46 Abstract 47 48 Objective: To characterize the evolution of healthcare workers' mental health status over the 49 1-year period following the initial COVID-19 pandemic outbreak and to examine baseline 50 characteristics associated with resolution or persistence of mental health problems over time. 51 Methods: We conducted an 8-month follow-up cohort study. Eligible participants were 52 healthcare workers working in Spain. Baseline data were collected during the initial pandemic 53 outbreak. Survey-based self-reported measures included COVID-19-related exposures, 54 sociodemographic characteristics, and three mental health outcomes (psychological distress, 55 depression symptoms, and posttraumatic stress disorder symptoms). We examined three longitudinal trajectories in mental health outcomes between baseline and follow-up 56 57 assessments (namely asymptomatic/stable, recovering, and persistently 58 symptomatic/worsening). 59 Results: We recruited 1,807 participants. Between baseline and follow-up assessments, the 60 proportion of respondents screening positive for psychological distress and probable 61 depression decreased, respectively, from 74% to 56% and from 28% to 21%. Two-thirds 62 remained asymptomatic/stable in terms of depression symptoms and 56% remained 63 symptomatic or worsened over time in terms of psychological distress. 64 Conclusions: Poor mental health outcomes among healthcare workers persisted over time. 65 Occupational programs and mental health strategies should be put in place. 66 67 Keywords: healthcare workers; anxiety; depression; mental health; COVID-19; prospective 68 cohort

The COVID-19 pandemic outbreak has had substantial mental health impact on healthcare workers (HCWs), largely due to increases in healthcare capacity requirements driving job redeployments and extended working hours in combination with very high risk of contagion and death. Estimates from cross-sectional studies conducted during the initial pandemic outbreak suggest that between 25 and 50% of HCWs may have experienced clinically significant symptoms of anxiety or depression (1-7) and posttraumatic stress (1,3,7).

The extent to which the deleterious mental health effects brought about by the initial pandemic outbreak may have subsequently led to negative mid- and long-term mental health outcomes among HCWs. However, these remain largely unexplored, despite important public health and clinical implications (8). Initially, it seemed plausible that a large proportion of the burden of mental health symptoms initially reported by HCWs would eventually resolve, either following cessation of exposure to the acute stressor or after adequate targeted interventions (e.g., self-care and low-intensity psychotherapeutic interventions). Nevertheless, because the initial pandemic outbreak has been followed by a series of ongoing subsequent pandemic waves that continue to strain health systems across the globe, there is a generalized concern that a substantial proportion of HCWs may be experiencing persistent mental health problems. According to the World Health Organization, reducing the long-term mental health impact of the pandemic on HCWs is considered a major clinical and public health priority. Estimating the mid- and long-term mental health impact of the COVID-19 pandemic among HCWs is paramount for occupational and mental healthcare planning purposes. In addition, identifying risk and protective factors for persistence of clinically significant mental health burden can help improve implementation of evidence-based detection and treatment strategies. Notwithstanding, evidence examining prevalence and predictors of persistence of mental health symptoms among HCWs from longitudinal cohort studies is scarce (9–12).

Here we used a large sample of HCWs during the one-year period following the initial pandemic outbreak in one of the largest COVID-19 hotspots globally to (1) characterize the evolution of HCWs' mental health status over the year following the initial pandemic outbreak, and (2) examine baseline sociodemographic and clinical characteristics associated with resolution or persistence of mental health problems over time.

Methods

Study design, setting, and participants

We conducted a prospective cohort study in Spain as part of an ongoing longitudinal multinational study (https://mentalnet.cl/en/home/). We collected data through an online survey at two timepoints. Baseline assessments were performed from April 24th to June 22nd, 2020 (during the initial pandemic outbreak in Spain). Follow-up assessments took place between January 26th and March 8th, 2021, which in Spain coincided with the third pandemic wave and with administration of COVID-19 vaccines for the majority of HCWs.

The study participants were HCWs aged 18 years and older, recruited from different outpatient and inpatient healthcare facilities, with clinical and non-clinical duties, and not necessarily involved in the direct care of COVID-19 patients. The sampling strategy was as follows. During both the baseline and follow-up assessments, key stakeholders (e.g., hospital managers, heads of worker unions) from healthcare facilities located in the study regions (Andalusia, Madrid, and Murcia) forwarded the survey link to all HCWs. Participants were also asked to forward the survey to peers in order to enhance response rates. In addition, during the follow-up period, we sent email or telephone survey reminders to baseline participants. Baseline assessments are described elsewhere (13). In this manuscript, we focus on participants who were assessed at follow-up only and on participants assessed at follow-up who had been assessed also during baseline procedures. We hereafter refer to these two subgroups as partial and full respondents, respectively.

COVID-19 impact on healthcare workers

All procedures contributing to this work comply with the Helsinki Declaration of 1975, as revised in 2013. It received approval from the Hospital La Paz Ethics Committee (Madrid, Spain) and was ratified by the local ethics committees from the participating sites.

Variables

Baseline assessments included the following COVID-19-related exposures: direct involvement in the care of COVID-19 patients (yes, no), adequate access to personal protective equipment, fear of getting infected, and fear of infecting loved ones (all rated from 0 to 3).

Both baseline and follow-up assessments included the following sociodemographic and mental health outcome variables.

Sociodemographic variables: Age in years, gender (male, female), educational level (primary, secondary, or university studies), and type of job. We collapsed job types into the following categories: physicians, nurses, health technicians (e.g., nurse, X-ray, and laboratory technicians), ancillary workers (e.g., security staff, drivers, administrative staff, and cleaning staff), other HCWs (e.g., clinical psychologists, physiotherapists, and biologists), and residential support workers (e.g., from mental health assisted living facilities, nursing homes).

Mental health outcomes: Psychological stress, as measured by the Spanish version of the 12-item General Health Questionnaire (14); and probable depression symptoms, as measured by the Spanish version of the 9-item Patient Health Questionnaire (PHQ-9) (15). We used widely accepted thresholds for detecting people screening positive for psychological distress (GHQ-12 higher than 2 points) (16,17) and for depression (PHQ-9 score higher than 9 points) (18). In addition, follow-up assessments also included posttraumatic stress disorder (PTSD) symptoms, as measured by the Spanish 5-item version of the Primary Care PTSD Screen for DSM-5 (PC-PTSD-5), where a total score higher than 2 points suggests probable PTSD (19).

Cronbach's alphas were 0.87 (95 percent CI: 0.86, 0.88) for the GHQ-12 total score; 0.89 (95 percent CI: 0.88, 0.89) for the PHQ-9 total score; and 0.70 (95 percent CI: 0.68, 0.72) for the PC-PTSD-5. To control for region-level cumulative COVID-19 incidence, we calculated region-specific 14-day cumulative incidence rates 2, 4, 6, and 8 weeks after the start of the follow-up period and, as rates were stable over time, classified regions as "high" or "low" incidence depending on whether average cumulative incidence over time points fell under or over 750 cases per 100,000 based on visual examination of region-specific cumulative incidence rates (**Supplementary Figures 1 and 2**).

Statistical analyses

First, we removed baseline respondents who provided informed consent but did not go on to initiate the survey (n = 95). We reported categorical variables as frequencies and valid percentages, and continuous and interval variables as either mean (standard deviation [SD]), or median (interquartile range [IQR]). Descriptive statistics were calculated separately for full and partial respondents.

Then, we used multivariable mixed-effects linear and binary logistic regression models to explore the associations between baseline variables, including sociodemographic characteristics (i.e., age, gender, and educational level) and COVID-19-related exposures (i.e., direct involvement in the care of COVID-19 patients, adequate access to personal protective equipment, fear of getting infected, and fear of infecting loved ones), and follow-up mental health outcomes (i.e., psychological distress, depression symptoms, and PTSD symptoms), defined both as continuous questionnaire scores and dichotomous variables. We conducted sensitivity analyses adjusted by baseline assessments of the follow-up outcome under

COVID-19 impact on healthcare workers

consideration. We used baseline GHQ-12 score for the model where follow-up PTSD was the outcome, as we did not have estimates for the latter in the baseline assessment. The GHQ-12 score, an instrument that has good convergent validity with the PC-PTSD-5 and accurately detects PTSD in primary care settings (20).

Next, we used baseline and follow-up mental health outcomes to categorize respondents into three mental health trajectories, separately for psychological distress and for depression, according to whether they screened negative at baseline and follow-up (*asymptomatic stable*), positive at baseline and negative at follow-up (*recovering*), or positive or negative at baseline and positive at follow-up (*persistently symptomatic/worsening*). For instance, if a respondent screened negative in the GHQ-12 and positive in the PHQ-9 at baseline, and subsequently screened positive in the GHQ-12 and negative in the PHQ-9 at follow-up, they would belong to the *persistently symptomatic/worsening* trajectory for psychological distress and to the *recovering* trajectory for depression. We selected these trajectory categories because of their potential implications for clinical practice.

Finally, we explored the association between baseline exposures and longitudinal psychological distress and depression trajectory membership, using multinomial regression models where *asymptomatic stable* was considered the reference category. Baseline exposures were age group, gender, educational level, direct involvement in the care of COVID-19 patients, adequate access to personal protective equipment (adequate vs. inadequate), fear of getting infected (not or slightly afraid vs. considerably or extremely afraid), and fear of infecting loved ones (not or slightly afraid vs. considerably or extremely afraid).

All models were adjusted by covariates to control for confounding based on prior causal knowledge, using direct acyclic graphs and backdoor criteria (21). Region-level cumulative incidence of COVID-19 was entered in all models as a fixed factor. We did not impute missing data. All analyses were performed using packages *dplyr*, *gtsummary*, *flextable*, *ggplot2*, *psych*, *multinom* of R Studio for Mac (Version 1.2.5042).

Results

Of 1,807 respondents who answered the survey at follow-up (between January 26th-March 25th, 2021), 1,471 (81.4%) completed the entire survey, with a median response time of 21 minutes. Most missing data pertained to the last section of the questionnaire, suggesting that data missingness was driven by survey extension and hence largely random. Respondents who did and did not complete the survey were comparable in terms of mean age (42 vs. 40 years, respectively) and gender distribution (78% vs. 74% female, respectively). Response rates were estimated across facilities and job types and ranged from 2.7% to 100% (see **Supplementary Tables 1 and 2**).

There were 1,058 (59%) partial respondents (i.e., assessed only at follow-up) and 749 (41%) full respondents (i.e., assessed at both baseline and follow-up). Of note, this indicates that we retained 32% of the 2,370 original baseline respondents for follow-up assessments (see **Figure 1**). Sociodemographic characteristics of follow-up respondents, overall and divided into full and partial respondents, are shown in **Table 1**. In short, full respondents were more frequently female and more likely to have completed university studies than partial respondents. Also, while most full respondents were physicians or nurses, partial respondents included a larger proportion of residential support workers.

Overall, 56% of follow-up respondents screened positive for psychological distress, 21% for probable depression, and 51% for PTSD. Psychological distress, probable depression, and PTSD were more frequent among younger and female respondents, and respondents with higher educational levels – with substantial heterogeneity across specific job types (see **Supplementary Table 3**). Notably, follow-up mental health outcomes were comparable

COVID-19 impact on healthcare workers

between full and partial respondents, with similar mean (SD) GHQ-12 score (3.9 [3.5] vs. 3.8 [3.4], respectively), mean (SD) PHQ-9 score (6.3 [5.1] vs. 6.4 [3.4], respectively), proportion of respondents screening positive for psychological distress (56% vs. 55%, respectively), and proportion of respondents screening positive for probable depression (21% vs. 21%, respectively).

Comparisons between baseline and follow-up mental health outcomes among full respondents are shown in **Table 2**. The proportion of respondents screening positive for psychological distress and probable depression decreased, respectively, from 74% to 56% and from 28% to 21%. **Figure 2** shows the distribution of trajectories of depression symptoms and psychological distress over time, overall and across baseline covariates. Trajectories show that, in terms of depression symptoms, 66% respondents remained asymptomatic/stable, 15% recovered, and 19% remained symptomatic or worsened over time. In terms of psychological distress, 18% respondents remained asymptomatic/stable, 26% recovered, and 56% remained symptomatic or worsened over time. The distribution of trajectories was heterogeneous across baseline covariates.

Table 3 shows crude and adjusted estimates of the association between baseline exposures and follow-up mental health outcome scores among full respondents. Overall, women had higher scores (i.e., worse mental health) than men, and job-related factors such as direct involvement in the care of COVID-19, inadequate access to protective equipment, or fear of infecting oneself or loved ones were associated with higher negative mental health outcome scores - especially for PTSD, and with higher odds of testing positive for psychological distress, probable depression, and PTSD (see **Supplementary Table 4**). We repeated all models including further adjustment by baseline mental health outcome scores: results did not change substantially (see **Supplementary Tables 5 and 6**).

Table 4 shows crude and adjusted associations between baseline exposures and trajectory membership for psychological distress and probable depression. Women showed higher symptom variability over time than men, as indicated by women's higher odds of belonging to both the *recovering* and the *persistently symptomatic/worsening* categories for both psychological distress and probable depression. In terms of psychological distress, reporting inadequate access to personal protective equipment was associated with *persistently symptomatic/worsening* category membership. In terms of probable depression, fear of infecting loved ones was associated with *recovering* category membership.

Discussion

This study followed a cohort of HCWs from one of the earliest COVID-19 pandemic hotspots over the one-year period after the initial pandemic outbreak. There was marked heterogeneity across individuals in terms of variation in mental health outcomes over time. While we detected general reductions in psychological distress (from 74 to 56%) and depression symptoms (from 28 to 21%), the overall burden of poor mental health among HCWs remained substantial 8 months after the pandemic onset (56% screened positive for psychological distress, 21% for probable depression, and 51% for PTSD). Our analysis of mental health outcome trajectories revealed that psychological distress and depression symptoms persisted or worsened over time for 56% and 19% of respondents, respectively. We identified prospective associations between certain baseline characteristics, such as being female, reporting inadequate access to personal protective equipment, or being afraid of getting infected and of infecting loved ones, and follow-up psychological distress, depression symptoms, and PTSD symptoms. These results highlight the importance of adapting, implementing, and scaling-up evidence-based public, occupational, and mental health interventions for HCWs to prevent their mental health from further deteriorating during the ongoing pandemic and its aftermath.

289 Early cross-sectional studies from high-incidence COVID-19 areas, such as the Chinese 290 region of Wuhan (22), Italy (3,5), or Spain (1), described the mental health toll taken by the 291 pandemic on HCWs' mental health, showing remarkable rates of psychological distress, 292 anxiety, depression, and PTSD symptoms. In our study sample, estimates of the point 293 prevalence of depression at baseline were similar than those found in Italy (25%) and Spain 294 (28%), probably due to similar sample characteristics and study settings. Likewise, our 295 baseline finding that three in four respondents were psychologically distressed is nearly 296 identical to that of Lai and colleagues in Wuhan at the beginning of the pandemic (late 297 January 2020). Additionally, a series of cross-sectional studies had already reported 298 associations between HCWs' characteristics, such as female gender, or inadequate access to 299 personal protective equipment and negative mental health outcomes (i.e., anxiety or 300 depression) (23–25). Our study found these associations to persist within a prospective cohort 301 design, lowering the risk of potential reverse causation bias and hence greatly enhancing 302 interpretability for decision-making.

Other prospective studies have sought to describe the evolution of HCWs' negative mental health outcomes over time using a variety of outcomes and follow-up periods (9-12,25-28). Somewhat in contrast to our results, López Steinmez and colleagues reported a slight increase in psychological distress (from 40% to 46% point prevalence) between May and September, 2020, in a sample of 300 HCWs from Buenos Aires, Argentina. Differences in follow-up time probably accounts for this between-study difference, as they may have captured the early consequences of the initial pandemic outbreak while we conducted our assessments later, when renovated reasons for optimism (e.g., vaccine development and roll-out) had already started to emerge. Using a highly homogeneous sample of 200 nurses, Pinho and colleagues reported stable trends in depression and decreasing trends in anxiety between April and November, 2020. Differences in sample composition make their results hardly comparable to our's. Other studies have either used much shorter follow-up periods (25,27,28) or reported outcomes not comparable to our's, such as insomnia (26) or job stress (12). Our's is the first prospective cohort analysis of risk factors for negative mental health outcomes among HCWs to adjust all associations of interest for potential confounding due to area-level COVID-19 cumulative incidence, in addition to adjustment for individual-level confounding. Notably, mounting evidence suggests higher rates of negative mental health outcomes among HCWs from regions with higher incidence (29).

To our knowledge, only one study has described the trajectories of mental health problems among HCWs during the COVID-19 pandemic (9). Using latent class modelling based on scores on three mental health outcomes (depression, anxiety, and PTSD symptoms) between May and September, 2020, they found four distinct trajectories which are remarkably similar to ours in terms of interpretation and prevalence within the study sample: 19% respondents belonged to their 'recovered' group (for 15% in our *recovering* group), 66% to their 'resilient' group (for 66% in our *asymptomatic stable* group), and 7% and 8%, respectively, to their 'subchronic' and 'delayed' groups (for 19% in our *symptomatic/worsening* group). These same trajectories have been identified is studies using latent growth mixture modelling across many different populations that have experienced adversity (30). Notably, this previous study did not assess psychological distress. Accordingly, our surprisingly high rates of persistence or worsening of psychological distress (56% of respondents) cannot be compared to other studies. While this result does not lend itself to easy interpretation until subsequent follow-up studies using the GHQ-12 emerge, it seems plausible that a substantial proportion of HCWs may potentially beneficiate from implementation of programs to lower psychological distress.

In addition to confirming associations previously reported in cross-sectional reports, our findings expand existing evidence in impactful ways for public health and clinical decision-making. First, by including a heterogeneous sample of HCWs with and without clinical duties, our study may serve to inform strategies aimed at non-clinical workers such as administrators or cleaners – largely overlooked in most studies examining mental health outcomes among

HCWs during the COVID-19 pandemic. Second, our finding of scarce evidence of reliable baseline predictors of mental health outcome trajectories over time suggests that all HCWs should be offered easy-to-access mental health resources tailored to their needs (i.e., self-care and low-intensity psychotherapeutic interventions), regardless of profile in terms of sociodemographic characteristics and baseline clinical features.

Our study has limitations. First, we used a non-random sample that increases probability of some degree of collider bias and hinders transportability of study results across settings. Also, and in line with other multi-center studies (1.4), response rates varied significantly across sites and facilities, and the possibility of self-selection bias cannot be ruled out. Nevertheless, the baseline sociodemographic characteristics and mental health outcomes were however similar to another Spanish study with a larger and somewhat more representative sample of HCWs (1) and to other, similar European studies (2,3). Second, because of the use of observational data, effect estimates are potentially subject to some degree of residual confounding. Notably, substantial residual confounding is unlikely given that we included measures on all major individual- and region-level confounders and that estimates from crude and adjusted associations are roughly similar. Moreover, sensitivity analyses exploring differences between subsamples (e.g., full vs. partial respondents) and adjusting for baseline measurements of mental health outcomes obtained similar results, suggesting that our models were robust to different model specifications. Third, two thirds of baseline respondents were lost to followup. Dropout was independent from age, gender, and mental health outcomes at baseline, but people lost to follow were slightly more concerned about getting the virus and infecting their loved ones (data not shown). Fourth, limitations of self-reports for diagnostic screening are widely known (31). In the context of HCWs' reactions to an initial pandemic outbreak, available diagnostic thresholds might have misclassified early, adaptive reactions to acute stressors as probable disorders (i.e., false positives). Notwithstanding, we used widely accepted screening instruments with good psychometric properties validated worldwide. Last, we calculated outcome trajectories based on information from two time points only. Future steps will include ascertainment of mental health outcomes in subsequent follow-up assessments and adoption of data-driven latent growth modelling approaches in addition to previously established categories based on clinical implications.

This is the first study to describe the trajectories of change of a large sample of HCWs from an early pandemic hotspot over a long follow-up period. Our results suggest preventative and restorative strategies at various levels (i.e., public, occupational, and specialized mental health), and outlines modifiable factors that might inform resource allocation, such as provision of protective equipment or being in direct care of COVID-19 patients. Further studies exploring the long-term impact of the pandemic among HCWs are warranted.

Other	80 (5)	59 (6)	21 (3)				
Missing	118	63	55				

Note

506 507 All percentages are valid percentages

HCWs = healthcare workers

^a Health technicians include nurse, X-ray, or laboratory technicians, among others

^b Other HCWs include clinical psychologists, physiotherapists, or biologists, among others

^c Ancillary workers include security staff, drivers, administrative staff, or cleaning staff, among others

Table 2. Mental health outcomes among full respondents (N = 749) at baseline and follow-up. [The COVID-19 HEalth caRe wOrkErS (HEROES) Study, Spain, 2021]

	Baseline	Follow-up			
Psychological distress (GHQ-12)					
Total score, <i>M</i> (SD) ^a	5.3 (3.5)	3.9 (3.5)			
Probably distressed, n (%) b	504 (74)	364 (56)			
Missing	72	100			
Depression symptoms (PHQ-9)					
Total score, <i>M</i> (SD) ^a	7.5 (5.5)	6.4 (5.1)			
Probably depressed, n (%) ^b	186 (28)	137 (21)			
Missing	86	110			
PTSD symptoms (PC-PTSD-5) *					
Total score, <i>M</i> (SD) ^a	-	2.54 (1.62)			
Probable PTSD, n (%) ^b	-	321 (52)			
Missing	-	130			

Note

508

All percentages are valid percentages

GHQ-12 = General Health Questionnaire – 12, PHQ-9 = Patient Health Questionnaire – 9, PTSD = posttraumatic stress disorder, PC-PTSD-5 = Primary Care PTSD Screen for DSM-5

^a GHQ-12 score ranges from 0 to 12; PHQ-9 score ranges from 0 to 27; PC-PTSD-5 scores range from 0 to 5

^b Cutoff scores: PHQ-9 > 9, GHQ-12 > 2, PC-PTSD-5 > 2

^{*} PC-PTSD-5 not included at baseline assessment

Table 3.

Association between participants' sociodemographic characteristics and COVID-19-related exposures, measured at baseline, and mental health outcomes' total scores (psychological distress, depressive symptoms, and posttraumatic stress disorder symptoms), measured at follow-up (8 months). [The COVID-19 HEalth caRe wOrkErS (HEROES) Study, Spain, 2021]

	Psychological distress (GHQ-12)					Depression sym	ptoms (PHO	Q-9)	PTSD symptoms (PC-PTSD-5)
