premenopausal women.

55 Epigenome-wide association studies (EWAS), using surrogate tissues such as peripheral blood
56 DNA, have also had some success testing the relation of DNA methylation with cancer risk [7–
57 9]. However, unlike genetic variation and germline alterations that confer cancer risk, cytosine
58 modifications that contribute to cancer risk as disease initiating and promoting events are
59 overwhelmingly tissue specific. Defining and leveraging knowledge of tissue-specific early DNA
60 methylation alterations for screening or risk models in normal, nontumor human tissues is
61 challenging for most common tumor types. Yet, use of breast-specific substrate to investigate
62 breast cancer risk has shown promise in early studies measuring cell composition, cytology, and
63 candidate gene DNA methylation from nipple aspirate fluid, though as a substrate, nipple
64 aspirate fluid can be challenging to obtain and typically yields very low volume [10–14].
65 Recently, the utility of altered DNA methylation in cancer screening and risk assessment was
66 established in colon cancer as part of the Cologuard multi-target assay where a tissue-specific
67 biospecimen (stool) is obtained and measured without using an invasive procedure [15].

68

69 The majority of extensive DNA methylation alterations observed in invasive breast cancer
70 compared with normal breast tissue, are already present in pre-invasive disease [16], [17]. In

71 addition, age-related variation in normal breast tissue DNA methylation has been shown to
72 occur at CpG sites that are more likely to be altered in breast tumors [18], suggesting that early
73 measures of DNA methylation in the pathologically normal breast has value as a biomarker for
74 future breast cancer risk [18]. Typically, mammary epithelial cells cannot be accessed without
75 invasive procedures (breast biopsy), lavage, or other relatively impractical methods. However,
76 exfoliated mammary epithelial cells are abundant in breast milk [19], a tissue-specific substrate
77 obtained without invasive procedure. These cells are an excellent target for biomarker
78 development, and prior candidate gene studies have shown that methylation-induced silencing
79 of tumor suppressor genes in breast milk is related with history of breast biopsy, an established
80 risk factor for breast cancer [20–22]. Given that 85% of 40 year-old women in the USA have
81 given birth [23], breast milk is a viable noninvasive source of mammary epithelial cells [24]. We
82 investigate the relation of early epigenetic alterations with breast cancer risk using cells
83 obtained from breast milk in controls compared with prospectively collected milk specimens
84 from subjects who were later diagnosed with breast cancer.

85 **METHODS**

86 **Study population**

87 Two different study populations were included in this study: 1) women from the “Molecular
88 Biomarkers for Assessing Breast-Cancer Risk” project at the University of Massachusetts
89 Amherst (UMass), and 2) participants of the New Hampshire Birth Cohort study (NHBCS) at
90 Dartmouth College. UMass subjects were women older than 18 years of age. They were either
91 lactating or have recently given birth, and they had a history of either breast biopsy or breast
92 cancer. UMass subjects were asked to provide one or two breast milk samples expressed in a
93 single pumping session. NHBCS participants characteristics has been described previously [25].
94 Briefly, NHBCS eligibility criteria included: English speaking, literate, and mentally competent
95 women carrying a singleton pregnancy, 18–45 years of age, and whose primary source of

96 residential water was a private well. Women who planned to move during pregnancy were
97 excluded from this study. NHBCS participants were asked to bring bilateral breast milk samples
98 to the postpartum follow-up appointment. All study participants provided written informed
99 consent prior to the study according to the guidelines of Institutional Review Board of the
100 University of Massachusetts Amherst and the Committee for the Protection of Human Subjects
101 at Dartmouth. Women in both studies were asked to complete a questionnaire about general
102 health, reproductive health, and personal breast biopsy and breast cancer history. Each
103 woman's samples were classified into five different groups: (1) no breast cancer history, (2)
104 healthy breast, contralateral breast cancer before donation, (3) ipsilateral breast cancer
105 diagnosis before donation, (4) healthy breast, contralateral cancer diagnosis after donation, and
106 (5) sample from the ipsilateral breast with cancer after donation. For this analysis, we report the
107 results of model milk samples from control subjects and from subjects with a subsequent
108 diagnosis of breast cancer.

109 **Sample collection**

110 Using a previously described method [24], breast milk was processed within 24 hours of sample
111 collection to obtain DNA. Briefly, DNA was extracted from 1 - 10 mL of milk from each breast
112 and stored at -20 °C until DNA extraction.

113 **DNA extraction and genome-wide DNA methylation array**

114 DNA was isolated using the Qiagen DNeasy Blood and Tissue Kit (Qiagen, Valencia, CA) and
115 bisulfite converted using the EZ DNA Methylation kit (Zymo, Irvine, CA). Samples were
116 randomized across several plates and subsequently subjected to epigenome-wide DNA
117 methylation assessment using Illumina Infinium HumanMethylation450 BeadChip, which
118 measured ~485,000 CpG sites genome-wide (Illumina, San Diego, CA). Microarrays were
119 processed at USC core facility following standard protocols. The data were assembled using

120 GenomeStudio methylation software (Illumina, San Diego, CA) without normalization per the
121 manufacturer's instructions. The methylation status for each individual CpG locus (β -value) was
122 calculated as the ratio of fluorescent signals ($\beta = \text{Max}(M,0) / [\text{Max}(M,0) + \text{Max}(U,0) + 100]$),
123 ranging from 0 (no methylation) to 1 (complete methylation) using the average probe intensity
124 for the methylated (M) and unmethylated (U) alleles. We read the idat files using the minfi R
125 package [26]. β -values were background corrected using methylumi-noob and normalized using
126 functional normalization.[27] Our pipeline included array control probes to assess sample quality
127 and evaluate potential problems such as poor bisulfite conversion or color-specific issues for
128 each array as described previously [28,29]. All CpG loci on X and Y chromosomes, CpH, and
129 loci with potential problems of cross-reactivity, tracking to polymorphisms with minor allele
130 frequencies over 5% for the general population, or common copy number alterations,[30] were
131 excluded from the analysis, leaving 368,171 autosomal CpG loci in 92 samples. Principal
132 components analysis and multiple dimension scaling were used to identify potential technical
133 batches. Additionally, we used a principal component regression analysis to investigate the top
134 eight principal components in relation to potential batch-associated differences. Subjects with
135 missing covariate data were excluded from modeling, resulting in 87 samples. DNA methylation
136 β -values were logit_2 transformed to M-values for the analyses [31].

137 **Cell mixture analysis**

138 In order to identify and adjust for potential cell type heterogeneity in the breast milk samples we
139 used a reference-free decomposition (RefFreeCellMix) of the DNA methylation matrix into cell-
140 type distributions and cell-type methylomes, using the expression $Y = M * \Omega^T$ [32]. We explored a
141 range of k cell types from 2 to 10. Note that the decomposition will be based on Y, but Yfinal (=Y
142 by default) was used to determine the final value of M based on the last iterated value of Ω)

143 **Locus-by-locus analysis for detecting differentially methylated CpG loci**

144 We implemented a locus-by-locus analysis to identify differentially methylated CpG sites
145 between samples obtained from control subjects without breast cancer diagnosis and those
146 from healthy and diseased breasts before or after the cancer development using the R package
147 *limma* [33]. Five groups were compared: 1) Controls with no breast cancer history, 2)
148 Contralateral Prior Diagnosis (sample from healthy breast of a woman previously diagnosed
149 breast cancer), 3) Ipsilateral Prior Diagnosis (sample from affected breast of a woman
150 previously diagnosed breast cancer) 4) Contralateral New Diagnosis (sample from healthy
151 breast of a woman with incident breast cancer), and 5) Ipsilateral New Diagnosis (sample from
152 affected breast of a woman with incident breast cancer). Briefly, linear mixed effects models
153 were fit to each CpG site separately, with the CpG β -value as the response against the five
154 groups. A random effect for subject was included to control for within subject correlation in
155 subjects with bilateral samples (30 subjects). The models were adjusted for time from delivery
156 (in months), maternal age (in years), RefFreeCellMix proportion estimates (5 putative cell
157 types), and the microarray Slide to control residual batch confounding. *P*-values were adjusted
158 for multiple comparisons by computing the Benjamini–Hochberg *q*-values [34], and we defined
159 loci with *q*-value < 0.05 to be statistically significant. We focus on CpGs identified as
160 differentially methylated in both prospectively diagnosed groups (ipsilateral and contralateral),
161 and report individual group results in supplemental material. All analyses were carried out using
162 the R statistical package, version 3.5.0 (Vienna, Austria; www.r-project.org/) [35].

163 **Repetitive elements prediction and analysis**

164 We use the package REMP, Repetitive Element Methylation Prediction [36], to estimate the
165 DNA methylation levels on both *LINE-1* and *Alu* transposons using the information from the
166 DNA methylation microarray. This random forest approach covers 37 *Alu* subfamilies and 115
167 *LINE-1* subfamilies. We computed the average *Alu* and *LINE-1* methylation levels for each
168 sample, and tested the association with prospectively diagnosed breast cancer, excluding the

169 three samples from subjects with a prior diagnosis of breast cancer. *P*-values were computed
170 using the Kenward-Roger approach.

171 **Enrichment analyses**

172 The probes that were differentially methylated were tested for pathway and gene set enrichment
173 using missMethyl [37] and the MSigDB v.6.2 curated database [38]. A minimum of two genes
174 were required for further exploring the specific pathway. We also tested for over- or
175 underrepresentation of differentially methylated CpGs identified in the locus-by-locus analysis in
176 1) enhancer regions and 2) CpG island regions. Loci with a *q*-value < 0.05 were considered to
177 be statistically significant. Odds ratios, 95% confidence intervals, and *P*-values were computed
178 with the Cochran-Mantel-Haenszel test and were adjusted for probe type.

179 **Predicted methylation age and stem cell divisions**

180 We used Horvath's DNA methylation age estimation algorithm [39] to calculate predicted
181 methylation age (*mAge*) using the *agep* function from *wateRmelon* [40]. Using those estimates,
182 age acceleration was defined as: $Age\ acceleration = mAge - Age$. We tested for differences in
183 age acceleration between control subjects and subjects with breast cancer using a linear mixed
184 effects model. *P*-values were calculated using the Kenward-Roger approach. Additionally, stem
185 cell divisions were estimated using the *epiTOC* method [41], but only 334 of 385 CpGs were
186 available to calculate estimates. *epiTOC* estimates were compared between cases and controls
187 using unadjusted linear mixed effect models analogously to the age acceleration models.

188 **RESULTS**

189 Genome-scale DNA methylation was measured in breast milk samples from 87 subjects using
190 the Illumina HumanMethylation450 beadchip. Subject demographic and sample details are
191 provided in **Table 1**. 64 (73%) samples were from cancer-free subjects and 23 were from
192 subjects who had a breast cancer diagnosis of which 20 (87%) were collected prior to diagnosis.

193 Milk samples from subjects with any breast cancer diagnosis were classified according to
 194 whether the cancer was in the ipsilateral or contralateral breast. Overall, about 70% of samples
 195 from subjects with subsequent breast cancer were collected from the ipsilateral breast (n=14)
 196 and 30% were from the contralateral breast (n=6).

197 Table 1. Subject characteristics

Variable	N (%) or Mean [Range]		P
	Controls (n = 64)	Breast Cancer (n = 23)	
Age (years)	33.2 [23 - 44]	36.3 [29 - 45]	0.01
BMI	26.5 [18.2 - 43.6]	25.2 [18.4 - 38.7]	0.40
BMI category			0.20
Normal/Underweight	28 (43.8)	8 (34.8)	
Overweight/Obesity	27 (42.2)	13 (56.5)	
Missing	9 (14.1)	2 (8.7)	
Breast biopsy			<0.001
No	50 (78.1)	0 (0.0)	
Yes	14 (21.9)	23 (100.0)	
Time since delivery (months)	2.2 [0 - 10]	10.8 [0.2 - 20]	<0.001
Parity	2 [1 - 5]	2 [1 - 4]	<0.001
Milk sample			N/A
Ipsilateral	N/A	16 (69.6)	
Contralateral	N/A	7 (30.4)	
Milk collection			N/A
Pre-diagnostic	N/A	20 (87.0)	
Post diagnosis	N/A	3 (13.0)	

198

199 We used a reference-free cell type estimation approach to identify the number of putative cell
 200 types and the proportions of each cell type in each breast milk sample. The reference-free
 201 method identified five putative cell types in human milk. In unadjusted models, we observed
 202 differences in cell type proportions between breast milk samples from women who did not
 203 developed breast cancer (henceforth named as “controls”) compared with those diagnosed with
 204 breast cancer for three of the five putative cell types. The proportions of cell types 2 and 3 were
 205 higher in subjects with a prospective diagnosis of breast cancer than controls ($P=5.2E-06$ and

206 7.1E-04), and the proportion of cell type 4 was lower in milk from subjects with breast cancer
207 compared to controls ($P=1.2E-05$) (**Figure 1**). In these models, differential abundance of
208 putative cell types in controls versus cases was similar irrespective of whether the samples
209 were from the ipsilateral or contralateral breast, or whether the breast cancer diagnosis
210 occurred prior or subsequent to breast milk sample collection (see figure **Additional File 1**).
211 After adjusting for maternal age (years), time since delivery (months), and BeadArray slide
212 number, cell type proportions were no longer associated with breast cancer diagnosis.

213 DNA methylation was compared using linear mixed effect models adjusted for time since
214 delivery in months, maternal age in years, estimated cell type proportions, and array chip with
215 subject as a random effect. We identified 57 significantly differentially methylated CpG sites
216 associated with milk from the ipsilateral breast after correction for multiple comparisons (q -value
217 < 0.05). Among these 57 CpGs, one CpG in an island region and associated with both the
218 *LRRC61* and *ACTR3C* genes was significantly hypermethylated in breast milk from subjects
219 who were later diagnosed with breast cancer (**Figure 2**). The remaining 56 CpG sites were
220 significantly hypomethylated in prospectively collected breast milk from the ipsilateral breast of
221 subjects who developed cancer compared with controls (**Figure 2**). The most statistically
222 significantly hypomethylated CpG site related to breast cancer diagnosis was located in the
223 island region of the *CLCC1* gene. Additional genes with hypomethylated loci included *TMSB10*,
224 *ZNF584*, *MAP10* (previously *KIAA1383*), *TRIM27*, and *SEPTIN7* (previously *SEPT7*). A total of
225 32 of these CpGs also were hypomethylated in prospectively collected milk from women who
226 developed cancer in the contralateral breast compared to controls (**Table 2**). The full set of the
227 EWAS results are available as **Additional Files 2 and 3**.

234 We accessed TCGA breast tumor data using cBioportal to determine whether genes we
235 identified as having hypomethylated CpGs related to breast cancer were associated with gene
236 regulation. We found negative correlations between DNA methylation with mRNA expression z-
237 scores (RNA seq) for many of these genes including *ZNF584* ($P=2.41E-17$), *MAP10* ($P=1.61E-$
238 76), *TRIM27* ($P=6.01E-14$), *LIMD2* ($P=1.14E-59$), and *LDHA* ($P=6.06E-06$). In contrast, there
239 was little to no correlation between DNA methylation and expression of *CLCC1* (Spearman $\rho=-$
240 0.03 , $P=0.5$), *TMSB10* ($\rho = -0.08$, $P=0.07$) and *SEPTIN7* ($\rho = -0.05$, $P=0.2$), see **Additional File**
241 **4**. The range of DNA methylation level observed for each CpG tested in the TCGA tumors was
242 comparable to that observed in our samples.

243 Given the preponderance of CpG-specific breast milk DNA hypomethylation associated with
244 breast cancer, and that repeat element hypomethylation is well established in cancer, we further
245 assessed repetitive element methylation. To do so, we inferred Alu (37 subfamilies) and LINE-1
246 (115 subfamilies) DNA methylation using array data and the repetitive element methylation
247 prediction (REMP), as detailed in the methods section. None of the individual repetitive
248 elements reached statistical significance after multiple comparison correction. The nominally
249 significant are summarized in **Additional File 5, Table S5**. Mean Alu subfamily methylation was
250 significantly lower in breast cancer cases compared to controls ($\beta = -0.21$, p -value = $2.9E-4$),
251 and mean LINE-1 subfamily methylation was also lower in cases than controls ($\beta = -0.073$, p -
252 value = 0.10) (**Figure 3**).

253 To evaluate the location in the genome where breast cancer-related DNA methylation
254 alterations in breast milk were occurring we performed enrichment analyses for both genomic

255 context and gene sets. Differentially methylated CpGs (q -value<0.05) associated with a
256 subsequent diagnosis of breast cancer were enriched for CpG island regions in milk from both
257 the ipsilateral and contralateral breast (**Table 3**). Among CpGs whose methylation was
258 significantly related with cancer diagnosis we also tested for enrichment of gene sets using the
259 molecular signatures database (MSigDB) v. 6.2, and identified 7 gene sets enriched for the 32
260 CpG sites that were differentially methylated in both ipsilateral and contralateral samples. The
261 top two pathways are related to highly conserved motif clusters matching transcription factor
262 binding sites [42]. Three pathways are related to upregulation of genes in CD8(+) T
263 lymphocytes, T regulatory cells and dendritic cells. Finally, two gene sets are associated to
264 tumor invasion [43] and granulocyte differentiation in acute promyelocytic leukemia [44], see
265 **Additional File 5, Table S6**.

266 Table 3. Enrichment for genomic context in CpGs with $q < 0.05$

Breast Cancer Group ²	Island Regions		Enhancer Regions	
	OR (95% CI)	P^1	OR (95% CI)	P^1
Ipsilateral	3.48 (1.75, 7.45)	9.3E-05	1.05 (0.45, 2.18)	8.5E-01
Contralateral	4.28 (1.64, 13.30)	8.6E-04	1.01 (0.30, 2.67)	1.0E+00

267 ¹ P determined using the Cochran-Mantel-Haenszel test

268 ²Reference level is controls with no breast cancer history

269 In univariate linear mixed effect analyses we also tested for DNA methylation age acceleration
270 and elevated epigenetic mitotic clock tick rate (epiTOC) in association with breast cancer status.
271 The epiTOC estimates were significantly higher amongst breast cancer subjects ($\beta = 0.013$, p -
272 value = 3.2E-04, **Figure 4a**). A marginally significant increase in age acceleration subjects with
273 breast cancer compared to controls was also observed ($\beta = 2.7$, p -value = 0.071, **Figure 4b**).
274 After adjusting for covariates, neither epiTOC estimates nor methylation age were related to

275 breast cancer status. In the adjusted analyses, putative cell type proportions were related to
276 epiTOC estimates and age acceleration.

277 **DISCUSSION**

278 We identified significant differences in DNA methylation after controlling for cell type and other
279 confounders in subjects with a subsequent diagnosis of breast cancer compared with controls.
280 In the subjects who were diagnosed with breast cancer after the milk collection, nearly all of the
281 significantly differentially methylated CpGs were hypomethylated. Several of the genes whose
282 CpG sites were differentially methylated in prospectively diagnosed cases have previously been
283 associated with breast cancer. For example, *TMSB10* is overexpressed in breast cancer cells,
284 has elevated protein expression in serum of breast cancer patients, and is elevated with
285 increasing breast cancer stage and distant metastasis [45]. Linking a systemic marker of breast
286 cancer risk to our tissue-specific approach, promoter CpG island hypomethylation of *ZNF584*
287 was associated with a breast cancer diagnosis both here and in peripheral blood DNA from
288 breast cancer patients [46]. Further, using TCGA breast tumor data, we showed the functional
289 relationship of *ZNF584* DNA methylation with gene expression. We also observed
290 hypomethylation at CpGs in *SEPTIN7*, *TRIM27*, *LIMD2*, and *LDHA*, which have been
291 associated with breast cancer metastasis, invasion, and proliferation, [47–50]. Apart from
292 *SEPTIN7*, all these genes showed negative correlation between gene expression and DNA
293 methylation in TCGA breast cancer samples, again demonstrating functional consequences of
294 altered DNA methylation to gene regulation. These results support our hypothesis that
295 epigenetic alterations in human milk have utility for noninvasive molecular assessment of breast
296 cancer risk.

297 Amongst subjects with incident breast cancer, the group of hypomethylated CpGs found to be
298 significantly differentially methylated in milk samples from both contralateral and ipsilateral
299 breast compared to those from controls were enriched for CpG island regions. Methylation at

300 CpG island regions can reduce gene expression in associated genes [51]. Since the majority of
301 differentially methylated CpGs were hypomethylated, this may correspond to increased
302 expression of genes with promoters in these regions, and consistent with our observations of
303 local and potentially systemic effects, our pathway enrichment analyses identified both proto-
304 oncogene signatures and immune dysregulation signatures. One pathway with strong
305 enrichment is associated with a motif for the *ELK-1* a regulator of the *c-Fos* protooncogene
306 which has been linked to growth suppression in breast cancer cells [52]. The second pathway
307 includes CpGs related to a motif for *SP-1*, a part of the Kruppel-like family that also has been
308 associated as a prognostic factor in breast cancer [53]. Three more pathways pointed to genes
309 upregulated in CD8(+) T lymphocytes, activated T-regulatory cells, and dendritic cells,
310 cornerstones of tumor immune response in breast cancer murine models [54]. The remaining
311 two pathways were related to tumor invasion and granulocyte differentiation.

312 We also observed differences in measures of methylation age including the epiTOC estimator
313 and Horvath's methylation age between breast cancer subjects and control subjects, but these
314 associations were not robust to adjustment for potential confounders. Notably, in our study
315 population the subjects with a cancer diagnosis were slightly older than control subjects.
316 Putative cell type proportions, however, were related to all measures of methylation age.
317 Although CpG loci utilized in each algorithm are not supposed to be dependent on cell type,
318 there have been consistent trends of accelerated age in breast tissues when using the Horvath
319 methylation age approach. Accelerated biologic age inferred using DNA methylation has
320 recently been associated with breast cancer risk in a very large prospective study using
321 peripheral blood [55]. However, to date, unlike peripheral blood, there are no DNA methylation
322 clocks for inference of biologic age that are calibrated to biospecimens from the breast. In the
323 future, larger breast-tissue-specific studies are needed to advance our understanding and

324 opportunity to leverage biologic age estimates for breast cancer risk assessment and primary
325 prevention.

326 This study has several strengths and limitations. Strengths of our study include the use of
327 prospectively collected specimens, tissue-specific measures of DNA methylation, and two
328 independent cohorts. Although some subjects were potentially had clinically occult disease
329 when providing a milk specimen, others were not diagnosed until years later. One limitation of
330 this study is sample size, though investigating genome-scale DNA methylation measures in
331 breast milk is novel. One potential limitation is that we pooled controls from two different cohorts
332 processed in different technical batches. Although we controlled for technical differences in our
333 models and used a conservative approach that adjusted for cell estimates which also captures
334 technical differences, we cannot completely exclude some residual technical noise between
335 cohorts affecting our results.

336 We identified early DNA methylation alterations in breast milk associated with subsequent
337 breast cancer occurrence. These loci were either in genes expressed in breast cancers, related
338 to breast cancer progression, or found in peripheral blood samples women with breast cancer.
339 Importantly, because we identified both overlapping results with work that used peripheral blood
340 as a surrogate biospecimen and results distinct to breast milk we expect that our tissue-specific
341 approach has high potential for follow up work. We expect that future investigations of DNA
342 methylation changes present in cells from breast milk from disease-free women will have value
343 for risk assessment and primary prevention of breast cancer, perhaps with specific strength in
344 application to premenopausal disease. However, larger studies are needed to validate our
345 findings and to further establish the utility of breast milk as a biospecimen for understanding the
346 molecular basis of disease risk and prospective risk assessment.

347 **Conclusions**

348 We assessed genome wide DNA methylation in breast milk from subjects with and without
349 breast cancer, specific loci were hypomethylated in breast cancer subjects compared to control
350 subjects. These differentially methylated regions were more likely to occur in island regions of
351 the genome. Our results suggest that breast milk has utility for prospective assessment of
352 breast cancer risk.

355 Epigenome-wide association studies (EWAS), epigenetic mitotic clock tick rate (epiTOC),
356 molecular signatures database (MSigDB), University of Massachusetts Amherst (UMass), New
357 Hampshire Birth Cohort study (NHBCS), methylation age (*mAge*).

358 **Declarations**

359 **Ethics approval and consent to participate:** All study participants provided written informed
360 consent prior to the study according to the guidelines of Institutional Review Board of the
361 University of Massachusetts Amherst and the Committee for the Protection of Human Subjects
362 at Dartmouth.

363 **Consent for publication:** Not applicable

364 **Availability of data and material:** The datasets generated and analyzed during the current
365 study are available in the GEO (<https://www.ncbi.nlm.nih.gov/geo/>) under the accession number
366 GSE133918.

367 **Competing interests:** The authors declare that they have no competing interests

368 **Funding:** This work was supported by funds of the COBRE Center for Molecular Epidemiology
369 at Dartmouth P20GM104416, and R01CA216265 to BCC; NIEHS P01ES022832 and EPA
370 RD83544201 to MRK; and R01CA230478-01A1 to KFA

371 **Authors' contributions:** LAS and SNL elaborated the analysis plan, analyzed the data and
372 wrote the first draft of the manuscript, EPB, ECP, DLA, MRK provided technical and
373 methodological feedback to the original analysis and final version, KFA and BCC generated the
374 original idea and codirected the analyses. All authors approved the final version of this
375 manuscript.

376 **Acknowledgements:** Not applicable.
