11

12 **1. Abstract**

13 The pandemic of the COVID-19 disease extended from China across the north-temperate
14 zone, and more recently to the tropics and southern hemisphere. We find no evidence that
15 spread rates decline with temperatures above 20 °C, suggesting that the COVID-19 disease is
16 unlikely to behave as a seasonal respiratory virus.

21 **2. Introduction**

22 On 30 January the WHO declared the novel coronavirus (COVID-19) outbreak a
23 public health emergency of international concern (<http://www.euro.who.int/en/home>). The
24 epidemic spread gradually from Wuhan province in China, to other Asian nations, the middle
25 east and Europe. By early March the epidemic was mostly concentrated in territories

26 extending between 30°N and 50 °N (Sajadi et al., 2020), now in late winter, leading to the
27 suggestion, echoed by the global media, that the epidemic is likely to be temperature-
28 dependent. This supported speculation of possible decline in severity with the advent of
29 warmer spring and summer temperatures in north-temperate latitudes (Sajadi et al.,
30 2020; Wang et al., 2020), comparable to many viruses affecting human respiratory systems,
31 including SARS (Tan et al., 2005; Gaunt et al., 2010).

32 However, recent (updated up to March 26, 2020; cf. Methods) data revealed the
33 spread of the epidemic across territories experiencing warm temperatures in the tropics (e.g.
34 Indonesia, Singapore, Brazil) and southern hemisphere as well (e.g. Australia, Argentina).
35 The current distribution of the epidemic challenges, therefore, the inference that SARS-CoV-
36 2 may behave as a seasonal respiratory virus based on previous statistical analyses from
37 earlier realized distributions.

38 Here we examine the relationship between the apparent exponential rate of SARS-
39 CoV-2 spread (γ) and the Basic Reproductive number of infection (R_0) and the average daily
40 temperature (T_{avg}) across nations and Chinese provinces where epidemics, with at least 100
41 case reported, have been reported (data updated up to 26 March, 2020).

42 **3. Methods**

43 *Novel Coronavirus (COVID-19) Cases Data*

44 The Novel Coronavirus (COVID-19) daily data are confirmed cases for affected
45 countries and provinces of China reported between 31st December 2019 to 26th March 2020.
46 The data was collected from the reports released by WHO, European Centre for Disease
47 Prevention and Control (ECDC), and John Hopkin CSSA. Data include confirmed and a
48 cumulative total of COVID-19 cases in affected countries/provinces.

49

50 *Average ambient temperature*

51 The average temperatures of all the affected countries were collected
52 from <https://www.timeanddate.com/>. The monthly mean temperature of February and the
53 three-weeks mean temperature of March of capital cities for the various nations were used as
54 reference temperatures for the country.

55

56 *Statistical Analysis*

57 The number of COVID-19 incidences follows the expected exponential growth,
58 although rates are only robust when cases exceed 100 persons for any country or province.
59 Hence, we fitted the exponential model to each country and each province of China. We
60 calculated exponential rate parameters for the countries where the COVID-19 incident has at
61 least a 10-day growth period, and the total number of cases was at least 100.

$$62 \quad N = ae^{\gamma Days}, \quad \gamma > 0$$

$$63 \quad \log N = \alpha + \gamma Days.$$

64 Where N is the cumulative number of diagnosed persons and Days is the number of days and
65 γ is the exponential rate ($100 \times \gamma = \%$ increase per day).

66

67 To calculate the effect of temperature on the exponential rate parameter, we first
68 regressed the exponential rate parameters retrieved from the exponential model on *Temp* and

$$69 \quad Temp^2$$

$$\gamma \sim Temp + Temp^2$$

70 If the squared term is significant, it provides evidence of nonlinearity.

71 The thermal performance of COVID-19 was characterized by fitting spread rate estimate or
72 growth parameter (γ) and temperature to the Gaussian function;

$$\gamma = ae^{\left[-0.5\left(\frac{Temp-opt}{tot}\right)^2\right]},$$

73 *Temp* is the average temperature (in °C) that best encompasses the growth period of COVID-
74 19 cases since its first incidence in a country/region of China. Where, *a* (amplitude) is the
75 coefficient related to maximum of spread rate of countries, the optimum (*opt*) on the
76 temperature gradient is where the maximum of spread rate is attained and the tolerance (*tol*)
77 gives the width of the response curve. This model has non-linear form, and the model
78 parameters *opt* and *tol* occur nonlinearly in the model function. Parameter of thermal
79 performance curve was estimated by fitting Gaussian model to the growth rate and
80 temperature of infected countries. The initial values for the Gaussian parameters
81 *opt*, *tol* and *a* were obtained directly using maximum-likelihood polynomial regression for
82 the Gaussian function.

83 Estimated the basic reproductive number (R_0) for COVID-19 from China and other
84 countries using the Statistical exponential growth model method adopting serial interval from
85 an average of SARS (mean=8.4 days, SD=3.8 days) and MERS (mean=7.6 days, SD=3.4
86 days). All analyses were performed using R statistical computing software.

87

88 **4. Results**

89 Our results show that evidence for a temperature-dependence of the transmission
90 reported in previous papers was likely to be an artifact, reflecting the pathways of spread, and
91 that there is no evidence for thermal dependence of the transmission across the -10 to 31°C
92 T_{avg} range across the affected regions. This suggests little basis to expect evidence for the
93 virus to behave as a seasonal respiratory virus.

94 Epidemiological data consisting in the rate of increase in accumulated diagnosed
95 cases among nations (global) shows γ ranging from 5.6 % day⁻¹ to 34.8 % day⁻¹ (except
96 Turkey; Figure S1), with an average of 22.39 ± 0.94 % day⁻¹ (Figure 1, Figure S1), and
97 apparent R_0 of 1.90 ± 0.07 (Figure 1, Table A1). Surprisingly, γ and R_0 across Chinese

98 provinces (mean \pm SE = 4.1 ± 0.1 % day⁻¹ and 1.09 ± 0.01) were well below those of other
99 nations (mean \pm SE = 22.39 ± 0.94 % day⁻¹ and 1.90 ± 0.07), possibly because much faster
100 confinement of the Chinese population did not allow for the potential exponential rates under
101 uncontrolled conditions to be realized. The broad variability in realized γ and R0 between
102 nations (global) and provinces (China) largely reflects differences in detection likelihood
103 along with the timing and rigour of adoption of confinement measures.

104 The relationship between γ and R0 and T_{avg} shows no evidence for a reduced spread
105 rate with warming (Figure 1), unlike analyses based on previous data. A number of nations
106 with T_{avg} > 20 °C, including subtropical and tropical (Brazil, Qatar, Saudi Arabia and
107 Indonesia), and southern-hemisphere (Peru, Chile, Argentina) nations (Figure 2), support γ
108 and R0 above the median values of 23.8% day⁻¹ and 1.75, respectively (Figure 1). However,
109 the same analysis conducted one weeks ago (15th March), did provide some evidence for low
110 γ and R0 for T_{avg} > 20 °C (Figure S2). Our updated results (Figure 1) show, however, that
111 this apparent temperature-dependence was confounded with a prevailing zonal pattern of
112 spread across the north-temperate zone, possibly reflecting the main patterns of human
113 mobility, which delayed arrival of the epidemics to the southern hemisphere and the tropics.

114 **5. Discussion**

115 These results suggest that, contrary to prior assessments, the spread rate of the
116 COVID-19 pandemic is temperature-independent, suggesting that there is little hope for relief
117 as temperatures in the northern hemisphere increase, and that poor nations with weak health
118 systems in tropical regions, such as African, are at great risk.

165 **Figure 1.** The relationship between the apparent exponential rate of SARS-CoV-2 spread (B)
166 and the Basic Reproductive number of infection (R_0) and the average daily temperature (T_{avg})
167 across nations and Chinese provinces where > 100 cases of COVID-19 have been reported
168 (data last accessed 26 March, Figure S1). Green symbols represent provinces in China while
169 red symbols represent other nations. Neither the double exponential function with
170 temperature nor the Gaussian function provided a significant ($p < 0.05$) fit for either γ or R_0
171 with temperature.

172

173 **Figure 2.** Distribution of the apparent exponential rate of SARS-CoV-2 spread (γ) and the
174 Basic Reproductive number of infection (R_0) and the average daily temperature (T_{avg}) across
175 nations where > 100 cases of COVID-19 have been reported (data last accessed 26 March).

176

177 **Appendix Figure S1.** The apparent average (\pm SE) exponential rate of SARS-CoV-2 spread
178 (γ), the average (and 95% confidence limits) of Basic Reproductive number of infection (R_0)
179 and the average daily temperature (T_{avg}) total case and number of days since the first case
180 reported across nations and Chinese provinces where epidemics, with at least 100 case
181 reported, have been reported (data updated through 26 March, 2020).

182

183 **Appendix Figure S2.** The relationship between the apparent exponential rate of SARS-CoV-
184 2 spread (γ) and the Basic Reproductive number of infection (R_0) and the average daily

185 temperature (T_{avg}) across nations and Chinese provinces where > 100 cases of COVID-19
186 have been reported, as of Figure 1, but with data updated only until 15th March. The Gaussian
187 function with temperature provided a significant fit for γ with temperature.
