## Summary

**Introduction:** The pandemic caused by the new coronavirus (COVID-19) has led to changes in the development of health care activities by health professionals. We analysed whether there is an association between the appearance of “de novo” headache according to the type of mask used, the related factors, as well as the impact of the headache on health professionals.

**Method:** cross-sectional study in a tertiary hospital in Extremadura, Spain. We administered an online questionnaire to healthcare workers during the period of maximum incidence of COVID-19 in our setting.

**Results:** n=306, 244 women (79.7%), with an average age of 43 years (range 23-65). Of the total, 129 (42.2%) were physicians, 112 (36.6%) nurses and 65 (21.2%) other health workers. 208 (79.7%) used surgical masks and 53 (20.3%) used filtering masks. Of all those surveyed, 158 (51.6%) presented “de novo” headache. The occurrence of headache was independently associated with the use of a filtering mask, OR 2.14 (IC95% 1.07-4.32), being a nurse OR 2.09 (IC95% 1.18-3.72) or another health worker OR 6.94 (IC95% 3.01-16.04) or having a history of asthma OR 0.29 (IC95% 0.09-0.89). Depending on the type of mask used there were differences in headache intensity. And the impact of headache in the subjects who used a filtering mask was worse in the all aspects evaluated.

**Conclusions:** The appearance of “de novo” headache is associated with the use of filtering masks and is more frequent in certain health care workers, causing a greater occupational, family, personal and social impact.

**Key words:** Headache, risk factors, personal protective equipment, face-mask, COVID-19.

## Introduction

In December 2019, a new coronavirus, SARS-CoV-2, started an outbreak in the Chinese city of Wuhan. In January 2020 its clinical picture was defined as a disease associated with coronavirus-2019 (COVID-19) [1,2]. This outbreak has evolved into a pandemic and as of May 24, 2020, 216 countries have been affected, 5,206,614 cases have been confirmed worldwide, and 337,736 deaths have occurred [3]. In Spain, 233,037 cases have been documented and 27,940 patients have lost their lives [4]. In the region of Extremadura, 3,047 cases and 506 deaths have been reported [5].

During the increase in cases of COVID-19 in our environment, the national and local authorities established the mandatory use of Personal Protective Equipment (PPE) by health professionals. This PPE consists of a protective suit, surgical gloves, protective goggles, shield and face mask. In the case of face masks, they must be highly effective, with type FFP2 (in Europe), N95 (USA) and KN95 (China) recommended [6]. There are other types of masks (surgical masks or FFP1 among others), of lesser effectiveness, which are used by healthcare personnel who are not in direct contact with COVID-19 [7]. The use of protective material in a strict manner is crucial, as it can reduce transmission to highly exposed populations such as healthcare workers, as well as reduce the spread of infection from healthcare workers to healthy patients.

In "frontline" work, the use of masks can be very prolonged [8]. Although, in general, highly effective masks are well tolerated, some problems have been reported, such as: general discomfort, decreased visual, auditory or vocal capacity; excessive heat or humidity, facial pressure, skin lesions, itching, fatigue, anxiety and claustrophobia [9]. Another effect, already described in the 2003 SARS epidemic, was headache, whose prevalence reached 37.3% of the health personnel studied [10]. Headache associated with mask use could be related to

mechanical factors, the presence of hypoxemia and hypercapnia or to the stress associated with mask use [11, 12].

Our aim is to demonstrate whether there is an association between the appearance of “de novo” headache with the type of mask and its time of use, as well as the impact of this headache on health professionals.

## Method

The study was conducted in the health area of a tertiary hospital, where our health system in the COVID period was mandated to use PPE during contact with patients.

These protective systems were mandatory among health workers, both in high-risk areas (intensive care units, isolation rooms for infected patients, emergency rooms or operating theatres), and in general medical wards, central hospital radiology and diagnostic imaging areas or outpatient clinics. This involved the use of different types of more or less tight-fitting masks, and sometimes glasses or screens.

Using a self-administered questionnaire addressed to health workers in our health area, we carried out a cross-sectional study during the first week of May 2020. In the previous month, the number of admissions for COVID-19 was very high and attendance protocols required the use of these devices by all workers.

The questionnaire collected the following information: (1) demographics (gender, age, profession, shifts); (2) medical history, including SARS-Cov2 infection; (3) type and pattern of mask use (surgical masks vs. self-filtering masks of particles and liquid aerosols (FFP), average number of hours of use per day) and use of other protective devices (glasses or screens); (4) frequency and characteristics of pre-existing primary headache (changes in headache frequency, attack duration and frequency, as well as drug use and response), (5) the main variable of the study was personal opinion about the presence of new headache in the

period in which these protective systems were mandatory (duration of headache episode, intensity and frequency, as well as drug use and response); (6) presence of other symptoms potentially associated with the use of facial protection equipment (fatigue, sleep disorder, lack of concentration, irritability, nausea or vomiting or others); (7) we evaluated the self-perceived impact of the presence of new-onset headache using the Likert scale on social, occupational, family and personal aspects; (8) we also evaluated the self-perceived impact that headache conditions have on the performance of work activities and (9) lastly, we analyzed self-perceived work stress by means of the Psychosomatic Problems Questionnaire (PPQ) [13].

The questionnaire was written after an analysis of the literature and a thorough reflection on the problem to be investigated. It included a request for voluntary collaboration, information on the reason for the survey, instructions for completing the questionnaire and consent. The average time taken to complete the questionnaire was about 20 minutes.

The information collection procedure chosen was the online survey. The survey was scheduled to be conducted over five consecutive days, between 1 and 6 May 2020, with the data collected referring to the previous month.

The data collected in the study respects the anonymity of the subject and there is no possibility of access to any personal information of the individual. The data analysed is restricted to the study investigators, health authorities and the Clinical Research Ethics Committee, when required, in accordance with current legislation.

### Statistical Analysis

Prior to the analysis of relationships between variables, descriptive analyses of the different areas that make up the study have been carried out. These descriptive analyses include percentage distributions of the different categories of the analysed variables and, in the case

of quantitative variables, average and standard deviation. These same analyses, shown as a cross between variables by means of contingency tables or comparison of averages, have also been elaborated as a preamble to the statistical tests that have been carried out to corroborate if there is a relationship between different variables, thus showing the hypotheses to be contrasted.

Depending on the nature of the variable (qualitative or quantitative) and the distribution of the sample (normal, admitting parametric contrasts, or non-normal, needing non-parametric contrasts), different tests have been used. We used the chi-square test to contrast whether there is independence between two categorical variables using a contingency table when the data are not paired.

For the analysis of the predictive factors with the appearance of a “de novo” headache, we used binary logistic regression methods by steps backwards, to maximize sensitivity, variables with a univariate association of  $P < 0.200$  were included as candidates in the multivariate model.

To measure the relationship between the different variables in the study, statistical tests with a 95% significance level were used as an acceptance threshold for the hypotheses to be tested, i.e. a p-value of 0.05. All statistical analyses were performed using the SPSS version 25.0 statistical package program for Windows (SPSS Inc, 2003, Chicago, IL, USA).

## Results

A total of 306 health professionals and other health workers participated in the study, 62 men (20.3%) and 244 women (79.7%), with an average age of 43 years (SD, 11; range, 23-65). Of these, 129 (42.2%) participants were physicians, 112 (36.6%) nurses and the rest, 65 (21.2%) other health workers (assistants, guards, technicians, administrative staff). With regard to the work shift, 89 (34.1%) worked in the morning and on duty, 91 (34.9%) in morning, afternoon

and night shifts and 81 (31.0%) in morning shifts only. The surgical mask was used by 208 (79.7%) of those surveyed and the filtering mask (FFP2 or KN95) was used by 53 (20.3%), with no difference in the mean time of use of 7.0 (SD 2.3) hours vs 6.7 (SD 2.5) hours,  $p=0.289$ . 46.4% (121) reported not habitually using other facial protection devices such as glasses, screens or PPE. The rate of confirmed SARS-CoV 2 infection in the study population was 4.6%.

The most frequently reported diseases in the total sample in order of frequency were: allergy 34 (13.0%), thyroid diseases 28 (10.7%), anxiety 26 (10.0%), high blood pressure 18 (6.9%), asthma 17 (6.5%), dyslipemia 14 (5.4%) and diabetes 2 (0.8%). 15.7% (41) indicated tobacco consumption.

Of the 306 persons surveyed, 158 (51.6%) reported the appearance of a new headache during the period of study, of whom 65 (41.1%) had previously had a headache (migraine: 27 (17.1%), tension: 26 (16.5%) and others: 11 (6.9%)). There were 103 (33.7%) subjects who did not observe the appearance of new headache. A 14.7% were undecided on the answer ("I don't know") or the answer was "maybe"; these 45 subjects were eliminated from the analysis.

They were also asked about the presence of other symptoms such as sleep disturbance, loss of concentration, irritability, photophobia, sonophobia, nausea or vomiting. Table 1 shows the characteristics of the population according to the appearance or not of headache.

During April, the month immediately prior to the survey, participants with "de novo" headache presented a median of 12 (IQR 13) days of headache, median of 4 days (IQR 3) in the week prior to the survey and the pain presented an average intensity on the visual analogue scale of 6 (SD 1.5). In 74 (47.4%) subjects the duration was from 1 to 4 hours, in 46 (29.5%) from 4 to 8 hours, in 21 (13.5%) from 8 to 12 hours and in 15 (9.6%) more than 12

hours. In subjects with previous headache the duration of episodes was significantly higher ( $p=0.008$ ). The response to analgesics was good or very good in 61.4% of the cases. Only 2 (1.3%) subjects had to consult the emergency department for headache, and no subject had been admitted to hospital for headache. With respect to the impact of headache in the work setting, lack of concentration on tasks was the main complaint (105 (66.5%) subjects). Table 2 shows the main characteristics of “de novo” headache.

83.1% (54) of the 65 subjects with previous headache indicated a modification in the characteristics of their habitual headaches, 81.0% (47) a change in location, 67.2% (39) in frequency, 36.2% (21) in intensity and 25.9% (15) in the response to habitual analgesics.

In the univariate analysis, the factors associated with the appearance of “de novo” headache were: age, female sex, type of professional, use of filter mask (KN95 or FFP2), work shift, being a tobacco user, suffering from anxiety or asthma. In the multivariate analysis, the use of filter masks and the type of professional behaved as independent predictors of headache risk, while being asthmatic behaved as a protective factor. The occurrence of headache is associated with the use of a filtering mask (FFP2 or KN95), OR 2.14 (IC95% 1.07-4.32), being a health worker OR 6.94 (IC95% 3.01-16.04) or a nurse OR 2.09 (IC95% 1.18-3.72).

Table 3.

According to the type of mask used there was no difference in the number of days with headache in the month prior to the survey 13.4 (SD 7.4) vs 12.6 (SD 6.9), nor in the previous week 3.9 (SD 1.6) vs 3.6 (SD 1.7), but in the intensity according to VAS 5.7 (SD 1.5) vs 6.5 (1.2),  $p=0.004$ .

The impact of headache in subjects with a filtering mask as opposed to surgery mask was worse in the four aspects evaluated by the Likert scale: occupational 4.44 vs 3.81 ( $p=0.206$ ), family 5.10 vs 4.20 ( $p=0.065$ ), personal 5.64 vs 4.84 ( $p=0.05$ ) and social 5.46 vs 4.58

( $p=0.076$ ) (Figure 1). The impact was also greater in subjects with previous headache in the four aspects evaluated, see table 2.

Regarding the evaluation of self-perceived work stress by means of the 12 items of the PPQ, individuals with “de novo” headache versus those without headache have significantly worse scores in all aspects evaluated, except for the decrease in appetite where no significant differences are observed. Figure 2 shows graphically the evaluation of occupational stress according to the presence of headache or not. The use of a filtering mask compared with surgical mask only implies a significantly worse score in two aspects: gastrointestinal discomfort ( $p=0.047$ ) and greater sensation of extreme tiredness ( $p=0.004$ ).

## Discussion

The current situation experienced by the COVID-19 pandemic has led to a substantial change in the work flows of health professionals. One of the most important features has been the use of PPE for the care of patients with suspected or infected SARS-COV2. According to the data obtained, we demonstrate a statistically significant association between the use of filtering masks and the appearance of headache.

In the physiopathology of new-onset headache, the exact mechanisms may be multiple, complex and not always well known. Peripheral nociceptive structures and central sensitization mechanisms may be involved in their development [14, 15]. The current International Headache Classification proposes, generically for secondary headaches, that the diagnostic criteria do not require remission or improvement of the underlying causal disorder before the diagnosis is formalized. There is criterion A (presence of the headache), criterion B (presence of the causal disorder) and criterion C (evidence of the etiopathogenesis). And for acute processes, a close temporal relationship between the onset of the headache and the onset of the suspected causal disorder is usually sufficient [11]. Following this classification,

mask-associated headache would probably be a multifactorial disorder with unknown etiopathogenesis at present. Hypothetically, a number of factors may explain the association with filtering mask use, including hypoxia, hypercapnia, local compression and mechanical phenomena, as well as anxiety about wearing the device [10].

In the scientific literature there are not many studies that relate the use of face masks to changes in the concentration of oxygen and/or carbon dioxide but it seems a plausible hypothesis due to the barrier element that is interposed in the physiological ventilation mechanism.

In a Taiwanese cohort of 39 patients with end-stage renal disease who wore N95 masks during the 2002 SARS outbreak, they measured, among other variables, the level of PaO<sub>2</sub> before and after a 4-hour hemodialysis session. The study concluded that there was a significant reduction in PaO<sub>2</sub> from baseline and an increase in other respiratory adverse effects [16]. Another study conducted in a cohort of 130 astronauts subjected to high CO<sub>2</sub> pressures during controlled training showed a significantly higher incidence of headache in the exposed group, in addition to respiratory symptoms and difficulty in concentrating [17]. At the University of Wollongong (Australia), a study on the effects of CO<sub>2</sub> inhalation on workers wearing respiratory protection devices showed that high levels of carbon dioxide were associated with feelings of discomfort and significantly reduced tolerance and time of device use [18]. In the world of sport, the effect on respiratory physiology and muscle performance of wearing training masks designed to simulate a variable altitude situation has been studied. The results are mixed in terms of objective performance parameters, however, it does seem common that mask use reduces working speed and negatively influences levels of alertness and task focus [19]. In 2014, a pilot study evaluated the consequences on respiratory physiology of surgical mask and N-95 face mask use in a sample of 87 patients and the extent to which nasal inspiratory and expiratory resistance and discomfort were

altered in the individuals. Physiological changes such as increased respiratory resistances were observed after three hours of use [20]. Headache associated with filtering mask use could be included according to ICHD-3 [11] in the section on headaches due to homeostatic disorders where those related to alteration of oxygen and carbon dioxide partial pressure parameters are included.

Another phenomenon probably related to the physiopathology of headache after PPE use is the external compression that it generates, as recently reflected by the group of Ong JJ et al [21]. In most cases there is a temporal relationship between the use of devices and the headache, as well as the topographical location of the headache. As with homeostatic changes, ICHD-3 typifies a type of headache attributable to uninterrupted compression or traction of pericranial soft tissues [11]. In this situation there is more room for the external compression subtype where the elements of the PPE (glasses or protective shields and masks, mainly N95) produce compression over several hours on different facial regions.

Kymchatowski et al. analysed a cohort of 82 military police in Rio de Janeiro exposed to the regulatory helmet, and reported headache occurrence in all cases after wearing the helmet for at least 1 hour, with 92.7% disappearing after the removal. In addition, they reported that headache was clearly different from other headaches suffered in 64.6% of the cases. One third of the sample presented migraine, referring to the fact that the new headache was more intense and completely limited the development of their activity. It was also observed in all subjects of the cohort that the headache did not reproduce after removing the stimulus for five weeks [22]. Finally, a study of 212 health professionals assessing demographic factors, time of N-95 mask use and the existence of previous headaches showed a relatively high prevalence of mask headache among health workers who worked in high-risk areas during the 2003 SARS epidemic [10].

The last factor to be mentioned is the level of anxiety or stress. Multiple ways of relating the level of stress to the occurrence of headache have been described, either as “de novo” occurrence or as exacerbation in an individual with primary headache [23]. In the case of the SARS-CoV-2 pandemic, health care workers may be affected by critical incident stress (CIS). Critical incidents are events in which people witness or experience tragedy, death, serious injury or threatening situations, which can have a strong emotional impact. The signs and symptoms of CIS can be physical, cognitive, emotional and behavioural [24]. In our work, we observed that the level of stress in headache subjects is significantly worse in all aspects measured by PPQ.

We also showed that the risk of developing headache is higher among nurses and other health professionals than among physicians. The explanation for this result is complex, but there are three plausible hypotheses. As a general rule, doctors live with a higher level of stress in the course of their work, and therefore, situations considered conflicting do not increase their usual stress threshold excessively [25]. It could also be explained by the use of negative coping strategies in some professional groups as opposed to others [26], these strategies, which we have not measured in our work, would be related to professional level. The third potential explanation, in line with some published studies, is that the higher risk of headache among nurses and other health professionals than in the medical group, is due to the differential characteristics of the workers' occupation, which would involve the use of other devices, cleaning materials, activities with greater energy expenditure or changing work shifts [27].

Different factors or comorbidities that may influence the development of headache have been described in the literature [28]. If we look at risk markers, age and sex deserve special attention. The female sex is closely related to the development of “de novo” headache [29]. Age is a determining factor in the classification of headache according to the International

Headache Society [11]. Several studies have shown that pain intensity [30], the degree of headache disability, and the possibility of secondary headache occurrence are age-related factors [31]. In terms of other individually modifiable risk factors, the relationship between blood pressure changes and primary headache should be highlighted, as they share mechanisms of action such as vascular endothelial dysfunction or poor cardiovascular autonomic regulation [32]. However, in our study we did not find a clear association between different comorbidities of the individual and the appearance of headache, except for tobacco consumption in the univariant analysis.

In a review of the relationship between smoking, its different components and the occurrence of headache, controversial data were obtained. The studies conducted in this regard are mostly retrospective and limited, and there is no definite evidence that tobacco is an independent cause of headache occurrence. However, most migraine patients define it as a trigger [33]. Headache is one of the most pronounced symptoms in patients suffering from asthma, a fact that has been described in a few studies so far. In a study of 93 patients, a statistically significant difference was found in this area, as 62.4% of asthmatics had headache (migraine or tension), whereas in the control group the percentage was only 32.8%. Other factors such as the use of steroid inhalers, the presence of rhinitis, conjunctivitis or respiratory parameters such as FEV1 were studied and characterized [34]. In our study, being asthmatic would act as a protective factor against headache associated with mask use, perhaps because of a greater tolerance to hypoxia, and therefore a higher threshold for developing headache for this reason.

### Limitations

Our study has some limitations that should be noted: the sample is one of convenience and there has been no previous probability sampling. We could not include or under-represent

some professional groups. The study is cross-sectional, which helps us to formulate hypotheses, but we cannot prove causality. We have not taken into account the temporal evolution of the headache in the health professionals who present it. Nor have we taken into account other external factors that may influence the headache, such as the exact conditions of the site and type of work.

## Conclusion

In our study, we described the occurrence of “de novo” headache with the use of filtering masks and its negative impact on multiple dimensions of the life of healthcare professionals. We propose headache associated with the use of this type of mask as a new subtype of headache, of a multifactorial nature and complex etiopathogenesis. And since the use of these devices will tend to become more widespread due to the implications of the pandemic, we believe it is important to promote prevention and protection strategies that guarantee the safety of workers, without undermining their quality of life.

Table 1. Baseline Conditions and mask and Personal Protective Equipment usage among healthcare workers.

	De Novo Headache		P-value
	NO (n=103)	YES (n=158)	
Age (years)	40.8 (11.4)	44.4 (10.1)	0.009
Female Gender	73 (70.9%)	135 (85.4%)	0.004
Occupation			0.0001
Doctor	61(59.2%)	51 (32.3%)	
Nurse	33 (32.0%)	62(39.2%)	
Others	9(8.7%)	45(28.5%)	
Work shift			<0.0001
Mornings and 24 h. duties	51 (49.5%)	38 (24.1%)	
Rotating shifts	26 (25.2%)	65 (41.1%)	
Others	26 (25.2%)	55 (34.8%)	
Type of face mask			0.029
Surgical mask	89 (86.4%)	119 (57.2%)	
N95/FFP2	14 (13.6%)	39 (24.7%)	
Number of hours worn per day (SD)	6.8 (2.4)	7,0 (2,2)	0.474
Use of another PPE:			0.203
Face shield	21 (20.4%)	33 (20.9%)	
Protective eyewear	13 (12.6%)	20 (12.7%)	
Complete PPE	16 (15.5%)	30 (19.0%)	
Confirmed COVID-19	4 (3.9%)	8 (5.1%)	0.161
Pre-existing headache	45 (43.7%)	65 (41.1)	0.683
Comorbidity			
Allergy	16 (15.5%)	18(11.4%)	0.331
Asthma	11 (10.7%)	6 (3.8%)	0.028
Tobacco	8 (7.8%)	33 (20.9%)	0.004
Arterial hypertension	6 (5.8%)	8 (5.1%)	0.789
Cardiopathy	0 (0.0%)	1 (0.6)	0.419
Dyslipidemia	7 (6.8%)	7 (4.4%)	0.760
Diabetes	1 (1.0%)	1 (0.6%)	0.760
Thyroid disease	9 (8.7%)	19 (12%)	0.402
Anxiety	6 (5.8%)	20 (12.7%)	0.072
Others	4 (3.9%)	12 (7.6%)	0.222
Other symptoms			
Sleep disturbance	11 (10.7%)	68 (43%)	0.0001
Loss of concentration	14 (13.6%)	59 (37.3%)	0.0001
Irritability	18 (17.5%)	56 (35.4%)	0.002
Photophobia	8 (7.8%)	23 (14.6%)	0.097
Sonophobia	6 (5.8%)	18 (11.4%)	0.128
Sickness/vomiting	11 (10.7%)	13 (8.2%)	0.503

h.: hours; PPE: Personal Protective Equipment; HCW: healthcare workers; SD: standard deviation; VAS: visual analogic scale

Table 2. Characteristics of Headache in healthcare workers mask users.

	All HCW	HCW with de novo headache (n=93)	HCW with pre-existing headache (n=65)	P-Value
Days with headache per month (SD)	13.2 (7.2)	13.0 (7.4)	13.5 (7.1)	0.746
Days with headache per week (SD)	3.8 (1.7)	3.8 (1.7)	3.9 (1.7)	0.827
Mean pain level, VAS (SD)	5.9 (1.5)	5.8 (1.5)	6.1 (1.4)	0.08
Duration time				0.008
1-4 hours	74 (47.4%)	52 (57.1%)	22 (33.8%)	
4-8 hours	46 (29.5%)	23 (25.3%)	23 (35.4%)	
8-12 hours	21 (13.5%)	12 (13.2%)	9 (13.8%)	
>12 hours	15 (9.6%)	4 (4.4%)	11 (16.9%)	
Analgesic response				0.342
Good or very good	97 (61.4%)	61 (65.6%)	36 (55.4%)	
Regular	46 (29.1%)	23 (24.7%)	23 (35.4%)	
Bad or very bad	15 (9.5%)	9 (9.7%)	6 (9.2%)	
Headache impact on HCW				
Occupational	4.0 (2.6)	3.5 (2.6)	4.6 (2.5)	0.020
Family	4.4 (2.7)	4.1 (2.6)	4.9 (2.5)	0.084
Personal	5.0 (2.6)	4.7 (2.7)	5.5 (2.4)	0.049
Social	4.8 (2.8)	4.4 (2.8)	5.4 (2.7)	0.021

HCW: healthcare workers; SD: standard deviation; VAS: visual analogic scale

Table 3. Univariate and multivariate analysis of Factors of Baseline Conditions

VARIABLES	UNIVARIATE ANALYSIS				MULTIVARIATE ANALYSIS			
	OR	CI 95%		p-value	OR	CI 95%		p-value
Age	1.03	1.01	1.06	0.009				
Female Gender	2.41	1.31	4.45	0.005				
Doctor	Ref	Ref	Ref	0.0001	ref	ref		<0.0001
Nurse	2.25	1.28	3.94		2.09	1.18	3.72	
Other HCW	5.98	2.67	13.4		6.94	3.01	16.04	
Filter mask vs Surgical	2.08	1.07	4.07	0.026	2.14	1.07	4.32	0.027
Mornings and 24 h duties	Ref	Ref	Ref	0.0001				
Rotating shifts	3.35	1.81	6.23					
Others work shifts	2.83	1.52	5.32					
Asthma	0.33	0.12	0.92	0.03	0.29	0.09	0.89	0.026
Tobacco	3.13	1.39	7.01	0.003				
Anxiety	2.34	0.91	6.05	0.063				

HCW: healthcare workers; h.: hours.

## Figure legends

Figure 1: Impact of headache in subjects with a filtering mask as opposed to surgery mask in the four aspects evaluated by the Likert scale. Likert Scale Rating: Likert Scale Rating

It indicates the degree of limitation due to headache in different areas of life. 0: none; 10: maximum.

Figure 2: Evaluation of self-perceived work stress by means of the 12 items of the Psychosomatic Problems Questionnaire.

□ Surgical-Mask ■ Filter-Mask
