31

32 **40-word summary:** In household transmission clusters of SARS-CoV-2 children are unlikely
33 to be the index case. Children are also less likely than adults to be infected with SARS-CoV-2
34 from a family member.

35

36 **NOTE:** This preprint reports new research that has not been certified by peer review and should not be used to guide clinical practice.

37 **ABSTRACT**

38 The role of children in the spread of SARS-CoV-2 remains highly controversial. To address this
39 issue, we performed a meta-analysis of the published literature on household SARS-CoV-2
40 transmission clusters (n=213 from 12 countries). Only 8 (3.8%) transmission clusters were
41 identified as having a paediatric index case. Asymptomatic index cases were associated with
42 a lower secondary attack in contacts than symptomatic index cases (estimate risk ratio [RR],
43 0.17; 95% confidence interval [CI], 0.09-0.29). To determine the susceptibility of children to
44 household infections the secondary attack rate (SAR) in paediatric household contacts was
45 assessed. The secondary attack rate in paediatric household contacts was lower than in adult
46 household contacts (RR, 0.62; 95% CI, 0.42-0.91). These data have important implications for
47 the ongoing management of the COVID-19 pandemic, including potential vaccine
48 prioritization strategies.

61 INTRODUCTION

62 At the time of writing severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has
63 infected >50 million people resulting in >1 million deaths [1]. Large data analyses have shown
64 that the elderly are particularly susceptible to severe forms of coronavirus disease 2019
65 (COVID-19) [2]. However, the role of children in the transmission of SARS-CoV-2 remains
66 controversial [3-9]. During a typical influenza virus season, children have been identified as
67 having the highest infection rate of any age group (up to 43%). Accordingly, children may play
68 a major role in the spread of influenza virus and are a key target population for influenza
69 vaccination to prevent infection and reduce transmission [10]. In the context of coronaviruses,
70 paediatric infections with SARS-CoV-1, SARS-CoV-2 and MERS are typically mild [9, 10].
71 Nevertheless, a lower incidence of clinical symptoms raises concerns that children could be
72 an important, undetected source of SARS-CoV-2 in transmission in the community [8, 11].
73 Answering this question is of key importance to public health as it will help identify priority
74 groups for vaccination. However, findings remain controversial, with some studies suggesting
75 that children may play a key role in disease transmission and shed virus at equivalent titres to
76 adults [12-17]. In contrast, others find little evidence of paediatric infections or spread [7, 8,
77 18-21]. Moreover, it is unclear if SARS-CoV-2 transmission differs amongst children of
78 differing age groups.

79

80 Studying the source and route of viral transmission from children in the community is fraught
81 with difficulties, due to the multiple different potential sources of infection. Furthermore, it
82 is thought that households are one of the most common settings in SARS-CoV-2 transmission
83 [22]. Household transmission clusters therefore offer the unique opportunity to study viral
84 transmission and susceptibility to infection in a more defined setting.

To address the role of children in the transmission of SARS-CoV-2, we performed a meta-analysis on household transmission clusters. We investigated prevalence of paediatric index cases in household transmission clusters of SARS-CoV-2 as well as the secondary attack rate (SAR) of different age groups.

109 **METHODS**

110 **Definitions**

111 A household transmission cluster was defined as a group of ≥ 2 confirmed cases of SARS-CoV-
112 2 infections in co-habiting individuals in whom the diagnosis of cases occurred within 2 weeks
113 of each other. The index case was defined as the individual in the household cluster who first
114 developed symptoms. Household contacts were defined as co-habiting individuals, typically
115 family members, close relatives, housemates or house helpers. An individual with laboratory
116 confirmation of SARS-CoV-2 was considered to be infected. Household secondary attack rates
117 were defined as the proportion of confirmed infections among all household contacts. Unless
118 otherwise stated, adults were defined as individuals ≥ 18 years whilst children were defined
119 as individuals < 18 years of age.

120

121 **Data collection**

122 Following the PRISMA statement for the reporting of meta-analysis [23], we searched
123 published, de-identified, data made available between Dec 1, 2019, and August 24, 2020.
124 Information was accessed from the World Health Organization news¹¹, Google Scholar,
125 PubMed, the Lancet COVID-19 resource centre¹², Clinical Infectious Disease Journal and New
126 England Journal of Medicine. We searched for databases using the search terms (“COVID-19”
127 OR “SARS-CoV-2” OR) AND (“household transmission” OR “family cluster” OR “household
128 contact”) AND (“transmissibility” OR “attack rate”). To identify missing studies, we checked
129 the reference list for each selected paper. Studies that were duplicate publications, pre-prints
130 and/or reviews were excluded (Figure 1).

131

132 Our search strategy aimed to identify all articles that assessed the prevalence of children as
133 index cases in a family SARS-CoV-2 cluster and/or the secondary attack rate of children and
134 adults in household transmission clusters. Depending on the level of information available,
135 studies were included in the index case analysis or the secondary attack rate meta-analysis.

136

137 All studies included in the index case analysis were household SARS-CoV-2 transmission
138 clusters that i) identified the index case of the cluster ii) defined the number of infected
139 contacts in the household and iii) recorded the initial disease onset date of all cases in the
140 cluster.

141

142 All studies included in the secondary attack rate meta-analysis were household SARS-CoV-2
143 transmission clusters that i) defined the secondary attack rate within the cluster and ii)
144 defined the age of contact cases in the cluster. Studies which did not meet bare minimum
145 data required for the index case analysis nor the secondary attack rate meta-analysis were
146 excluded (Figure 1). Where the same family cluster was included in more than published
147 report, data was only extracted from one study. Collected data was verified by a second
148 researcher.

149

150 **Statistical analysis**

151 Susceptibility to infection was estimated by calculating the secondary attack rate for
152 household close contacts associated with the index case in each transmission cluster. We
153 estimated the Relative Risk (RRs) for SARS CoV-2 infection stratified by the age of household
154 contacts for each study. We then pooled these RRs using a random effects model with
155 DerSimonian and Laird weights[24]. We used a random effects model, equalizing the weight

156 of the studies to the pooled estimate. Where relevant, we stratified the analysis by pre-
157 specified characteristics. 95% confidence intervals (CI) were used to assess statistical
158 significance in all models. The I^2 statistic was used to evaluate heterogeneity between studies.
159 A threshold of $I^2 > 50\%$ was used as indicating statistically significant heterogeneity. All
160 summary analyses and meta-analysis were performed using R statistical software (version
161 3.6.1).

179

180 **RESULTS**

181 We identified 1208 articles that described SARS-CoV-2 household transmission clusters,
182 rejected 1151 articles due to a lack of sufficient and or appropriate data and derived a total
183 of 57 articles. Household transmission clusters were drawn from cases in 12 countries: China,
184 Japan, France, Germany, Italy, USA, Vietnam, Malaysia, Singapore, Morocco, Greece and
185 South Korea. 43 articles were included in the index case analysis[5, 25-66] whilst 14 articles
186 were used in the secondary attack rate meta-analysis[66-79]. The full detail of all family
187 clusters and characteristics of studies included in meta-analysis are shown in Supplementary
188 Tables 1 and 2.

189

190 **Children are infrequently identified as the index case of household SARS-CoV-2 clusters**

191 In analysis of the cluster index cases, we included 43 articles, in which there were 213 SARS-
192 CoV-2 transmission clusters and only 3.8% (8/213) were identified as having a paediatric index
193 case (Table 1 & Supplementary Tables 1 & 3). Of 611 individuals in the 213 clusters there were
194 102 children. These paediatric cases only caused 4.0% (16/398) of all secondary cases,
195 compared to the 97.8% of secondary cases that occurred when an adult was identified as the
196 index case in the cluster (Table 1).

197

198 The limited number of defined SARS-CoV-2 household clusters with children as the index case
199 could have been influenced by the fact that COVID-19 in children is frequently asymptomatic
200 [11]. Accordingly, it is possible that within a household cluster, children were not correctly
201 identified as the index case of the infection (i.e. the first to develop symptoms) and were
202 instead mistakenly identified as a contact case. To exclude this possibility, we reanalysed the
203 data looking at household clusters where a paediatric contact case was SARS-CoV-2 positive

204 but asymptomatic. In such a scenario we assumed the child to be the ‘true’ index case of the
205 cluster. Clusters where the asymptomatic/symptomatic status of the contact cases was not
206 described were excluded from the analysis. Even with this broader definition, only 39 (18.5%)
207 children were identified as the index case in the household clusters (Table 2).

208

209 It is also possible that these data were influenced by the fact that early in the SARS-CoV-2
210 outbreak, infections were associated with travel to outbreak areas (i.e. initially to Wuhan
211 itself and later to the entirety of Hubei). Travel is much more likely to be undertaken by an
212 adult in the family, potentially confounding the results. To control for this factor, we reanalysed
213 the data only including household transmission clusters where the index case had no history
214 of travel or the whole family was associated with an outbreak area. Clusters where this
215 information was not available were excluded from the analysis. This resulted in a total 152
216 index cases, 32 of which (21.1%) were identified as having a child as the index case in the
217 cluster (Table 3).

218

219 A final factor which may have confounded this analysis is the fact that in some countries a
220 strict lockdown was imposed during the period of data collection. This would have limited the
221 activity of children outside of the house and may therefore have artificially reduced the
222 number of children identified as an index case. To control for this factor, a sub-analysis was
223 performed only using data collected when the regional area or country was not in a period of
224 ‘lockdown’. In this sub-analysis only 3.0% of clusters were associated with a paediatric index
225 case (Table 4, Supplementary Table 1).

226

227 **Asymptomatic index cases are associated with a lower secondary attack rate**

228 We then further examined the household clusters identified in Table 1 where a child was
229 identified as the index case in order to define the secondary attack rate of cohabiting family
230 members (Supplementary Table 4). Clusters where the total number of infected and
231 uninfected family members was not recorded was excluded from the analysis. Accordingly,
232 sufficient information was only available to calculate the secondary attack rate of five clusters
233 with a paediatric index case (mean = 46.7%; SD = 28.2%). Three of these index cases were <
234 10 years and 3 index cases were aged 10 – 19 years. Only 22 clusters with an adult index case
235 were eligible for this analysis (mean = 65.8%; SD = 23.3%) (Supplementary Table 5). Therefore,
236 there was insufficient case numbers to determine whether children are more or less able to
237 transmit SARS-CoV-2 in a household setting compared to adult index cases.

238
239 It has previously been suggested that asymptomatic individuals may be less infectious than
240 those who develop symptoms [7, 80, 81]. The prevalence of mild/asymptomatic infections in
241 children may therefore affect the secondary attack rate in SARS-CoV-2 household clusters
242 where children were identified as the index case. To assess this possibility, we examined the
243 secondary attack rate in household clusters where the index case was symptomatic vs. the
244 secondary attack rate in household clusters where the index case was asymptomatic, (but
245 known to be SARS-CoV-2 positive Figure 2). Asymptomatic index cases were associated with
246 a significantly lower secondary attack in contacts than symptomatic index cases RR = 0.17 (95%
247 CI, 0.09-0.29), although a significant overall effect was observed with heterogeneity ($I^2=87\%$,
248 $P<0.01$).

249

250

251 **Children have a lower secondary attack rate than adults in household SARS-CoV-2**
252 **transmission clusters**

253 Several studies have suggested that children are less likely than adults to be infected with
254 SARS-CoV-2 [20, 82]. However, small scale studies can be biased by the fact that community
255 testing is often only performed on symptomatic individuals, few of whom may be children.

256

257 We therefore used the second data set collected in this study to examine the secondary attack
258 rate of children versus adults in household clusters where adults were identified as an index
259 case. In 11 observational studies of household transmission clusters, the secondary attack
260 rate in tested paediatric household contacts (<18 years old) was significantly lower than that
261 in adult household contacts RR=0.62 (95% CI, 0.42-0.91) (Figure 3).

262

263 In a subset analysis where additional information was provided on the age of the paediatric
264 contact, younger children (<10 years) were no more or less susceptible to infection compared
265 to older children (>10 years) RR = 0.69 (95% CI, 0.26-1.82) with no significant heterogeneity
266 ($I^2=33\%$, $P=0.17$, Figure 4). Together, these data suggest that children (<18 years old) are less
267 susceptible to SARS-CoV-2 infection in a household transmission cluster.

268

269

270

271

272

273

274

275 **DISCUSSION**

276 The transmission of SARS-CoV-2 to and from children has remained controversial throughout
277 the course of the COVID-19 pandemic. In the present study, we only recorded a limited
278 number of household transmission clusters (3.8%) where children (<18 years) were identified
279 as the index case. This observation is supported by previous study from China, where a study
280 of 66 family transmission clusters showed that children were never the first in the family to
281 be diagnosed with COVID-19 [83]. Other reviews have also found limited evidence of children
282 as the index case in household transmission clusters [4, 20]. Indeed, in a family based study
283 by the Dutch National Institute for Public Health and the Environment there were no
284 indications in any of the 54 participating families that a child <12 years old was the source of
285 COVID-19 within the family[84]. A more recent study of households in Tennessee and
286 Wisconsin suggested that of 101 family SARS-CoV-2 clusters, only 14 had paediatric index
287 cases [85].

288

289 There are multiple possible reasons as to why children may be infrequently identified as the
290 index case in household transmission clusters. This may reflect limited interaction of children
291 outside the home during the period in question or the higher probably of an adult traveling
292 to a COVID-19 endemic area than a child (. An alternate hypothesis is that children are less
293 susceptible to SARS-CoV-2 infection than adults. Indeed, this is consistent with our
294 observation that in household transmission clusters, children were significantly less likely to
295 acquire SARS-CoV-2 than their adult family members. Interestingly, we found that older
296 children were not significantly more likely than younger children to acquire the virus, in
297 contrast to previous pre-print suggestions [4].

298

299 A reduced incidence of SARS-CoV-2 infection in children outside the home has previously
300 been reported [2, 4, 8, 18]. [86]. [87]. Indeed, these data are congruent with survey data from
301 Vo', Italy [88]. Here, all age groups were homogenously sampled yet no children tested
302 positive for SARS-CoV-2 infection. This was despite the fact that at least 13 of these children
303 lived together with infected family members [88].

304

305 Once infected, it remains to be determined as to whether children are more or less likely to
306 transmit the SARS-CoV-2 to a family member as an infected adult. Whilst the mean number
307 of infected household members was lower when a child was identified as the index case of
308 the cluster, the low number of clusters eligible for inclusion in this analysis precluded any
309 definitive conclusions. However, these data are consistent with recent U.S. data suggesting
310 that the SAR from paediatric index cases (18 years old) was less than that of adults (43% and
311 57% respectively) [86]. It has previously been suggested that children are less likely to
312 transmit SARS-CoV-2 compared to adults [7, 8, 18-20]. Such suggestions have remained
313 controversial amongst other findings that children have equivalent nasopharyngeal viral loads
314 to adults [14, 16, 17]. However, reanalysis of the aforementioned studies have shown that i)
315 young children (<10 years old) did indeed have a significantly lower viral load [19] ii) that the
316 comparison was being performed between children in the first 2 days of symptoms and
317 hospitalized adults with severe disease[17] and iii) datasets included few children younger
318 than 16 years[16]. Similarly, pre-print suggestions that the risk of SARS-CoV-2 transmission to
319 contacts is greatest from infected individuals <14 years old may be affected by limited case
320 numbers in this age group (14/1489 total cases)[12].

321

322 Should children be less likely to transmit the virus, it is interesting to speculate the possible
323 mechanism by which this occurs. There is an emerging body of evidence that mild or
324 asymptomatic patients are less infectious than those with pronounced clinical symptoms [7,
325 13, 80, 81, 89]. Indeed, our meta-analysis showed that an asymptomatic index case was
326 associated with a significantly lower secondary attack rate compared to a symptomatic index
327 case. It is therefore tempting to hypothesise that children may be less infectious than adults
328 infected with SARS-CoV-2 due to their more mild clinical manifestation of disease. However,
329 such a hypothesis requires validation across a larger and more diverse dataset.

330

331 The present study was subject to several important limitations. Firstly, as we were
332 conservative during the data collection only a limited number of studies were included,
333 potentially contributing to the high I2 value observed. This study also assumes that SARS-CoV-
334 2 infections in the household contacts of infected individual were the result of a direct
335 transmission event. However, it is possible that the household contact acquired the virus from
336 another source (e.g. from community exposure) and that the first in the family to develop
337 symptoms was not necessarily the index case. We were also unable to control for the chance
338 of a 'common exposure' where two individuals were infected by the same source at the same
339 time, but one individual was incorrectly identified as the sole index case of the cluster as they
340 were the first to develop symptoms. Indeed, this appears to have confounded the analysis of
341 a series of family clusters identified in South Korea [5, 15]. It is also important to note that we
342 were unable to differentiate between pre-symptomatic and asymptomatic infections and
343 therefore the number of identified asymptotically infected individuals may be
344 overestimated. Finally, it is important to note that these data should not be extrapolated to
345 SARS-CoV-2 transmission outside the home where children tend to make more social contacts

346 than adults[18]. This could significantly influence transmission dynamics in the community
347 setting, although our data are congruent with the low rate of SARS-CoV-2 transmission in
348 Australian schools [90].

349

350 We are almost one year into the COVID-19 pandemic and many countries are still struggling
351 to control outbreaks of SARS-CoV-2. At the time of writing, numerous countries in Europe
352 have been forced into a second lockdown. However, unlike the first lockdown many countries
353 (including the U.K. and Germany) have elected to keep schools open. The data presented in
354 this manuscript suggest that should children become infected at school during this period,
355 they are unlikely to spread SARS-CoV-2 to their co-habiting family members.

356

357 There is now a growing body of evidence that a safe and at least partially effective vaccine
358 will be soon licenced for human use. However, due to the global demands, SARS-CoV-2
359 vaccines are likely to be first administered to pre-defined priority populations. Whilst
360 prioritising the vaccination children against influenza has proved an effective tool in the
361 reducing the spread of influenza virus in the community[10], our data suggest that a similar
362 strategy would be unlikely to significantly decrease the household transmission of SARS-CoV-
363 2.
