Abstract

Overwhelming evidence suggests that chronic hepatitis infection is associated with extrahepatic cancers. However, uncertainties exist about this association as much of the current evidence evolve from observational studies which are susceptible to confounding. We performed two-sample Mendelian randomization (MR) to explore the causal associations between chronic hepatitis infection and extrahepatic cancers. Genetic variants associated with chronic hepatitis B virus (HBV) infection and chronic hepatitis C virus (HCV) infection were identified from a large genome-wide association study. Summary level data for cancer of the biliary tract, cervix, colorectum, endometrium, esophagus, gastric, liver, lung, ovary and pancreas were obtained from the Biobank Japan. Using the inverse variance weighted method, we found chronic HBV infection to be causally associated with gastric cancer (odds ratio [OR] = 1.19 and 95% confidence interval [CI] = 1.13-1.25, P-value = 0.001) and lung cancer (OR = 1.21, 95% CI = 1.14-1.28, P-value = 0.001). Moreover, chronic HBV infection (OR = 1.34, 95% CI = 1.17-1.53, P-value = 0.007) and chronic HCV infection (OR = 2.75, 95% CI = 2.21-3.42, P-value = 0.0008) were all causally associated with liver cancer, supporting a well-established association between chronic hepatitis infection and liver cancer. In conclusions, our MR findings revealed that chronic HBV infection is causally associated with extrahepatic cancers including gastric and lung cancers.

Keywords: HBV, HCV, cancer, Mendelian randomization, genetics, SNPs

Introduction

Globally about 360 million people are chronically infected with hepatitis B virus (HBV) and hepatitis C virus (HCV) [1, 2]. Overwhelming evidence indicates that chronic hepatitis infection is the risk factor for liver cancer [3–5]. Further evidence suggests that chronic hepatitis infection is associated with extrahepatic cancers [6–10]. Moreover, our previous analysis revealed that chronic HBV infection is associated with cancer of the liver, pancreas, kidney, colorectum, ovary, non-Hodgkin’s lymphoma, gallbladder and extrahepatic bile duct whilst chronic HCV infection was associated with cancer of the liver, ovary, non-Hodgkin’s lymphoma, gallbladder and extrahepatic bile duct [11]. However, uncertainties exist about the association between chronic hepatitis infection and extrahepatic cancers as much of the current evidence evolve from observational studies [6–11], which are susceptible to confounding. Hence this association needs further evaluation using a different approach.

Mendelian randomisation (MR) is an analytical approach that uses genetic variants as instrumental variables to infer the causality of exposure to an outcome [12]. The MR is based on the idea that the inheritance of alleles are independent [13], thus suggesting that the exposure predicted by the genetic variants are independent of other exposures, thereby reducing biases commonly observed in observational studies. Unlike observational studies, MR analyses are not confounded by some unmeasured factors owing to the random independent segregation of alleles during meiosis [13, 14]. Besides, MR analyses are not prone to reverse causation as genetic variants are fixed and do not change over time [15]. This makes MR an ideal approach for inferring causality of an exposure on an outcome. However, for MR estimates to be valid, three main assumptions must be met (i) instrumental variables must be strongly associated with the exposure (ii) instrument variables are not associated with other confounders of the exposure and outcome association and (iii) there is no horizontal pleiotropy between the instrument variables and outcome variable [16].

Here we performed a two-sample MR to examine the causal associations between chronic hepatitis infection and risk of extrahepatic cancers using genetic variants associated

with chronic HBV infection and chronic HCV infection as instrumental variables. Genetic variants associated with chronic HBV infection and chronic HCV infection were identified from a recent genome-wide association study (GWAS) [17]. We examined the causal associations of genetic variants with risks of the biliary tract, cervical, colorectal, endometrial, esophageal, gastric, liver, lung, ovarian and pancreatic cancers.

Methods

Exposure data

Instrumental variables for chronic hepatitis infection were selected from a recent large GWAS with more than 200, 000 individuals of East Asian descent in Japan [17]. A total of 1,394 chronic HBV patients and 5,794 chronic HCV patients were used in the analysis. Independent single nucleotide polymorphisms (SNP) were defined when it was one megabase away from the lead SNP. A total of six and four conditionally independent SNPs were identified to be strongly associated with chronic HBV and chronic HCV infection, respectively at the genome-wide significance threshold (P -value $< 5 \times 10^{-8}$). Detailed information for the genetic variants used in this analysis is provided in Table.S1.

Outcome data

Summary level data for the associations of genetic variants and risks of biliary tract cervical, colorectal, endometrial, esophageal, gastric, liver, lung, ovarian and pancreatic cancers were obtained from GWAS of the East-Asians ancestry [17]. All participants included in the analysis were of East-Asian descent from Japan recruited into the Biobank Japan (BBJ) [18], which was launched in 2003 to provide evidence for the implementation of personalized medicine in Japan by investigating the role of environmental and genetic factors associated with various diseases and phenotypes [18]. The BBJ has over 47 diseases and phenotypes including 13 site-specific cancers.

Statistical analysis

Our analyses were performed using the simple median method, weighted median method, and MR-Egger method and inverse-variance weighted (IVW) method. The IVW was our primary MR method and it provides accurate estimates when there is no heterogeneity and directional pleiotropy between the exposure and outcome [19]. We performed a two-sample MR using the fixed-effect IVW method. The heterogeneity of causal association

between chronic hepatitis infection and extrahepatic cancers were investigated by estimating Cochran's Q statistics and I^2 statistics assuming a fixed-effect model [20].

We performed sensitivity analyses to check and correct for the presence of pleiotropy in the causal estimates [19]. We defined the presence of heterogeneity if the Q statistics were significant at a P-value ≤ 0.05 and consequently, we used a random-effect IVW method in our analysis [21]. We assessed the presence of horizontal pleiotropy using MR-Egger regression based on its intercept terms and Mendelian randomisation pleiotropy residual sum and outlier (MR-PRESSO) [22, 23]. When the MR-Egger intercept deviates from zero or its P-value is statistically significant at P-value ≤ 0.05 it indicates the presence of horizontal pleiotropy in the MR analysis [24] and a different MR method was used to report the results. In this analysis, we used the weighted median method in the presence of heterogeneity and horizontal pleiotropy. The weighted median methods can give valid estimates under the presence of horizontal pleiotropy when up to 50% of the instruments variables are valid [19]. MR-PRESSO was used to detect and remove outlier instrumental variable in the MR analysis [23]. Additionally, we performed a multivariable MR analysis using the fixed-effect IVW method with chronic HBV infection adjusted for chronic HCV infection and chronic HCV infection adjusted for chronic HBV infection [25]. All the statistical analyses were performed using the Mendelian Randomisation [26] and Two Sample MR [27] packages in the R programming language.

Multiple testing correction

We performed multiple testing using the Bonferroni correction method [28]. Since we used six instrumental variables in the MR analysis for chronic HBV infection and extrahepatic cancers and to adjust for multiple testing, our statistically significant P-value was ≤ 0.0083 . For chronic HCV infection, we used four instrumental variables and an adjusted P-value ≤ 0.0125 was used for determining statistically significant results of the causal association between chronic HCV infection and extrahepatic cancers.

Results

We identified six and four conditionally independent SNPs that were strongly associated with chronic HBV infection and chronic HCV infection, respectively from the BBJ (Table.S1). We defined the SNP to be independent if it were one megabase away from the lead SNP. Notably, most of these SNPs are mapped on chromosome 6 except rs8113007, which is mapped on chromosome 19.

Chronic HBV infection MR estimates

The IVW was our primary MR method in the absence of horizontal pleiotropy with MR-Egger regression intercept P-value > 0.05 (Table.S2). Firstly, we evaluated whether chronic HBV infection is causally associated with extrahepatic cancers. We found chronic HBV infection to be causally associated with a 34% higher risk of liver cancer, odds ratio (OR) = 1.34 and 95% confidence interval (CI) = 1.17-1.53, P-value = 0.007 (Table 1, Fig.1G). Additionally, chronic HBV infection was causally associated with extrahepatic cancers including gastric cancer (OR = 1.19, 95% CI = 1.13-1.25, P-value = 0.001, Fig.1F) and lung cancer (OR = 1.21, 95%CI = 1.14-1.28, P-value = 0.001, Fig.1H). Moreover, we found chronic HBV infection to be positively associated with esophageal cancer (OR = 1.12, 95% CI = 1.01-1.25, P-value = 0.039), however after correction for multiple testing our results were not statistically significant at P-value \leq 0.0083 (Table 1).

Chronic HCV infection MR estimates

For this analysis, we only found chronic HCV infection to be causally associated with liver cancer (OR = 2.75, 95%CI = 2.21-3.42, P-value = 0.0008, Fig.2G). Besides IVW method, simple median method (OR = 2.83, 95%CI = 2.06-3.88, P-value = 0.0009), weighted median method (OR = 2.61, 95%CI = 1.96-3.49, P-value = 0.001) and MR-Egger method (OR = 2.24, 95%CI = 1.33-3.75, P-value = 0.002) all show consistent causal association between chronic HCV infection and liver cancer (Table 1).

Sensitivity analyses

We performed sensitivity tests using MR-PRESSO and multivariable MR analysis. We found no evidence of horizontal pleiotropy for chronic HBV infection with all site-specific cancers with P-values >0.05 for the MR-Egger regression intercept approach (Table.S2). However, we found evidence of horizontal pleiotropy for chronic HCV infection with colorectal cancer and ovarian cancer with MR-Egger regression intercepts P-value = 0.012 and 0.030, respectively, (Table.S2). Moreover, we found the presence of heterogeneity for the causal association of chronic HBV infection with cervical cancer ($I^2 = 66.2\%$, $P_{\text{het}} = 0.011$) and also with liver cancer ($I^2 = 60.9\%$, $P_{\text{het}} = 0.025$, Table.S2). For chronic HCV infection, we found evidence for high heterogeneity for colorectal cancer ($I^2 = 62.4\%$, $P_{\text{het}} = 0.046$) and also in ovarian cancer ($I^2 = 66.5\%$, $P_{\text{het}} = 0.029$, Table.S2).

We then performed a sensitivity analysis and our results revealed rs116113866 as a genetic instrument driving the null association between chronic HBV infection and cervical cancer (OR = 1.04, 95%CI = 0.98-1.10, P-value = 0.209, Fig.1B). However, when we performed MR-PRESSO, which identify and remove outlier instrumental variables in MR analysis. Our outlier corrected MR-PRESSO for chronic HBV infection was causally associated with cervical cancer (OR =1.30, 95%CI = 1.12-1.51, P-value = 0.0263). However, this finding was not statistically significant after Bonferroni corrections. Interestingly, for chronic HBV infection and liver cancer, our MR-PRESSO analysis was similar to the IVW method regardless of the presence of heterogeneity, which was corrected by using the random IVW method. Since there were heterogeneity and horizontal pleiotropy for chronic HCV infection with colorectal cancer, and ovarian cancer (Table.S2), we, therefore, used the weighted median method for MR analysis, which gives valid estimates under the presence of horizontal pleiotropy when up to 50% of the instruments variables are valid. However, our weighted median MR analysis for colorectal cancer (OR =1.09, 95%CI = 0.94-1.27. P-value = 0.266) and for ovarian cancer (OR =1.18, 95%CI = 0.75-1.87, P-value =0.474) were not statistically significant (Table 1).

We further performed the multivariable MR analyses adjusting for chronic HCV infection and our results were largely unchanged from our main IVW results. Similarly, adjusting for chronic HBV infection did not attenuate the statistically significant results of chronic HCV infection and liver cancer.

Discussion

Our MR study was set out to investigate whether chronic hepatitis infection was causally associated with extrahepatic cancers. We found chronic HBV infection to be causally associated with extrahepatic cancers including gastric and lung cancer. Additionally, chronic HBV infection and chronic HCV infection were all causally associated with liver cancer, supporting the overwhelming evidence from observational studies that chronic hepatitis infection is a risk factor for liver cancer [3–6].

Using the IVW method, we found chronic HBV infection to be causally associated with gastric cancer, corroborating previous observational studies [7, 29]. However, our previous analysis using the Taiwan National Health Insurance datasets failed to find any significant association between chronic HBV infection and gastric cancer [11]. In this MR analysis, only chronic HBV infection was significantly associated with gastric cancer suggesting that HBV may play a crucial role in tumorigenesis of gastric cancer. Although we found chronic HCV infection not to be significantly associated with gastric cancer (OR = 1.11, 95% CI = 0.98-1.24, P-value = 0.093), the odds of developing gastric cancer was high among patients with chronic HCV infection (Table 1). Observational studies reported a high risk of developing lung cancer among patients with chronic HBV infection [6, 30], supporting our MR analysis that chronic HBV infection is a risk factor for lung cancer. HBV a partially circular double-stranded DNA virus encode HBV protein X, a transcriptional coactivator that plays a pivotal role in tumorigenesis by modulating key regulators of the apoptosis, interfering with the DNA repair pathways and tumour suppressor genes [31].

Prior evidence indicated that chronic HBV infection is associated with biliary tract, esophageal, endometrial, pancreatic, and colorectal cancer [6, 7, 9, 11, 30]. Although, we failed to find any significant association between chronic HBV infection and these site-specific cancers, our ORs for these associations were >1 (Table 1), suggesting that chronic HBV infection may be a risk factor for these site-specific cancers. Surprisingly, we found chronic

HBV infection to be inversely associated with ovarian cancer, which is contrary to our previous analysis in Han Chinese patients [11]. However, this association was not statistically significant and further validations are needed by future studies.

Chronic HCV infection was causally associated with liver cancer, supporting the overwhelming evidence of a well-known causal association between chronic HCV infection and liver cancer from previous observational studies [3–5]. However, our MR analysis failed to find any significant association between chronic HCV infection and extrahepatic cancers, which is contrary to our previous analysis indicating that chronic HCV infection is a risk factor for ovarian, non-Hodgkin's lymphoma, gallbladder and extrahepatic bile duct cancer [11]. In this analysis, we did not have summary level data for non-Hodgkin's lymphoma, gallbladder and extrahepatic bile duct cancer, limiting our ability to assess this association further. Nevertheless, chronic HCV infection was not significantly associated with ovarian cancer, but our OR was 1.19 thus suggesting a possible positive association between chronic HCV infection and ovarian cancer which requires further follow up. Moreover, chronic HCV infection was not significantly associated with the biliary tract and endometrial cancer, suggesting that chronic HCV infection may not be a risk factor for these site-specific cancers.

Our study has several strengths include the use of the MR approach, which eliminate some confounders commonly observed in epidemiological studies. Moreover, we used multiple SNPs, which were strongly associated with chronic hepatitis HBV and chronic HCV infection. Besides, we use a homogenous population which minimises heterogeneity commonly observed when individuals of different ancestry population are used in genetic studies. However, our study had some limitations including a lack of power to find a significant association between chronic hepatitis infection and certain site-specific cancers. Our analyses included individuals of East Asian descent where there is a high prevalence of chronic hepatitis infection and therefore our results might not be generalizable to other ancestry populations. Another limitation is the possibility of having overlapping individuals in predictor and outcome summary statistics, which might introduce some bias in our MR estimation. Nevertheless, we

performed a sensitivity analysis using four different approaches and our results were consistent and robust.

Conclusions

In summary, our MR results support a well-established relationship between chronic hepatitis infection and liver cancer and suggest that chronic HBV infection may also be a risk factor for gastric cancer and lung cancer. However, we found no evidence for the causal association between chronic HCV infection and extrahepatic cancers and future studies should investigate this further.

IVW; inverse –variance weighted methods, MR; Mendelian randomization, OR; odds ratio, CI; confidence interval

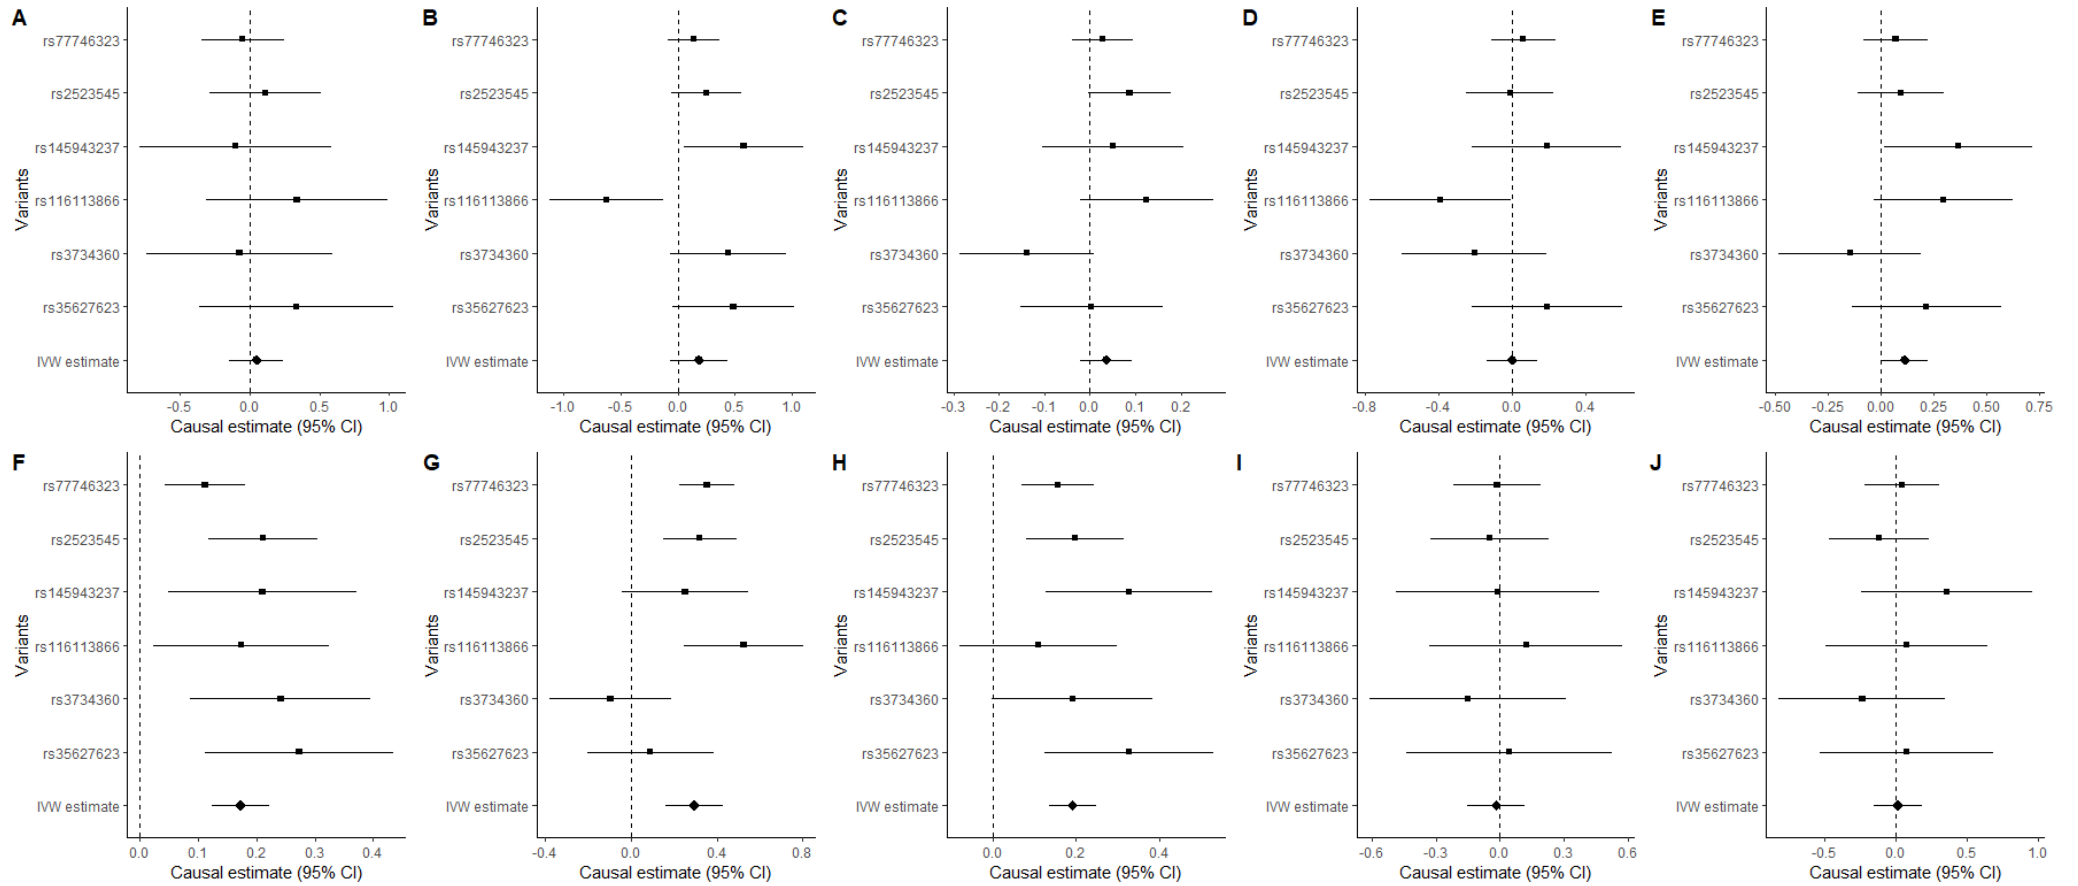

Fig.1 Mendelian randomization of chronic HBV infection and site-specific cancers. (A) biliary tract (B) cervix, (C) colorectum, (D) endometrium, (E) oesophagus, (F) gastric, (G) liver, (H) lung, (I) ovary, and (J) pancreas.

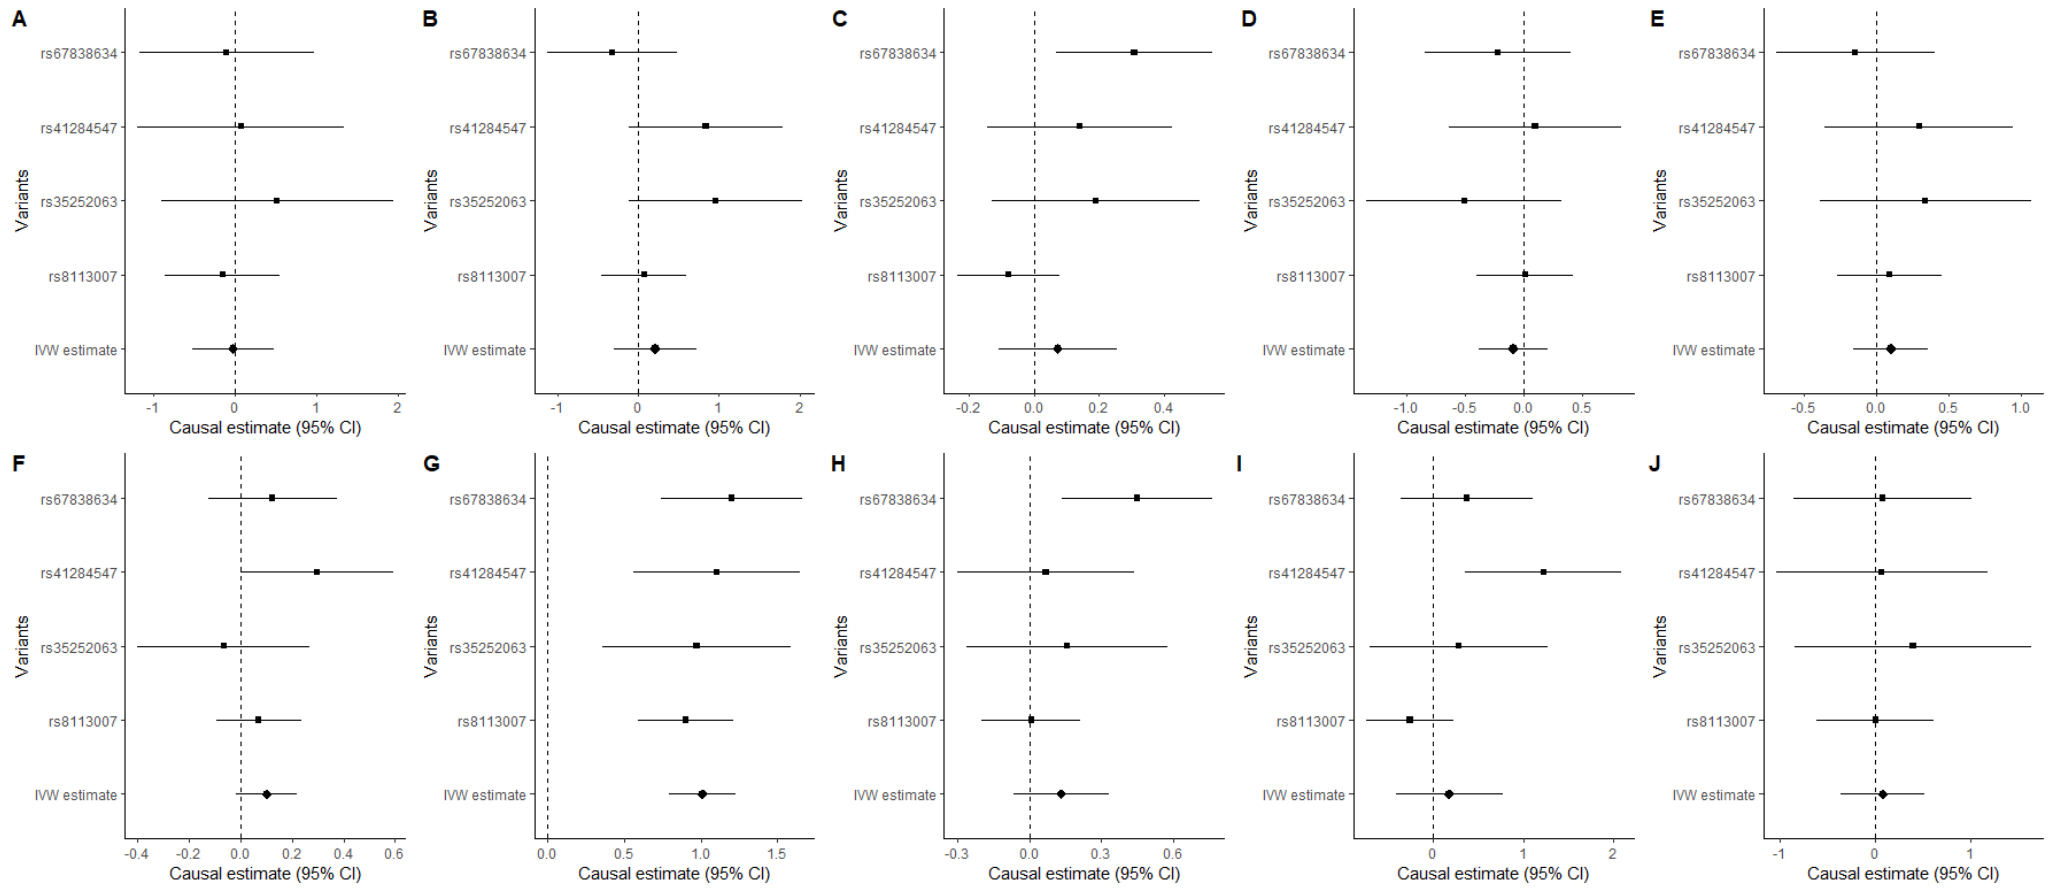

Fig.2 Mendelian randomization of chronic HCV infection and site-specific cancers. (A) biliary tract (B) cervix, (C) colorectum, (D) endometrium, (E) oesophagus, (F) gastric, (G) liver, (H) lung, (I) ovary, and (J) pancreas.

Supplementary material

Table S1. Instrumental variables used in the causal analysis of chronic hepatitis infection with various site-specific cancers.

SNP	Chr	Position	A1	A2	MAF	Beta	SE	Nearest genes	P-value
Hepatitis B									
rs77746323	6	33036401	C	T	0.599	0.517	0.040	<i>HLA-DPA1</i>	1.32 x 10 ⁻³⁸
rs2523545	6	31333499	G	A	0.872	0.551	0.060	<i>DHFRP2</i>	5.61 x 10 ⁻²⁰
rs145943237	6	26865972	G	T	0.725	0.271	0.048	<i>GUSBP2</i>	1.18 x 10 ⁻⁰⁸
rs116113866	6	30286105	C	G	0.043	-0.582	0.102	<i>HCG17</i>	1.34 x 10 ⁻⁰⁸
rs3734360	6	34100568	G	A	0.033	-0.640	0.116	<i>GRM4</i>	3.36 x 10 ⁻⁰⁸
rs35627623	6	28583377	A	C	0.885	0.355	0.065	<i>SCAND3</i>	4.54 x 10 ⁻⁰⁸
Hepatitis C									
rs67838634	6	32662128	A	G	0.437	-0.142	0.019	<i>MTCO3P1</i>	8.11 x 10 ⁻¹⁴
