34 **Abstract**

35 COVID-19 vaccination is being conducted in over 190 countries/regions to control
36 SARS-CoV-2 transmission and return to a pre-pandemic lifestyle. However,
37 understanding when non-pharmaceutical interventions (NPIs) can be lifted as
38 immunity builds up remain a key question for policy makers. To address it, we built a
39 data-driven model of SARS-CoV-2 transmission for China. We estimated that to
40 prevent the escalation of local outbreaks to widespread epidemics, stringent NPIs
41 need to remain in place at least one year after the start of vaccination. Should NPIs
42 alone be capable to keep the reproduction number (R_t) around 1.3, the synergetic
43 effect of NPIs and vaccination could reduce up to 99% of COVID-19 burden and
44 bring R_t below the epidemic threshold in about 9 months. Maintaining strict NPIs
45 throughout 2021 is of paramount importance to reduce COVID-19 burden while
46 vaccines are distributed to the population, especially in large populations with little
47 natural immunity.

48 The novel coronavirus disease 2019 (COVID-19) pandemic is far from over with
49 cases still surging in many countries across the globe, particularly with India suffering
50 from a catastrophic second wave ¹. In 2020, epidemic suppression and/or mitigation
51 have relied on non-pharmaceutical interventions (NPIs), including social distancing,
52 school closure, masking, and case isolation. Although effective and widely adopted to
53 limit SARS-CoV-2 transmission and reduce COVID-19 burden, these interventions
54 entail enormous economic costs and negatively affect quality of life ². Additionally, in
55 many countries, relaxation of NPIs has led to a resurgence of the epidemic as herd
56 immunity has not been reached thus far ³.

57

58 Effective vaccines against COVID-19 remain the only foreseeable means of both
59 suppressing the infection and returning to pre-pandemic social and economic activity
60 patterns. Globally, several vaccines have been licensed, and vaccination programs
61 have been initiated in more than 190 countries/regions, including China ⁴. However,
62 the projected global production and delivery capacities are likely to be inadequate to
63 provide COVID-19 vaccines to all individuals who are still susceptible to
64 SARS-CoV-2 infection ³. The effectiveness of COVID-19 vaccination campaigns will
65 depend on several factors, including pre-existing immunity, vaccine supply,
66 willingness to receive the vaccine, and strategies for vaccine allocation and
67 deployment ⁵.

68

69 To avoid widespread transmission of SARS-CoV-2, since the end of the first

70 COVID-19 wave in the spring of 2020, China has implemented strict NPIs and has
71 successfully controlled local outbreaks, preventing a second widespread wave of
72 COVID-19. Since December 2020, China has given conditional approval for the use
73 of four COVID-19 vaccines and emergency use approval for one. As of May 7, 2021,
74 308 million doses (corresponding to 10.7% of the population) have been administered
75 ⁶. However, such a coverage is still extremely low and thus China remains highly
76 vulnerable to importations of SARS-CoV-2 and onward transmission, as proved by
77 several local outbreaks that occurred in the first four months of 2021, the largest of
78 which occurring in Heilongjiang province led to 659 reported cases and spilled over
79 to a neighboring province (419 cases were reported in Jilin) ⁷. At present, estimating
80 whether and when NPIs can be lifted, and the extent to which we need to rely on NPIs
81 while vaccines roll out represents a top priority for policy making.

82

83 This question has not been well addressed in China, one of the few countries in the
84 world where nearly the entire population is still susceptible to SARS-CoV-2 infection,
85 and home to almost 1.4 billion individuals (roughly 18% of the world population). To
86 fill this gap, we built on top of the wide body of work adopting mathematical models
87 of the infection transmission process to evaluate vaccination programs ⁸⁻¹². In
88 particular, we developed an age-structured stochastic model to simulate SARS-CoV-2
89 transmission triggered by cases imported in mainland China, based on a
90 susceptible-infectious-removed (SIR) scheme (Supplementary Fig.1). We consider a
91 situation in which: i) no ongoing widespread SARS-CoV-2 transmission, ii) nearly no

92 immunity in the population, and iii) high risk of importing SARS-CoV-2 infected
93 individuals, possibly leading to an upsurge of COVID-19 cases. Since COVID-19
94 vaccines are expected to continue rolling out throughout 2021-2022, we consider also
95 alternative scenarios where SARS-CoV-2 infections leading to an outbreak are
96 imported when 10% (close to the coverage as of May 2021), 20%, and 30% of the
97 Chinese population has already been vaccinated (according to the simulated
98 vaccination program).

99

100 In the model, we account for heterogeneous mixing patterns by age¹³ and progressive
101 vaccine deployment among different population segments based on a priority scheme
102 (essential workers, older adults and individuals with underlying conditions, etc.)¹⁴.

103 Further, we overlay a disease burden model on the transmission model to estimate the
104 number of symptomatic cases, hospitalizations, ICU admissions, and deaths under
105 different vaccination scenarios and based on empirical data¹⁵⁻²⁰. The resulting
106 integrated model is informed by data on COVID-19 natural history, age-mixing
107 patterns specific to China quantified during the pre-pandemic period, and the size of
108 the different vaccination targets in the Chinese population (e.g., individuals with
109 pre-existing conditions). A qualitative model description is reported in the Methods
110 section, a summary of model parameters and data sources is reported in

111 Supplementary Table 1, all other details are reported in Supplementary File 1-5.

112 The combined effect of NPIs and vaccination programs are evaluated in terms of their
113 ability in reducing the disease burden caused by outbreaks arising from possible

114 importation of cases.

115

116 We considered a baseline vaccination scenario where: 1) vaccination starts 15 days
117 after an outbreak triggered by 40 breakthrough imported SARS-CoV-2 infections; 2)
118 vaccine efficacy (VE) against SARS-CoV-2 infections for a two-dose schedule (with a
119 21-day interval) is set at 80% ²¹; 3) vaccination coverage is capped at 70% across all
120 ages ¹⁴; 4) 6 million doses are administered daily (4 per 1,000 individuals, informed
121 by the ongoing COVID-19 vaccination program ⁶, and estimates of vaccine supply till
122 2021 in China ²²⁻²⁶); 5) the first priority target consists of older adults and individuals
123 with underlying conditions (descriptions in details shown in Supplementary Table 2);
124 6) there is no prior population immunity from natural infection, which aligns with the
125 situation in most of China where there has been little circulation of SARS-CoV-2 as
126 of May 2021 ³; 7) we assume an initial reproductive number $R_t = 2.5$ at the start of the
127 outbreak ²⁷⁻³², in the absence of NPIs and vaccination; 8) Children under 15 years of
128 age were considered to have a lower susceptibility to SARS-CoV-2 infection as
129 compared to adults (i.e., individuals aged 15 to 64 years), while individuals aged 65+
130 years had the highest susceptibility to infection (Supplementary Table 1) ^{33,34}; and 9)
131 we let the model run for two years. To evaluate the impact of the baseline assumptions
132 on our results, we conduct comprehensive sensitivity analyses (SA).

133

134 **Results**

135 **Main analysis**

136 In the absence of NPIs, the vaccination program is too slow to lower and delay the
137 epidemic (Fig. 1a) and does not effectively reduce COVID-19 burden. R_t falls below
138 the epidemic threshold (<1) 69 days after the epidemic start (Fig. 1b), but this is
139 primarily attributable to immunity gained through natural infection rather than
140 vaccination. Indeed, in this time frame, 52.2% of population gets infected, while only
141 6.7% of population has been vaccinated (Fig. 1c). The cumulative number of
142 symptomatic cases and deaths over a 2-year period only decrease by 3.3% (95% CI,
143 3.1%-4.7%) and 6.7% (95% CI, 4.5%-8.9%), respectively, as compared to a reference
144 scenario where there is no vaccination and no NPIs, which would lead to 306.73
145 million (95% CI, 282.68-320.60) symptomatic cases, 99.25 million (95% CI,
146 92.55-104.51) hospitalizations, 7.19 million (95% CI, 6.00-7.83) ICU admissions, and
147 9.38 million (95% CI, 7.70-10.26) deaths (Fig. 2).

148

149 Provided that NPIs are in place and can keep R_t at 1.3 in the absence of vaccination
150 (*moderate NPIs scenario*), the vaccination program could reduce COVID-19 burden
151 by about 99% compared to the *reference no-vaccination scenario*, with 5.46 million
152 (95% CI, 2.47-13.36) symptomatic cases, 1.77 million (95% CI, 0.83-4.40)
153 hospitalizations, 73,500 (95% CI, 7,300-152,100) ICU admissions, and 76,700
154 (95% CI, 8,200-165,700) deaths (Fig. 2). In this context, vaccination decreases
155 COVID-19 burden by about 40% (Fig. 2) compared to a situation with moderate NPI
156 alone, and R_t falls below the epidemic threshold about 9 months after the epidemic
157 start (Fig. 1). At the time that R_t falls below 1, we estimate that 50.8% of the total

158 population would have been vaccinated, while 0.8% would have been naturally
159 infected (Fig. 1g-i). This highlights that a relevant proportion of the population would
160 be still susceptible to SARS-CoV-2 at that time. Although in the long-term
161 vaccination can ultimately lead to the suppression of transmission, it is necessary to
162 maintain NPIs for one year after the onset of vaccination. Indeed, if NPIs are relaxed
163 from moderate ($R_t=1.3$) to mild ($R_t=1.5$) 9 months after vaccination start, the
164 cumulative death toll could increase from 76,700 to 173,000. In contrast, a small
165 increase in cumulative deaths from 76,700 to 81,700 is expected if this relaxation
166 occurs one year after vaccination start, while earlier or more drastic relaxations of
167 NPIs lead to substantial increases in deaths (Extended Data Fig.1-3).

168

169 A combination of more stringent NPIs (i.e., capable of keeping $R_t=1.1$) and
170 vaccination (*vax + high NPIs* scenario) could suppress the epidemic, with <2,300
171 symptomatic cases, and <50 deaths on average. Although the majority of the
172 reduction of COVID-19 burden is ascribable to NPIs in this case (over 85%), the
173 deaths averted due to vaccination are about 1.2 million (Fig. 1j-l, and Fig. 2).

174

175 If we consider a set of mild NPIs (*vax + mild NPIs* scenario), even a relatively low
176 initial reproduction number under NPIs of $R_t=1.5$ could still lead to a disastrous
177 epidemic, with nearly two million deaths. Despite the high death toll of the resulting
178 epidemic, NPIs and vaccination would jointly reduce around 80% of the disease
179 burden compared to a scenario with no NPIs and no vaccination (namely, 239 million

180 symptomatic cases and 8.2 million deaths averted) (Fig. 1d-f, and Fig. 2).

181

182 **Vaccine distribution capacity**

183 Should the daily vaccination rollout be limited to 1.3 million doses (1 per 1,000
184 individuals – a slower rate than during the 2009 H1N1 pandemic), vaccination would
185 not effectively reduce COVID-19 related deaths unless there was adoption of
186 stringent NPIs. In a scenario where vaccination capacity reaches 10 million doses
187 administered per day (7 per 1,000 individuals), vaccination would reduce COVID-19
188 related deaths to <5,000 for moderate NPIs and <30 for high NPIs. Should the daily
189 vaccination capacity be increased to 15 million doses (10 per 1,000 individuals),
190 vaccination could effectively reduce deaths to <100,000 (similar to the annual
191 influenza-related death toll in China³⁵) even in the presence of mild NPIs. However,
192 even if the daily vaccination capacity could be increased to 30 million doses (20 per
193 1,000 individuals), in the absence of NPIs, we estimate that over 7.7 million deaths
194 would still occur (Fig. 3). Similar patterns are estimated for the number of
195 symptomatic cases, hospitalizations and ICU admissions (Extended Data Fig.4-6).

196

197 Increasing daily vaccination capacity could largely shorten the time needed to control
198 SARS-CoV-2 transmission. For instance, when considering a daily capacity of 10
199 million and 15 million doses and moderate NPIs, R_t would drop below 1 about 8 and
200 6 months respectively after epidemic onset (to be compared to the 9.3 months
201 estimated with the baseline capacity of 6 million doses). At that time, over 60% of the

202 population would be vaccinated and $\leq 0.1\%$ would be naturally infected. An upscale in
203 the daily capacity to 10 or 15 million doses would allow a relaxation of NPIs from
204 moderate to mild already 6 to 9 months after vaccination start, i.e., 3 to 6 months
205 earlier with respect to the baseline. On the other hand, more drastic relaxations of
206 NPIs (e.g., from moderate to no NPIs) would still lead to substantial increases in
207 symptomatic cases and deaths (Extended Data Fig.7-10).

208

209 **Vaccination prioritization**

210 We consider alternative vaccination scenarios that prioritize essential workers (staff in
211 the healthcare, law enforcement, security, community services, and individuals
212 employed in cold chain, etc.) to maintain essential services and then explore different
213 prioritization strategies for the rest of the population. Our results suggest that the
214 relative timing of the epidemic and of the vaccination rollout play a key role in
215 determining the most effective strategy. In particular if we consider vaccination to
216 start two weeks after 40 cases are detected, there is no clear prioritization strategy that
217 minimize deaths, as the outcome of the vaccination campaign heavily depends on the
218 timing at which the epidemic unfolds (Fig. 4 and Extended Data Fig. 11-12). Instead,
219 if the epidemic is already underway when the vaccination campaign starts ($>5,000$
220 cases), prioritizing working-age groups minimizes the number of deaths when $R_t \leq 1.3$.
221 In contrast, prioritizing older adults and individuals with underlying conditions is
222 more effective when $R_t \geq 1.5$ (direct benefits are higher, Fig. 4 and Extended Data Fig.
223 11-12). Two results are independent of the adopted prioritization strategy: i) if $R_t \geq 1.5$,

224 then an epidemic cannot be avoided; and ii) when $R_t = 1.1$, over 99% of deaths can be
225 averted (Extended Data Fig. 11-12).

226

227 **Population immunity at the onset of an outbreak**

228 In December 2020, vaccination has started in China, while measures to detect
229 imported cases and case surveillance are in place. The number of doses distributed per
230 day has changed over time, following an increasing trend and with a daily average of
231 about 6 million doses over the period April 20 – May 7, 2021 (Supplementary File 3).
232 As of May 7, 2021, the vaccination coverage is 10.7%⁶. The effectiveness of the
233 vaccination program and NPIs in preventing new COVID-19 outbreaks and limiting
234 COVID-19 burden will thus depend on the level of vaccine-induced immunity in the
235 population should an outbreak of locally transmitted cases start to unfold.

236

237 To simulate this situation, we initialize the model by considering different fractions of
238 vaccinated population ($SA1$: 10%; $SA2$: 20%; $SA3$: 30%) at the time the infection is
239 seeded. Given a certain level of NPIs in the absence of immunity, increasing
240 proportions of vaccinated individuals will decrease the effective reproduction number
241 (e.g., $R_t = 1.1$ in the absence of immunity, corresponds to R_t below the epidemic
242 threshold if 10% or more of the population has been vaccinated).

243

244 Should 30% of the population already been vaccinated before the start of a new wave,
245 continuing the vaccination program while adopting mild NPIs would reduce the death

246 toll by 98% (42,400 deaths as compared 1.8 million if no one was vaccinated).

247 However, in the absence of NPIs, even if 30% of population was already vaccinated
248 before the start of a new wave, carrying on with the vaccination program alone would
249 not be enough to prevent a widespread epidemic leading to 6 (95% CI: 4-7) million
250 deaths (Extended Data Fig.13).

251

252 **Vaccination coverage**

253 No significant difference in willingness-to-vaccination between age groups has been
254 reported in China³⁶⁻³⁸. Accordingly, we use a homogenous vaccine coverage of 70%
255 among all age groups in the main analysis. Here we present the results of a set of
256 sensitivity analyses assuming vaccination coverage of 50% (SA4) and 90% (SA5)
257 among all age groups, and considering heterogeneous coverages by age: 1) 70% for
258 adults ≥ 20 years and 50% for younger individuals (SA6); 2) 90% for adults ≥ 20 years
259 and 70% for younger individuals (SA7); 3) 70% for adults ≥ 20 years and no
260 vaccination for younger individuals (SA8).

261

262 By considering moderate NPIs ($R_t=1.3$) and a vaccination coverage of 50% in all age
263 groups, the number of symptomatic is estimated to decrease by 33% with an 8%
264 decrease of the death toll with respect to the baseline vaccination scenario (70%
265 coverage) (Extended Data Fig.14-15). In fact, the lower coverage in older age groups
266 would lead to an earlier vaccination in younger age groups who are characterized by
267 the highest contact rates¹³. Conversely, increasing the coverage to 90% would

268 decrease the death tolls but lead to an increase of symptomatic cases (Extended Data
269 Fig.14-15). It is important to remark that these results consider that moderate NPIs
270 remain in place over the entire duration of the epidemic, and they do not provide
271 indications of the coverage needed to suppress any further resurgences of cases.

272

273 As compared to the baseline vaccination scenario (70% vaccination coverage in all
274 age groups), if the vaccine is not distributed among individuals aged less than 20
275 years, we estimate an increase of the death toll of 69% and of symptomatic infections
276 of 55% (Extended Data Fig.14-15). The scenario assuming 90% vaccination coverage
277 for adults ≥ 20 years and 70% for younger individuals lead to a lower reduction of
278 COVID-19 burden as compared with the baseline vaccination scenario (Extended
279 Data Fig. 14-15). The higher coverage in the adult population result in a delayed start
280 of vaccination of the young population, which is characterized by higher contacts
281 rates¹³. Nonetheless, it is important to remark that this result depends on the timing of
282 the introduction of the initial seeds (see previous section).

283

284 **Vaccine efficacy**

285 Three types of COVID-19 vaccines are currently in use in China, including
286 inactivated, recombinant protein subunit, and adenovirus-vectored vaccines. VE for
287 these vaccines ranges from 65% to 90%, with the exception of the one tested in Brazil
288 where P1 variant is prevalent (VE=50%)³⁹⁻⁴³. With respect to an 80% VE adopted in
289 the baseline scenario, by considering VE=60% (SA9) we estimate a 1.02-fold increase

290 of the death toll and 1.64-fold increase of symptomatic cases. Whereas a 37% and 29%
291 decrease of deaths and symptomatic cases, respectively, is estimated for VE=90%
292 (SA10). (Extended Data Fig.14-15)

293

294 **SARS-CoV-2 variants**

295 Multiple SARS-CoV-2 variants have been documented globally, three of which are of
296 particular concern: lineage B.1.1.7 identified in UK, B.1.351 in South Africa, and P.1
297 in Brazil⁴⁴. These variants are estimated to have higher transmissibility^{45,46} and
298 possibly an increased mortality^{47,48}. To assess the effect of vaccination in this context,
299 we consider higher values of R_t (i.e., 1.7, 1.9, and 2.1 – about 30%-60% increased
300 transmissibility with respect to the main analysis⁴⁵) to account for enhanced
301 transmissibility, and use a mean death hazard ratio of 1.64 to account for higher
302 mortality⁴⁷. With the assumption of VE=80% against the new variant, COVID-19
303 burden substantially increases, compared to the scenario based on the historical
304 lineage. The number of symptomatic cases increase from 2 thousand to 173 million,
305 and death increase from <50 to 7 million even when strict NPIs are implemented
306 (Extended Data Fig. 16).

307

308 **Alternative vaccination parameters and scenarios**

309 A further set of sensitivity analyses are conducted to evaluate the impact of baseline
310 assumptions on our results for $R_t=1.3$ (moderate NPIs). Provided that vaccination can
311 only protect against illness (SA11) but not SARS-CoV-2 infections, COVID-19 related

312 deaths increase by 33 folds with respect to the baseline: from 76,700 to 2.66 million
313 (Extended Data Fig.14). In this case, maintaining stringent NPIs measures in place for
314 a prolonged time horizon would be necessary as such vaccine would not be effective
315 to suppress transmission (as reported in previous studies ⁴⁹). Assuming a shorter
316 duration of vaccine-induced protection of 6 months (*SAI2*) instead of a lifelong
317 protection (i.e., longer than the 2-year time horizon considered, Extended Data Fig.14)
318 has a similarly large effect on projections.

319

320 In our main analysis, we use the contact matrix estimated from a contact survey
321 conducted in Shanghai before the COVID-19 pandemic ¹³. Should a new COVID-19
322 wave start to unfold in China, it is unclear to what extent pre-pandemic contact
323 patterns could be representative of such a situation. Therefore, we have added a
324 sensitivity analysis where we assume the mixing patterns estimated in Shanghai in
325 March 2020 ⁵⁰, when schools were still closed as a response to the COVID-19
326 pandemic (*SAI3*). For $R_t=1.3$ and the baseline parameters for the vaccination, the
327 estimated number of deaths would be 16,000 as compared to 76,700 estimated using
328 the pre-pandemic mixing patterns (79% decrease, see Extended Data Fig.14). In fact,
329 the relative contribution of the adult population (which is the main target of the
330 vaccination campaign) to the overall transmission as compared to children is higher
331 than when considering pre-pandemic mixing patterns (when schools were open and
332 school-age individuals had the highest number of contacts).

333

334 Other factors such as excluding detected symptomatic cases from vaccination (*SA14*
335 and *SA15*), the time interval between two doses (*SA16 and SA17*), and assuming an
336 all-or-nothing vaccine (*SA18*), do not substantially affect estimates of deaths and
337 symptomatic infections (Extended Data Fig.14-15). A similar trend is observed for
338 hospitalized cases and ICU admissions.

339

340 **Discussion**

341 Using a stochastic dynamic model of SARS-CoV-2 transmission and COVID-19
342 burden tailored to the epidemiological situation in China, we find that in the absence
343 of NPIs, and independently of the vaccine prioritization strategy and capacity of the
344 vaccination campaign, timely rollout of an effective vaccine ($VE = 80\%$) would not be
345 enough to prevent a local outbreak to escalate to a major widespread epidemic.
346 Provided that NPIs are in place and capable to bring R_t to 1.3, a daily vaccine rollout
347 of 4 doses per 1,000 individuals could reduce around 99% of COVID-19 burden, and
348 bring R_t below the epidemic threshold about 9 months after the start of the
349 vaccination campaign. A relaxation of NPIs that bring the value of R_t to 1.5 could not
350 prevent sustained epidemic growth which would cause 1.8 million deaths. A net
351 reproduction number of 1.5 could only be sustained when accompanied by an
352 improvement of the vaccine administration capacity up to 10 doses per 1,000
353 individuals per day. Relaxation of NPIs in the first 6-9 months of vaccine rollout
354 could lead to substantial increases of COVID-19 burden if daily vaccination capacity
355 could not be enhanced to 10-15 million doses.

356

357 Bubar K, et al. evaluated COVID-19 vaccine prioritization strategies and found that
358 prioritizing older adults is a robust strategy to minimize deaths across countries when
359 $R_t=1.5$, while prioritization shifted to 20-49 years group when $R_t=1.15$ ⁵¹. The broad
360 scope of that multi-country analysis does not account for features of COVID-19
361 epidemiology and vaccination program that are unique to China. In particular,
362 differently from most countries where natural immunity is building up after
363 widespread epidemics, China has been able to suppress SARS-CoV-2 transmission for
364 most of 2020. As a result, prior immunity is very low, thus calling for specifically
365 tailored analysis. Nonetheless, our findings confirm that if NPIs can maintain
366 transmission rates at low levels during the vaccination campaign, strategies that target
367 indirect benefits perform better, while if transmission rates remain high, strategies
368 maximizing direct benefits may save more lives⁵¹.

369

370 As highlighted in vaccination studies in Italy⁵², in the race between the vaccination
371 campaign to build population herd-immunity and the progress of the epidemic, the
372 speed of vaccine deployment is critical. Considering the average vaccine distribution
373 capacity of the current COVID-19 vaccination campaign in China⁶, we use 6 million
374 doses administered per day in the baseline analysis. Several manufacturers state that a
375 total of 3.9 billion doses of COVID-19 vaccine could be produced in 2021, equivalent
376 to about 10 million doses per day²²⁻²⁶. China committed to provide COVID-19
377 vaccines to >100 countries, and thus that could reduce the number of doses to be

378 distributed locally. Even if these candidate vaccines could be licensed and
379 manufactured smoothly, it would take about one year to vaccinate 70% of the
380 population.
381
382 Five months after initiating vaccination program, 10.7% of Chinese population has
383 been vaccinated ⁶. Limited vaccine production capacity, particularly at the initial stage,
384 could slow the speed of vaccine rollout. Slower rates of vaccine production and
385 administration may result in a longer period of SARS-CoV-2 transmission. It is thus
386 crucial to keep monitoring local outbreaks and invest resources in outbreak
387 management (as currently done in China) in order to keep R_t close to the epidemic
388 threshold at least for the next 1-2 years. In the very unique context of China, a value
389 of R_t of 1.3 would result in about 76,700 cumulative deaths, comparable to the annual
390 influenza-related death toll in China³⁵. The development of detailed logistical plans
391 and tools to support an increased vaccination capacity as well as effective logistic
392 (vaccine transport, storage, and continuous cold-chain monitoring) are key factors for
393 a successful mass vaccination campaign.

394
395 In the early phase of COVID-19 spread in Wuhan in 2019, before interventions were
396 put in place, R_0 was estimated to be in the range 2.0-3.5²⁷⁻³². Given the knowledge of
397 mechanisms of SARS-CoV-2 transmission, and the devastating consequences of an
398 uncontrolled COVID-19 epidemic, the Chinese population would hold a precautious
399 behavior (such as clean hands often, cough or sneeze in bent elbow, avoid close

400 contact with someone who is sick, etc.) even without the need to impose NPIs. As
401 such, in our analysis simulating an epidemic triggered by imported cases, we decided
402 to consider an initial R of 2.5, which is at the lower end of the estimated spectrum.
403
404 SARS-CoV-2 variants are circulating globally and quickly became dominant in
405 countries like the UK and Italy (lineage B.1.1.7), and South Africa (lineage B.1.351).
406 Recently, a variant B.1.617 identified in India has raised global concern. As of May 7,
407 2021, Mainland China border control screenings have already identified imported
408 cases with SARS-CoV-2 lineage B.1.1.7 and B.1.617. Our study shows that the spread
409 of new more transmissible and/or more lethal variants could substantially decrease the
410 net benefit of vaccination. Strict border quarantine and isolation as well as genomic
411 surveillance will be key while vaccines roll out in China.
412
413 Our analysis on the vaccine efficacy shows that if we consider $VE=60\%$, both the
414 number of symptomatic cases and deaths are estimated to double as compared to the
415 baseline vaccination coverage of 80%. Given that the final composition of a
416 nation-wide rollout will likely include a combination of vaccines with varying
417 efficacy, monitoring vaccine effectiveness on the ground will remain a priority.
418
419 Here we propose a general framework to evaluate the impact of COVID-19
420 vaccination programs in the absence/presence of NPIs and to explore priority target
421 populations to minimize multiple disease outcomes. The proposed modeling

422 framework is adaptable to other country-specific contexts. However, it requires the
423 collection of country-specific data about the epidemiological situation (e.g., landscape
424 immunity of the local population, prevalence of infections), vaccination parameters
425 (e.g., vaccine supply and capacity of immunization services, efficacy of different
426 vaccines, target age groups), socio-demographic characteristics of the population (e.g.,
427 size of the priority population by age group, age-mixing patterns), and the priorities of
428 the pandemic responses (e.g., limit the death toll, prevent infections).

429

430 Our study has a number of limitations. First, we integrated the impact of NPIs through
431 a simple reduction in the value of R_t at the beginning of the outbreak, homogeneously
432 across age groups. However, our analysis does not suggest which combination of
433 NPIs should be adopted to lower R_t to a certain level, and how this would affect
434 transmission rates in different age groups. Li, et al, estimated that individual NPIs,
435 including school closure, workplace closure, and public events bans, were associated
436 with reductions in R_t of 13–24% on day 28 after their introduction⁵³. Further studies
437 are needed to pinpoint the specific NPIs to be adopted in parallel with the vaccination
438 campaign and their impact on the quality of life of the population.

439

440 Second, in China, vaccines have not been licensed for children, so we assume a 50%
441 lower or equivalent VE for them compared to other adults. Although we show that
442 variations in these rates do not substantially affect the overall effect of the vaccination
443 campaign, further data on age-specific vaccine efficacy could help refine priority

444 groups. Our sensitivity analyses on vaccine coverage reveal the importance of
445 extending the vaccination to the young population once the use of vaccines will be
446 authorized for that age segment of the population.

447

448 Third, we assumed that immunity after natural infections lasts more than the time
449 horizon considered (two years). If this is not the case, waning of immunity would
450 inflate the rate of susceptible individuals and thus require booster vaccinations. This
451 could become an issue with the emergence of immune-escape variants, as reported in
452 South Africa⁵⁴. Given limited information at this stage, we did not consider this
453 scenario in our analyses, but this is an important area of future research.

454

455 Fourth, age-mixing patterns are key to assess the impact of vaccination as individuals
456 of different ages are exposed to different transmission risks. In the main analysis, we
457 assumed the mixing patterns to correspond to those estimated before the COVID-19
458 pandemic, indicating the goal of a return to pre-pandemic interactions. We have also
459 performed a sensitivity analysis based on the mixing patterns estimated in China in
460 March 2020⁵⁰, after the lockdown was lifted but schools were still closed. How the
461 population would mix in case of a new wave of COVID-19 starts to unfold in China
462 remains to be seen.

463

464 Moreover, our study is performed at a national scale and thus our estimates of the
465 impact of vaccination should be interpreted cautiously at the local scale. In fact,

466 spatial heterogeneities within China in terms of risk of case importation,

467 socio-demographic characteristics of the population, mixing and mobility patterns,

468 vaccination coverage and capacity may affect our results.

469

470 Enhanced vaccination efforts in conjunction with NPIs have been successfully used

471 during the COVID-19 outbreak in Ruili city (Yunnan Province, China) in March-April,

472 2021. Our analysis, however, focuses on the assessment of whether and to what extent

473 we need to rely on NPIs to prevent a COVID-19 epidemic while vaccines are rolled

474 out. As such, our results cannot be used to guide a reactive spatially targeted strategy.

475 To properly capture the peculiarity of that context, specific modeling tools mirroring

476 the interventions adopted in China as a response to emerging outbreaks are needed.

477

478 Finally, it would be interesting to analyze adaptive vaccination prioritizations that

479 changes as the epidemiological situation evolves over time but that would require the

480 development of dynamic optimization algorithms that are beyond the scope of this

481 work⁵⁵. Nonetheless, our study provides estimates of the effect of relaxing NPIs over

482 the course of the epidemic.

483

484 In conclusion, vaccination alone could substantially reduce COVID-19 burden, but in

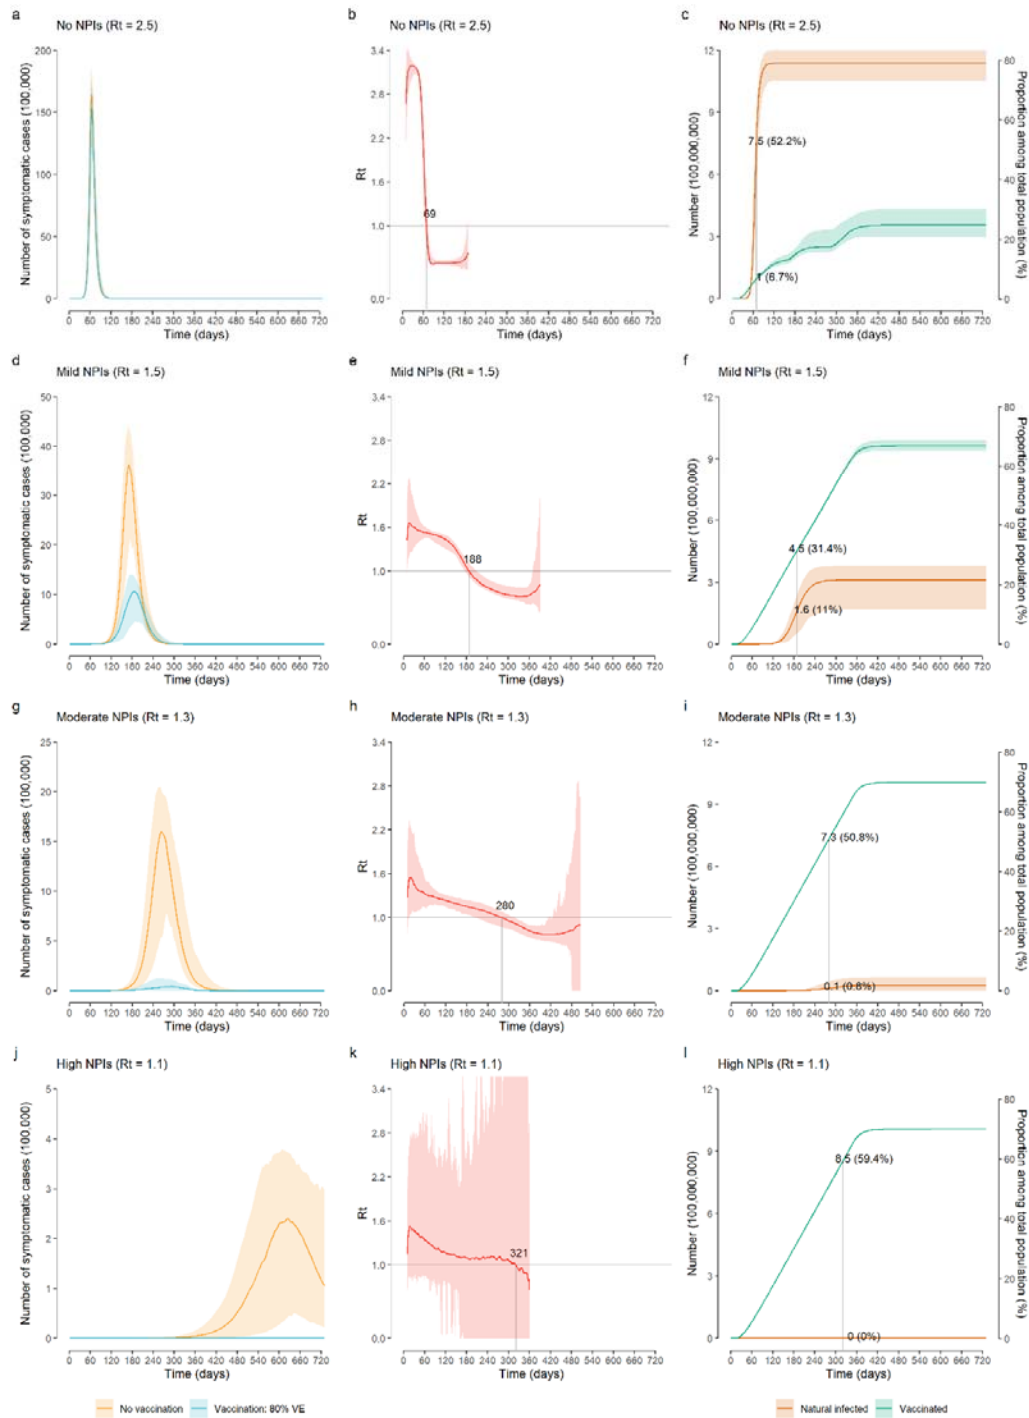

485 the foreseeable future may not be enough to prevent local outbreaks to escalate to

486 major widespread epidemics due to limitation in the vaccine production and supply

487 (particularly at the initial stage of the vaccination), as well as the capacity of

488 vaccination system. This is especially relevant in contexts where most of the
489 population is still susceptible to SARS-CoV-2 infection, as it is the case in most of
490 China. Maintaining NPIs (such as social distancing, testing, case isolation and contact
491 tracing, wearing masks, and limitation on large gatherings) throughout 2021 is
492 necessary to prevent the resurgence of COVID-19 epidemics until a sufficiently high
493 level of immunity is reached, which depends on the transmissibility of the variants
494 circulating at that time.

495 **Figure legend**

496

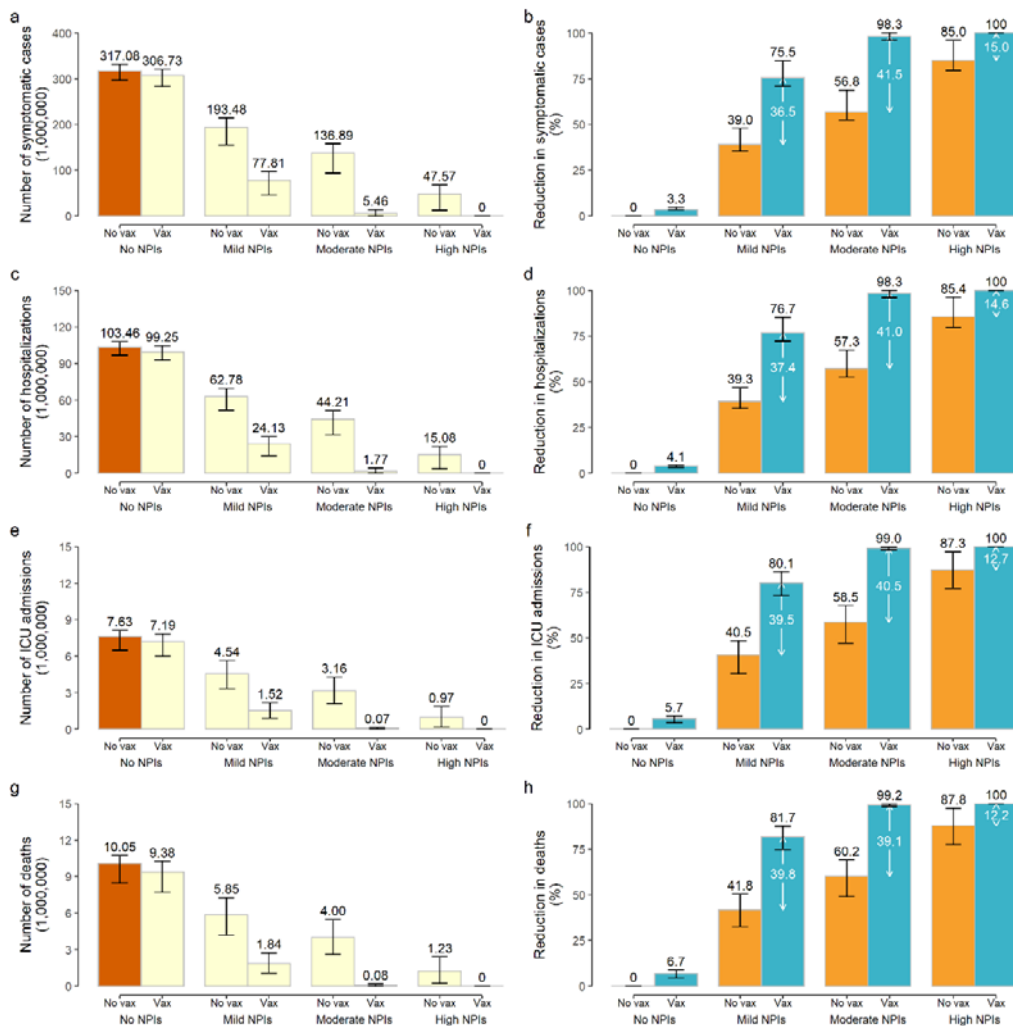

497 **Figure 1. Time series of symptomatic cases, effective reproductive number R_t ,**

498 **and population infected and vaccinated.**

499 a) Number of symptomatic cases over time as estimated in the no-NPIs scenario

500 (initial $R_t=2.5$) in the absence/presence of vaccination. b) Net reproduction number R_t
501 over time, as estimated using a Bayesian framework (Supplementary File 6) from the
502 time series of symptomatic cases in the no-NPIs scenario in the presence of
503 vaccination. The horizontal line indicates the epidemic threshold $R_t=1$ and the vertical
504 line indicates where R_t cross this threshold. Note that for the first few generations of
505 cases, R_t shows an increasing pattern linked to the highly stochastic nature of
506 epidemics in their initial phase when epidemics with initially larger R_t are more likely
507 to survive⁵⁶. c) Absolute numbers and proportion of the Chinese population infected
508 and vaccinated over time in the no-NPIs scenario in the presence of vaccination. The
509 population size of China in 2020 is 1,439,324,000⁵⁷. d)-f): as a-c but for the mild
510 NPIs scenario (initial $R_t=1.5$). g)-i): as a-c but for the moderate NPIs scenario (initial
511 $R_t=1.3$); j)-l): As a-c but for the high NPIs scenario (initial $R_t=1.1$). Line denotes
512 median, and shadow denotes quantiles 0.025 and 0.975.

513

514

515 **Figure 2. Burden of COVID-19 in the main analysis.**

516 a) Cumulative number of symptomatic cases as estimated under the different

517 scenarios in the absence/presence of vaccination over the simulated 2-year period. No

518 vaccination + no NPIs with $R_t=2.5$ at the beginning of the outbreak is called *reference*

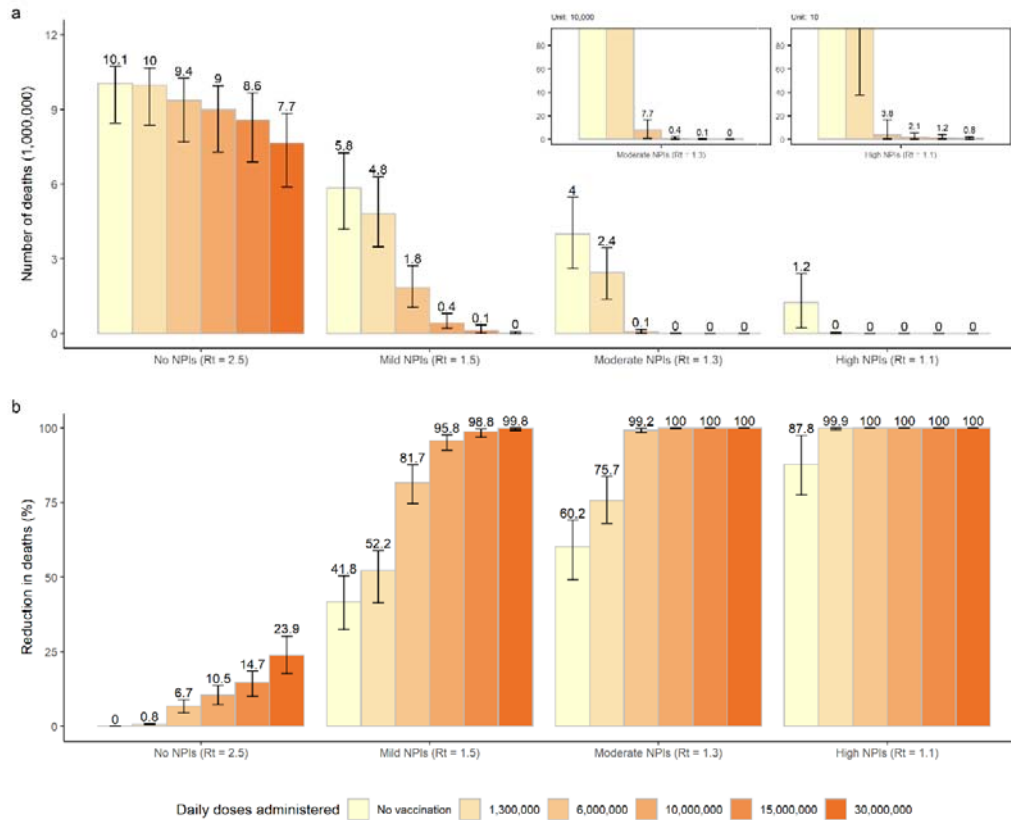

519 *scenario*, described using dark brown bars. Light yellow bars indicate scenarios

520 including vaccination and/or different levels of NPIs. b) Reduction in the cumulative

521 number of symptomatic cases with respect to the *reference scenario*. Orange bars and

522 black values indicate the contribution of NPIs, blue bars and black values indicate the

523 overall contribution of vaccination and NPIs, while the white values indicate net
524 contribution of vaccination; c)-d) As a-b but for hospitalized cases; e)-f) As a-b but for
525 cases admitted to ICU; g)-h) As a-b but for deaths. Number denotes median, and error
526 bars denote quantiles 0.025 and 0.975.

527

528 **Figure 3. Impact of daily vaccine administration capacity on COVID-19 deaths.**

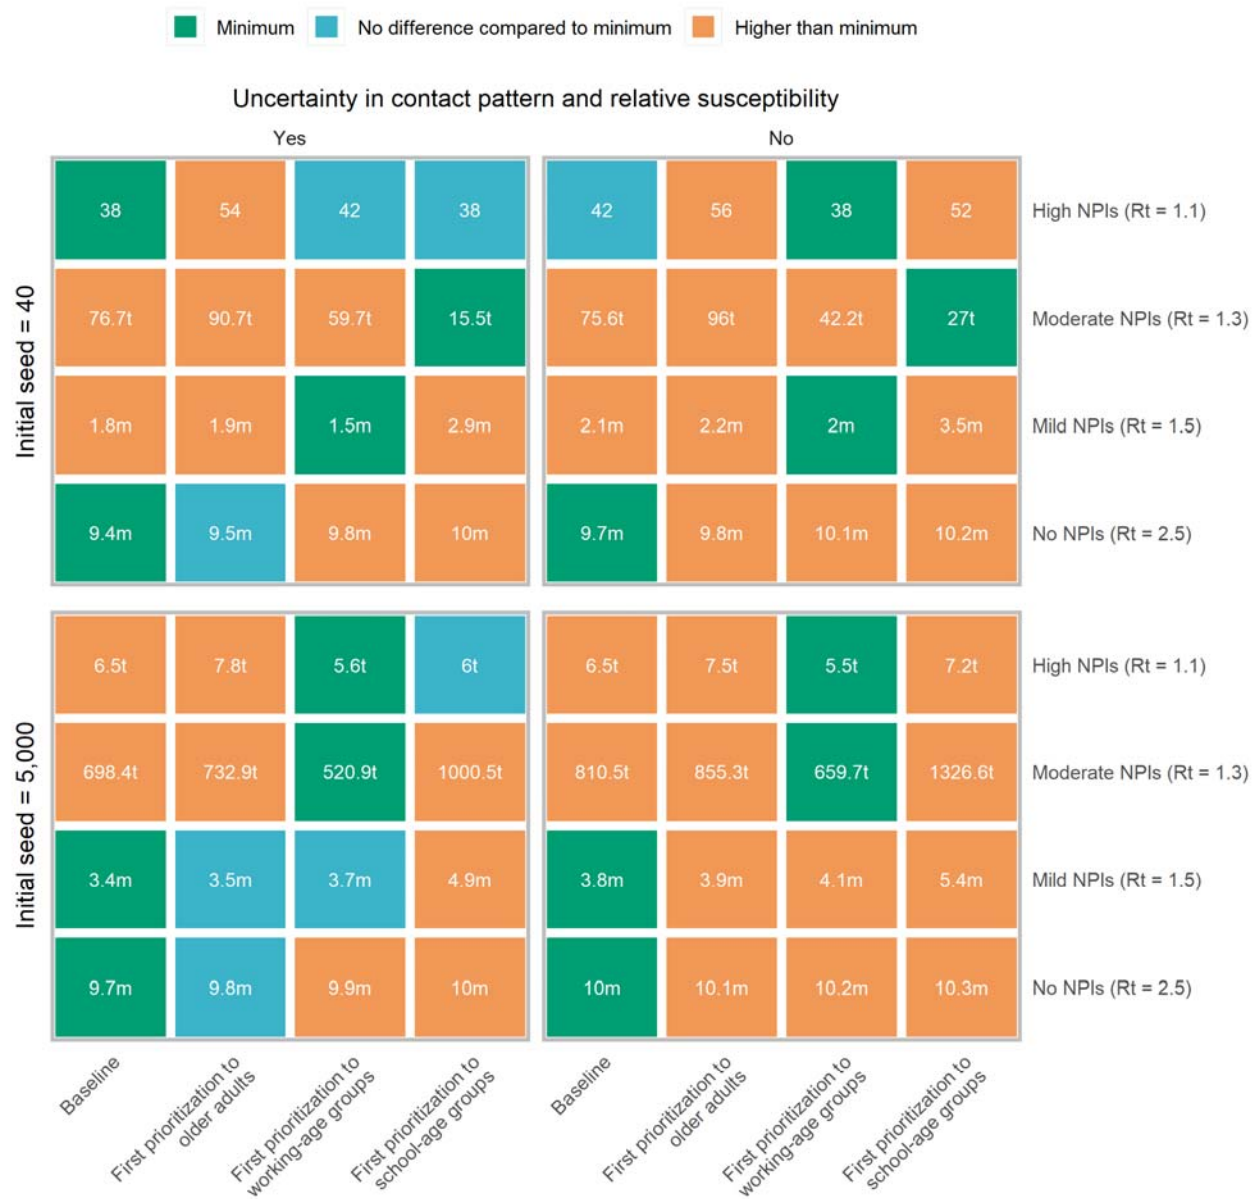

529 a) Cumulative number of COVID-19 deaths (millions) as estimated in the different

530 scenarios under progressively increasing values of the daily vaccination capacity; b)

531 Proportion of deaths averted compared to the *reference scenario*, i.e., *no vaccination*

532 + *no NPIs* with $R_t=2.5$ at the beginning of the outbreak. Number denotes median, and

533 error bars denote quantiles 0.025 and 0.975.

535 **Figure 4. Best prioritization strategy to achieve the minimal COVID-19 deaths.**

536 Initial cases denote breakthrough COVID-19 cases, which initiates the epidemic. We

537 consider the impact of uncertainty (i.e., “Yes” in the figure, which means 200

538 stochastic model realizations are performed in order to account for the ranges) in

539 contact patterns and relative susceptibility on prioritization, and use their mean values

540 as well (i.e., No). Baseline denotes first prioritizing older adults and individuals with

541 underlying conditions. Number in the box denotes the death toll (median), with t
542 representing thousand and m representing million. Minimum denotes the lowest
543 deaths in each scenario on the basis of median value. We compare other strategies to
544 that with minimum deaths using rank sum test. E.g., in the context of initial
545 cases=5,000, $R_t=1.5$ and using mean values of contact patterns and relative
546 susceptibility, the baseline is the optimal strategy to minimize deaths.

547 **Methods**

548 **SARS-CoV-2 transmission and vaccination models**

549 We developed a model of SARS-CoV-2 transmission and vaccination, based on an
550 age-structured stochastic susceptible-infectious-removed (SIR) scheme, accounting
551 for heterogeneous mixing patterns by age as estimated in Shanghai¹³. The Chinese
552 population was distributed in 18 age groups (17 5-year age groups from 0 to 84 years
553 and one age group for individuals aged 85 years or older)⁵⁷. Each age group was
554 further split into two subgroups: individuals with or without underlying conditions,
555 where the former was considered to be associated with an increased risk of severe
556 outcome of COVID-19¹⁴.

557

558 In the main analysis, susceptibility to SARS-CoV-2 infection was assumed to be
559 heterogeneous across ages. Children under 15 years of age were considered less
560 susceptible to infection compared to adults aged 15 to 65 years, while the older adults
561 more susceptible^{33,34}. Homogeneous susceptibility across age groups was explored in
562 sensitivity analysis (*SA19*). Asymptomatic and symptomatic individuals were
563 assumed to be equally infectious^{33,34}, and infectiousness was also assumed to be the
564 same across age groups^{33,34}.

565

566 Vaccine is administered with a two-dose schedule. In the baseline model, we assumed
567 that: i) vaccination reduces susceptibility to SARS-CoV-2 infection; ii) only
568 susceptible individuals are eligible for vaccination, i.e., we excluded all individuals

569 that have experienced SARS-CoV-2 infection; iii) duration of vaccine-induced

570 protection lasts longer than the time horizon considered (2 years).

571 The baseline model is schematically represented in Supplementary Fig.1 and it is

572 described by differential systems presented in Supplementary File 1-2.

573

574 **Model initialization**

575 In China, the first pandemic wave of COVID-19 was controlled by intense NPIs ^{58,59}.

576 Almost the entire population of mainland China is still susceptible to COVID-19 ³. As

577 such, the model is initialized with a fully susceptible population.

578

579 China has been facing mounting pressure of imported COVID-19 cases. Containment

580 of COVID-19 has been possible only through a combination of measures such as

581 complete- or partial-lockdown, citywide mass-screening using

582 reverse-transcriptase–polymerase-chain-reaction (RT-PCR) testing, tracing of contacts

583 and contacts of contacts of COVID-19 cases, which were promptly applied wherever

584 COVID-19 transmission has popped up in mainland China ⁶⁰. Despite all the efforts,

585 containment of COVID-19 appears a whack-a-mole game and sporadic outbreaks

586 inevitably occur. Simulations are thus initialized with 40 cases, roughly corresponding

587 to the number of cases with symptoms onset in Beijing before the detection of a local

588 outbreak in June 11, 2020 ⁶¹.

589

590 **Vaccination scenarios**

591 To explore the impact of vaccination, we ran a set of simulations in which neither
592 NPIs nor vaccination are implemented as a *reference scenario* (*no vax + no NPIs*, i.e.,
593 effective reproductive number $R_t=2.5$ at the beginning of simulations^{17,28,58}), and
594 compared it with a scenario in which vaccination only is implemented (*vax + no*
595 *NPIs*). Further, we considered different sets of simulations in which NPIs are used to
596 bring R_t respectively down to 1.5 (mild NPIs), 1.3 (moderate NPIs), and 1.1 (high
597 NPIs), with (*vax + mild/moderate/high NPIs*) or without vaccination program (*no vax*
598 *+ mild/moderate/high NPIs*). In the main analysis vaccination is assumed to begin 15
599 days after the epidemic start. Alternative scenarios about the seeding of the epidemic
600 were explored as sensitivity analyses. In particular, we considered the epidemic to
601 start when 10% (*SA1*), 20% (*SA2*), and 30% (*SA3*) of the Chinese population has
602 already been vaccinated.

603

604 The model is run considering daily time steps. Gradual delivery of vaccine doses is
605 implemented by vaccinating a fixed number of individuals each day. Although
606 manufacturers state that a total of 3.9 billion doses of vaccines could be available by
607 the end of 2021²²⁻²⁶, scale-up and delivery will take months. On the basis of the 2009
608 H1N1 influenza pandemic vaccination program implemented in mainland China⁶², in
609 the main analysis we assumed 6 million doses of COVID-19 vaccines could be
610 administered each day (4 doses per 1,000 individuals) until uptake reaches 70% for all
611 groups¹⁴. Different values of the daily vaccine administration capacity, i.e., 1.3
612 (*SA20*), 10 (*SA21*), 15 (*SA22*), 30 (*SA23*) million dose per day, are explored in

613 separate sensitivity analyses. Sensitivity analyses were also performed on the
614 vaccination coverage which is assumed either to be homogenous (*SA4* and *SA5*)¹⁴ or
615 heterogeneous by age (*SA6*, *SA7*, and *SA8*).

616

617 In the main analysis, vaccination is administered to susceptible individuals only. This
618 represents an ideal scenario where we assume that all infected individuals can be
619 identified (e.g., either via RT-PCR while infected or via serological assays later on)
620 and that SARS-CoV-2 infection confers a long-lasting immunity. Since infection
621 ascertainment could be challenging and pose additional strain to the health system, we
622 also consider two sensitivity analyses in which only detected symptomatic cases are
623 excluded from vaccination (*SA14-SA15*).

624

625 In the context of fast RT-PCR-based mass screening if there is an outbreak,
626 under-ascertainment of symptomatic cases could be only related with the sensitivity
627 of RT-PCR tests. The sensitivity is quite high (98%) if the interval between symptom
628 onset and RT-PCR test is within 7 days, and the sensitivity decreases to 68% if the
629 time interval is 8-14 days⁶³. The mean time interval from symptom onset to the date
630 of collection of the sample for PCR testing was estimated to be 4.7 days in Hunan³³.
631 Accordingly, we considered as ascertainment probabilities of symptomatic cases 70%
632 (*SA14*) and 90% (*SA15*).

633

634 ***Vaccination schedule and efficacy***

635 There are six COVID-19 vaccines developed by China in phase 3 clinical trials,
636 including five vaccines administered with a two-dose schedule with an interval of 14,
637 21, or 28 days and one single-dose recombinant adenovirus type-5-vectored vaccine.
638 For simplicity, in the main analysis, we modeled the administration of an inactivated
639 vaccine developed by the Beijing Institute of Biological Products,⁶⁴ which entail a
640 two-dose schedule across all age groups with an interval of 21 days. In separate
641 sensitivity analyses, we explored an interval of 14 days and 28 days (*SA16-SA17*).
642
643 China approved its first local COVID-19 vaccine (developed by Sinopharm) for
644 general public use on December 31, 2020, with an estimated vaccine efficacy (VE) of
645 79.3%.²¹ In the main analysis, we used a VE of 80% against infection in individuals
646 aged 20-59 years. In the developed model, vaccination confers a partial protection, i.e.,
647 vaccinated individuals are 80% less likely to develop infection upon an infectious
648 contact. Sensitivity analyses using a VE of 60% (*SA9*) and 90% (*SA10*) were
649 separately performed. The alternative values of VE were selected on the basis of
650 published upper efficacy of vaccines of 94-95% and in such a way to cover a
651 plausible efficacy range of forthcoming vaccines⁶⁵⁻⁶⁷.
652
653 Phase 2 clinical trials demonstrated that vaccine immunogenicity was lower among
654 older individuals than in younger adults⁶⁴. And for other inactivated vaccines like
655 influenza vaccine, a lower VE is observed in children compared to young adults⁶⁸.
656 Accordingly, we assumed an age-dependent VE. In particular, given a baseline

657 efficacy VE among individuals aged 20-59 years (80% in the main analysis), we
658 assumed a 50% lower VE in individuals <20 and ≥ 60 years of age (namely 40%). A
659 scenario without age-specific variations in VE was explored as sensitivity analysis
660 (*SA24*).

661

662 Individuals vaccinated with the first dose could still develop infections without any
663 immune protection, while the second dose vaccination could produce the expected
664 vaccine efficacy after an average of 14 days. In the main analysis we assume both
665 natural infection-induced and vaccine-induced immunity to SARS-CoV-2 infection
666 does not wane within the considered time horizon (2 years). In additional sensitivity
667 analyses, we considered an average duration of vaccine-induced protection of 6
668 months (*SA12*) and 1 year (*SA25*). We also consider a sensitivity analysis assuming
669 that vaccination is effective in preventing symptomatic illness, but not infection
670 (*SA11*), and another one assuming an all-or-nothing vaccine, i.e., the vaccine confers
671 full protection to VE percent of vaccinated individuals (*SA18*).

672

673 ***Priority order of vaccination***

674 The doses available to be distributed daily (6 million in the main analysis) are
675 assigned by considering the following order of priority¹⁴. In the main analysis,
676 healthcare workers are considered as the top priority (Tier 1 of the vaccination
677 strategy); law enforcement and security workers, personnel in nursing home and
678 social welfare institutes, community workers, workers in energy, food and

679 transportation sectors are included in Tier 2; adults ≥ 60 years of age with underlying
680 conditions, and adults ≥ 80 years of age without underlying conditions, who are at the
681 highest risk of severe/fatal COVID-19, are considered in Tier 3; individuals aged < 60
682 years with pre-existing medical conditions and pregnant women are included in Tier 4;
683 individuals aged 20-59 years without underlying conditions are included in Tier 5;
684 school-age children and younger children aged ≤ 5 years without underlying
685 conditions are recommended for vaccination in Tier 6 (Supplementary File 4).

686

687 Different priority orders are explored as sensitivity analyses. Healthcare workers and
688 the other essential workers listed above are fixed in Tier 1 and Tier 2 of vaccination,
689 while the remaining population is vaccinated as described in Supplementary Table 2
690 by considering different orders of prioritization only based on age and disregarding
691 the presence of underlying conditions (**SA26**: first prioritization to old adults; **SA27**:
692 first prioritization to working-age groups; **SA28**: first prioritization to school-age
693 groups). We explore the impact of 5,000 initial cases on the prioritization strategy
694 (**SA29**). To understand the impact in terms of number of infections by age, we
695 compare the prioritization strategy when we account for the uncertainty in the contact
696 matrix and in the susceptibility to infection by age, or not (in this context, median
697 values of contact numbers and relative susceptibility are used).

698

699 **COVID-19 burden model**

700 The main output of above transmission model is the age-specific number of new

701 infections per day in the subpopulation with or without underlying conditions. On top
702 of that, we developed a model of COVID-19 disease burden to estimate the number of
703 symptomatic cases, hospitalization, ICU admissions, and deaths in different scenarios
704 in the presence/absence of vaccination.

705

706 We computed the age-specific number of symptomatic infections in individuals with
707 and without underlying conditions on a daily-basis, by applying an age-specific
708 probability of respiratory symptoms, which is 18.1%, 22.4%, 30.5%, 35.5%, and 64.6%
709 separately for 0-19, 20-39, 40-59, 60-79, and 80+ years of age, as estimated from
710 contact tracing data in Lombardy²⁰. We assume that individuals with and without
711 underlying conditions have the same age-specific probability of developing
712 symptoms.

713

714 The daily age-specific number of hospital admissions in the two subpopulations was
715 computed by applying the age-specific proportion of laboratory-confirmed
716 symptomatic cases requiring hospitalizations (Supplementary File 5), delayed by an
717 average time of 3.8 days between symptom onset and hospitalization¹⁷.

718 The daily age-specific number of patients admitted to ICU in the two subpopulations
719 was computed by applying to hospitalized cases an age-specific probability of being
720 admitted to ICU¹⁹, and distinguishing patients requiring intensive care in survivors
721 and non-survivors. Survivors are admitted to ICU after an average time of 7 days
722 from hospitalization. Non-survivors are admitted to ICU after an average time of 8

723 days after hospitalization ¹⁶.

724

725 The daily age-specific number of deaths in the two subpopulations was computed by
726 applying the age-specific fatality ratio among symptomatic cases (Supplementary File
727 5), delayed by an average time of 13.9 days between symptom onset and death ¹⁸.

728

729 **Data analysis**

730 For each scenario, 200 stochastic model realizations were performed. The outcome of
731 these simulations determined the distributions of the number of symptomatic
732 infections, hospitalizations, ICU admissions, and deaths. 95% confidence intervals
733 were defined as quantiles 0.025 and 0.975 of the estimated distributions. We used a
734 Bayesian approach to estimate R_t from the time series of symptomatic cases by date
735 of symptom onset and the distribution of the serial interval ¹⁷. The methods were
736 described in Supplementary File 6 in details.

737

738 **Ethics approval** All these data were in the public domain. Ethical review for the
739 re-use of these secondary data is not required.

740

741 **Reporting summary**

742 Further information on research design is available in the Nature Research Reporting
743 Summary linked to this paper.

915 **End notes**

916 **Acknowledgments**

917 The study was supported by grants from the National Science Fund for Distinguished
918 Young Scholars (No. 81525023), Key Emergency Project of Shanghai Science and
919 Technology Committee (No 20411950100), European Union Grant 874850 MOOD
920 (MOOD 000).

921

922 **Author Contributions**

923 H.Y. conceived the study. H.Y., S.M., and M.A. designed and supervised the study.
924 J.Y., J. Z., J.C., W.W., Q.W., W.Z., Z.Z, K.D., and G.Z. participated in data collection.
925 V.M., G.G., P.P., and F.T. developed the model. V.M., J.Y., and X.D. analyzed the
926 model outputs and prepared the tables and figures. J.Y. prepared the first draft of the
927 manuscript. H.Y., V.M., and M.A. commented on the data and its interpretation,
928 revised the content critically. All authors contributed to review and revision and
929 approved the final manuscript as submitted and agree to be accountable for all aspects
930 of the work.

931

932 **Declaration of interests**

933 H.Y. has received research funding from Sanofi Pasteur, GlaxoSmithKline, Yichang
934 HEC Changjiang Pharmaceutical Company, and Shanghai Roche Pharmaceutical
935 Company. M.A. has received research funding from Seqirus. None of those research
936 funding is related to COVID-19. All other authors report no competing interests.

937
