1. Data
2. Estimating overdispersion parameter ( $K$ )
3. Supplementary analysis for the risk of superspreading events
4. Appendix Tables
5. Appendix Figures

## 1. Data

We acquired data on COVID-19 cases, confirmed by real-time reverse transcriptase-polymerase chain reaction (RT-PCR) and reported by Korean local public health authorities. The COVID-19 cases included were between 11 July 2021 and 1 September 2021, when the Delta variant accounted for more than 40% of local cases reported from the Korea Disease Control and Prevention Agency (1, 2). The data included contact tracing with other reported cases of COVID-19 and demographic characteristics of the patients, including age, sex, and date of symptom onset (<https://github.com/gentryu/COVID-19delta>).

## 2. Estimating overdispersion parameter ( $K$ )

Statistical methods utilized in this study followed our previous COVID-19 study for superspreading events (SSE) (3). The probability function of negative binomial distribution that an index case ( $i$ ) generate the number of secondary case ( $y_i$ ) is given by

$$Pr(Y = y_i) = \frac{\Gamma(k + y_i)}{y_i! \Gamma(k)} \left( \frac{k}{k + R} \right)^k \left( \frac{R}{k + R} \right)^{y_i},$$

where  $k$  and  $R$  are the estimated dispersion parameter and reproduction number, respectively, of index case  $i$ .

To understand the individual variation of infectiousness of COVID-19 during study period, observed offspring distributions were fitted to the negative binomial distribution.

Given the estimated reproduction number and dispersion parameter, the proportion of infected persons responsible for 80% of secondary cases,  $P_{80\%}$ , was calculated using equations from the previous studies (3-6). The proportion  $P_{80\%}$  is given by

$$1 - P_{80\%} = \int_0^X NB\left(\lfloor x \rfloor; k, \frac{k}{R+k}\right) dx,$$

where  $X$  satisfies

$$1 - 0.80 = \frac{1}{R} \int_0^X \lfloor x \rfloor NB\left(\lfloor x \rfloor; k, \frac{k}{R+k}\right) dx.$$

Furthermore, with the threshold for SSE as 6 secondary cases defined in the previous study (4), the proportion of SSE was estimated for each period with the equations below.

$$\int_6^{\infty} NB\left(\lfloor x \rfloor; k, \frac{k}{R+k}\right) dx = 1 - \int_0^5 NB\left(\lfloor x \rfloor; k, \frac{k}{R+k}\right) dx.$$

Finally, using the branching process, the expected probability that one index case of SARS-CoV-2 infection results in a cluster of size  $s$  were estimated with the equations from previous studies (3, 5, 6) given by

$$r_s = \frac{\Gamma(ks + s - 1)}{\Gamma(ks)\Gamma(s + 1)} \left(\frac{R}{k}\right)^{s-1} \left(\frac{k}{k+R}\right)^{ks+s-1},$$

where the probability of cluster of size  $s$  or greater could be estimated as follows:

$$p_s = 1 - \sum_{l=1}^{s-1} r_l.$$

With the condition that  $N$  seed cases were introduced into the totally susceptible populations, the estimated probability that at least one cluster of size  $s$  or greater occurs is

$$P_{N,s} = 1 - (1 - p_s)^N.$$

Note that  $P_{N,s}$  is equal to  $p_s$  when exactly one index case was introduced ( $N = 1$ ).

We used a Bayesian Markov Chain Monte Carlo simulation using *rstan* package. Four chains of 40,000 iterations were obtained with 5,000 burn-in. The prior distributions of dispersion parameter and reproduction number were uniform with lower and upper bounds set at 0 and 100.

Convergence was checked visually using a trace plot and the Gelman-Rubin-Brooks diagnostic (7). The posterior distribution of the estimates was demonstrated with the median and 95% credible intervals.

### **3. Supplementary analysis for the risk of superspreading events**

We estimated the expected proportion of cases responsible for 80% of the total secondary cases to identify the risk of SSE. Furthermore, the probability of SSEs using estimated  $R_0$  and  $k$  and the probability that one index case results in a cluster of 10 cases or more were estimated.

Based on the source of infection, we estimate the offspring distribution using infectee-infecter pairs. We fitted observed distribution of the secondary case into a negative binomial offspring distribution (Appendix Figure 1). The expected proportion of cases responsible for 80% of secondary cases was 22.99% (95% CrI: 21.97%, 24.03%) and 24.93% (95% CrI: 23.90.71%, 25.97%) for Period 1 and 2, respectively. The probability of SSE and the probability that one index case results in a cluster of 10 cases or more were 0.33% (95% CrI: 0.25%, 0.45%) and 4.71% (95% CrI: 3.92%, 5.60%) for Period-1, and 0.17% (95% CrI: 0.12%, 0.24%) and 4.254% (95% CrI: 3.51%, 5.11%) for Period-2.
