34 **Abstract**

35 We propose a mathematical framework to analyze and interpret the outcomes of human  
36 challenge trials. We present plausible infection risks with HCoV-229E and SARS-CoV-2  
37 over a wide range of infectious dose, and suggest ways to improve the design of future trials  
38 and to translate its outcomes to the general population.

39

## 40 Main text

41

### 42 Background

43 Quantifying the infectivity of pathogens is a crucial step towards the understanding of  
44 infection risks. In human challenge trials the infection risk is observed as the proportion of  
45 exposed participants that become infected. Dose-response models describe how this  
46 proportion infected changes with an increase in the infectious dose used to expose the  
47 participant [1,2]. Such dose-response models can be used to improve trial designs [3], to  
48 describe infectivity and immunogenicity in human hosts [4], and to simulate the infection  
49 risks via various transmission routes [5].

50 Dose-response models can account for variation in host susceptibility, and most often such  
51 variation has been modelled by a beta distribution [6,7]. However, when a proportion of  
52 individuals is completely immune, the variation is better captured by other distributions (e.g.,  
53 [8]).

54 Here, we start by reformulating dose-response models with a flexible description of the  
55 variation in host susceptibility that allows for an intuitive biological interpretation. We show  
56 how variation in susceptibility determines the dose-response relationship for the endemic  
57 human coronavirus HCoV-229E and we compute the plausible range of SARS-CoV-2 dose-  
58 response curves based on available outcomes of a challenge study.

59 Our approach suggests how the design of human challenge trials can be improved to better  
60 capture the variation in susceptibility, and suggests how to translate the outcomes of human  
61 challenge studies into infection risks for the general population.

62

### 63 Methods

#### 64 Human challenge studies

65 We conducted a literature search to collect available data from human challenge studies  
66 with endemic coronaviruses and SARS-CoV-2. The collected data consists of 5 studies with  
67 endemic coronaviruses HCoV 229E and one study with SARS-CoV-2. In all cases the study  
68 population consisted of healthy adult volunteers, and the participants were intranasally  
69 inoculated with certain doses in each trial. The challenge studies reported the challenge dose,  
70 the number of challenged individuals, and the number of infected individuals as summarized  
71 in **Supplementary Material, Table S1** and **Table S2**.

72

#### 73 Dose-response models to analyze human challenge studies

74 The reported infectious doses  $d$  are expectations of a Poisson distribution of the actual  
75 infectious dose, with mean  $d$ . If each host is equally susceptible, the probability of infection  
76  $P(d)$  given a challenge dose  $d$  is  $P(d) = 1 - \exp(-d)$ . This assumes that each infectious  
77 particle can independently establish an infection [2,9].

78 We capture the variation in susceptibility among study participants by assigning each a  
79 level of susceptibility  $s$ , according to a distribution  $f(s)$  with mean 1. A participant with a  
80 level of susceptibility  $s$  has  $s$  times higher probability of infection compared to an average  
81 individual, per infectious particle. The probability of infection upon challenge with a dose  $d$   
82 is  $P(d) = 1 - \int_0^\infty \exp(-sd)f(s)ds$ . By fitting this model for the probability of infection to  
83 the observed proportion of infections in human challenge studies we can infer the shape of the  
84 distribution  $f(s)$  using the method of maximum likelihood, see **Supplementary Material** for

85 details. We use four different models for the distribution: a Dirac delta distribution to reflect  
86 a situation where all individuals have the same level of susceptibility; a gamma distribution  
87 to reflect a situation where the level of susceptibility varies continuously; a bimodal  
88 distribution with one fraction of the population almost immune, and the remaining fraction  
89 with a single level of susceptibility; and a bimodal distribution with one fraction of the  
90 population almost immune, and the remaining fraction with a gamma distribution for the level  
91 of susceptibility to vary continuously. Detailed model descriptions and estimated parameters  
92 are provided in **Table S3**.

## 94 **Results**

95 Susceptibility distributions determine the shape of dose-response curves

96 We described the proportion of infections among individuals exposed to different doses of  
97 the endemic coronavirus HCoV-229E by fitting dose-response models. Since the collected  
98 trial data include participants who might have been exposed to viruses, we included bimodal  
99 distributions of susceptibility.

100 The results reveal a strong statistical support for a distribution reflecting a situation where  
101 a fraction of the population is almost immune whereas the remaining fraction of the population  
102 has a single level of susceptibility. There is no statistical support for a homogeneous level of  
103 susceptibility or continuous variation in susceptibility for all individuals (**Table S4**).

104  
105 Plausible SARS-CoV-2 dose-response curves

106 In the available human challenge study with SARS-CoV-2 all participants were healthy  
107 young adults with no evidence of previous SARS-CoV-2 infection or vaccination, and they  
108 were all exposed to the same single dose [10]. Here we show how the variation in  
109 susceptibility would affect the infection risk at different doses. Since participants had not had  
110 any prior exposure to this virus, we assumed a continuous variation in susceptibility only. We  
111 fitted the model with several gamma distributions for the level of susceptibility  $s$  to the  
112 observed SARS-CoV-2 challenge data, where we increased the coefficient of variation ( $CV$ )  
113 over orders of magnitude from small ( $10^{-6}$ ) to large ( $10^2$ ). The corresponding curves reveal  
114 that the infection risk increases more gradually with increasing  $CV$  in susceptibility (**Figure**  
115 **1A**).

116 We accounted for the statistical uncertainty in the fraction of the participants that were  
117 infected by taking 1000 bootstrap samples and fitting dose-response curves to each  
118 bootstrapped dataset, reflecting a situation where the susceptibility level is completely  
119 homogeneous ( $CV = 0$ ), and where the level is similar to that of the endemic coronavirus  
120 infection ( $CV = 1$ )(**Figure 1B** and **1C**).

121 We compared the bootstrapped SARS-CoV-2 dose-response curves with the dose-response  
122 curve from a SARS-CoV-1 mouse model obtained by Watanabe et al. [11], which has been  
123 widely used in risk assessments of SARS-CoV-2 (dotted lines in **Figure 1**). This reveals that  
124 using the current reference model based on mouse data with SARS-CoV-1 could lead to  
125 serious underestimation of the infection risk for SARS-CoV-2, irrespective of the shape of the  
126 distribution of susceptibility level. We also compared the SARS-CoV-2 dose-response curves  
127 with the observed outcomes from the challenge studies with endemic coronavirus (**Figure**  
128 **1D**). This suggests that the estimated range of infection risks of endemic coronavirus is  
129 consistent with the observed infection risk in the SARS-CoV-2 trial [12].

130

## 131 Discussion

132 In this study, we revealed the plausible range of infection risk over multiple orders of  
133 magnitude of the infectious dose for the endemic coronavirus HCoV 229E and SARS-CoV-  
134 2, based on human challenge trials. We presented how these dose-response relationships are  
135 shaped by the underlying distribution of susceptibility to infection.

136 The range of SARS-CoV-2 dose-response curves arises from the unknown distribution of  
137 background susceptibility in the population and the statistical uncertainty due to the limited  
138 number of participants that have participated in the human challenge study. Our results  
139 caution against assuming equal susceptibility in the population in risk assessments [5,11], as  
140 this assumption results in a lower bound for infection risks at lower doses.

141 Our results provide implications for further research. We address three of them here.

142 Firstly, our approach suggests a possible improvement in the design of human challenge  
143 trials. Conventional trials tend to use a single dose such as the median human infectious  
144 dose ( $HID_{50}$ ) [13]. Using two (or more) challenge doses would be highly informative for  
145 extrapolating the findings over a wider range of doses. If multiple challenge doses would not  
146 be feasible, we advise to consider using a different challenge dose than the doses used in  
147 previous studies. The outcomes of the different studies can be combined in a meta-analysis  
148 that takes advantage of those different doses to infer how infection risk changes with dose.  
149 This would elucidate the unknown variation in level of susceptibility among individuals.

150 Secondly, the dose-response models proposed here, as many other dose-response models,  
151 have underlying assumptions that the infectious particles are homogeneously mixed in the  
152 inoculates and act independently in causing an infection [2,9]. These assumptions suffice for  
153 describing the outcome of human challenge studies, even though it might not hold, for  
154 example, when virus particles aggregate. The dose-response model can be extended to allow  
155 for variation in the per-particle probability, using methods explored previously [2,14], which  
156 would allow for a built-in check of violating this assumption.

157 Thirdly, our approach offers guidance for the translation of the observed risk of infection  
158 in human challenge studies to the general population. Currently this translation is difficult as  
159 the study population of challenge studies, due to safety and ethical reasons, consists of  
160 healthy adult volunteers [15]. Such a study population is not representative of a general  
161 population which includes children and elderly. Besides, the general population now  
162 includes persons who have been exposed to SARS-CoV-2. The strict selection of healthy  
163 adult study participants with no evidence of previous exposure inevitably reduces the  
164 variation in susceptibility relative to the general population. The proposed dose-response  
165 models with flexible distribution of susceptibility allows for exploring the impact of an  
166 expected increase in variability of the level of susceptibility in the general population and a  
167 flattening of the dose-response curve.

168 In conclusion, our study reveals plausible dose-response relationships for SARS-CoV-2,  
169 based on information from human challenge trials, that are consistent with dose-response  
170 curves obtained for human endemic coronaviruses. Human challenge trials would be more  
171 informative if they use different doses. When translating the observed infection risks in the  
172 specific study population to the general population, the expected higher variability of  
173 susceptibility in the general population should be taken into account.

**Figure 1.** Dose-response curves of SARS-CoV-2 (panel **A**, **B**, and **C**) and comparison with an estimated dose-response curve of endemic coronaviruses (panel **D**) based on observed human challenge data. In panel **A-C**, light red dots stand for observations from human challenge data of SARS-CoV-2 (**Table S2**), and whiskers show Jeffrey's binomial confidence intervals (95%). Panel **A** illustrates that the steepness of fitted curves (blue lines) decreases over the increase in the coefficient of variation (CV) in susceptibility from  $10^{-6}$  to  $10^2$ . Panel **B** and **C** show curves fitted to 1000 bootstrapped samples from observed data where the CV is set as 0 and 1 respectively. These values are selected to consider two scenarios where the susceptibility level is completely homogeneous and where the level is comparable to that of endemic coronavirus infection. Dotted grey lines show reference dose-response curves of SARS-CoV-1 animal model [11]. In panel **D**, plots and whiskers are observed challenge data of endemic coronaviruses (**Table S1**), and dark and light blue lines indicate fitted SARS-CoV-2 models where the CV is fixed as 0 and 1 respectively.

## Materials and Methods

### Human challenge data

The challenge data of endemic coronaviruses and SARS-CoV-2 were collected from published articles. We conducted literature search using PubMed and Google Scholar, and 13 human challenge studies were found in total. For further analysis, 7 studies [1–7] were excluded because the information on inoculated doses was unavailable. Thus, 5 studies of endemic coronaviruses [8–12] and 1 study of SARS-CoV-2 [13] were used in the dose-response analysis. The data consisted of the number of exposed doses, total participants, and infected individuals in each trial. The summary of analyzed data with details (i.e., inoculation methods and references) is shown in **Table S1**.

To synthesize the obtained data, we set two assumptions. First, the infection status was comparable across those studies. Several studies defined the infection status by antibody level, while others defined it by the presence of viruses. Second, there was negligible effect of aggregation of viruses. Since the detailed information of inoculated samples was not available, the unit of dose is defined as the reported unit (i.e., TCID<sub>50</sub>, Median tissue culture infectious dose). If there is data that quantify the level of aggregation, further extension of the dose-response analysis is also possible (see [14,15]).

### Rephrased dose-response model

Here we denote the probability of infection in controlled infection experiments as  $P_{inf}(d)$ , a function of dose  $d$ . In a host, it is reasonable to assume that all the particles are independently infectious and effective to establish an infection (i.e., single-hit theory [15,16]). The simplest dose-response relationship is formulated by incorporating Poisson uncertainty in a microbial inoculum:

$$P_{inf}(d; r) = 1 - \exp(-rd) \quad Eq. 1$$

where  $r$  is the probability of establishing infection by a single-hit.

While previous studies formulated the variation in  $r$  (often with a beta distribution [15,17–19]), here we focus on the variation in a host. Suppose that the susceptibility to infection among individuals differs and is distributed as  $f(s)$  with a level of susceptibility  $s$ . The interpretation of variable  $s$  is that an individual with the level of susceptibility  $s = s'$  has  $s'$  times higher probability of infection compared to an individual with  $s = 1$ . By expanding Eq.1 and integrating the variation in susceptibility, the marginal probability of infection is written as

$$P_{inf}(d; r, \boldsymbol{\theta}) = 1 - \int_0^{\infty} \exp(-rds) f(s; \boldsymbol{\theta}) ds \quad Eq. 2$$

where  $\boldsymbol{\theta}$  is a parameter vector of  $f(s)$ . If a single-hit always results in infection, that is,  $r = 1$ , Eq.2 can be further simplified

$$P_{inf}(d; \boldsymbol{\theta}) = 1 - \int_0^{\infty} \exp(-ds) f(s; \boldsymbol{\theta}) ds = 1 - \mathcal{L}_s(d) \quad Eq. 3$$

where  $\mathcal{L}_s$  refers to the Laplace transform of  $f(s)$ .

As an illustrative example, we introduce the dose-response model where the level of susceptibility is distributed as a Gamma distribution,  $s \sim \text{Gamma}(\alpha, \beta)$ . By solving Eq.3, the dose-response model is derived as

$$P_{inf}(d; \alpha, \beta) = 1 - \left(1 + \frac{d}{\beta}\right)^{-\alpha} \quad Eq. 4$$

and this formula is the same as the so-called Beta-Poisson model [15,19]. Note that we can derive Eq.4 without violating the single-hit principle, and the equation can be interpreted as the relationship between dose-dependent infection probability and the susceptibility distribution within a host.

### Model fitting

Since the results of controlled infections are obtained as either infected or not in challenge experiments, such observation process leads to a binomial likelihood

$$L(\boldsymbol{\theta}) = \prod_i (1 - P_{inf}(d_i))^{(n_i - m_i)} P_{inf}(d_i)^{m_i}$$

and thus the log-likelihood is

$$\ell(\boldsymbol{\theta}) = \sum_i [(n_i - m_i) \ln(1 - P_{inf}(d_i)) + m_i \ln(P_{inf}(d_i))]$$

where for each trial  $i$  we have a dose  $d_i$  and a group of  $n_i$  volunteers of which  $m_i$  are infected. To estimate the set of parameters  $\boldsymbol{\theta}$ , maximum likelihood estimation (MLE) was performed. For this computation we used the `optim()` function in the R statistical programming environment version 3.5.1., and 95 % confidence intervals were computed from 1000 bootstrapped samples.

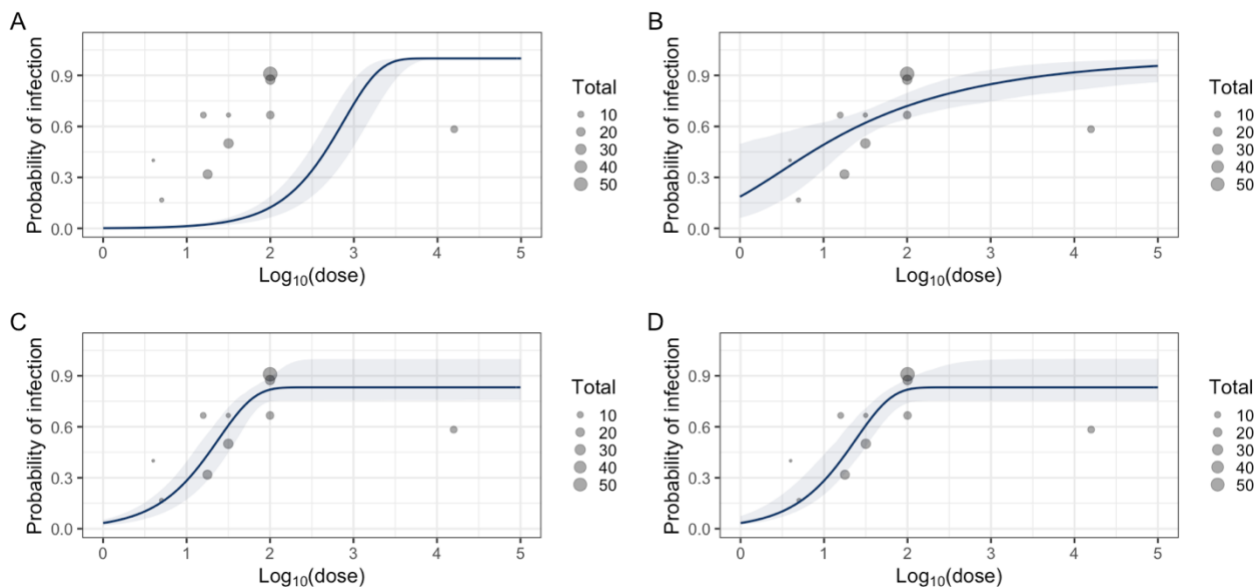

### Referred animal dose-response model

Current risk assessments of SARS-CoV-2 infection risk among humans often refer to the animal dose-response model obtained by Watanabe et al. [20]. Their study used a Delta model (i.e., the first model in **Table S3**) and fitted it to available SARS-CoV-1 data based on mouse experiments. As a result, the estimated parameter was  $a = \frac{1}{410}$  in **Table S3** notation. For details, see the original article [20]. For comparison of dose-response curves, we converted the unit of inoculated doses using the ratio of PFU to TCID<sub>50</sub> that is previously established as 0.7 [21].

## Supplementary figures and tables

**Figure S1.** Estimated dose-response models of endemic coronavirus based on observed human challenge data. Grey bubbles indicate the observed data, and the size of bubbles indicates the number of participants in each trial. To describe different heterogeneity in susceptibility, dose-response models with Delta (panel **A**), Gamma (panel **B**), Two-level (panel **C**), and Gamma with point-mass distributions (panel **D**) were fitted to the data.

**Figure S2.** Simulated SARS-CoV-2 dose response curves based on observed human challenge data. Red plot and whiskers indicate the observed data and its 95% binomial confidence intervals. Each curve is obtained by bootstrapping with a gamma model. From panel **A** to **F**, the coefficient of variation is decreased from  $10^2$  to  $10^{-3}$ .

**Table S1.** Human challenge data with endemic coronavirus.

Dose	Total	Infected	Unit	Pathogen	Age	Inoculation	Reference
100	24	21	TCID50*	HCoV-229E	21-53	Nasal drop	Bende 1989 (Table 1)
31.6	6	4	TCID50	HCoV-229E	18-50	Nasal drop	Bradburne 1967 (Fig 1)
5.0	6	1	TCID50	HCoV-229E	18-50	Nasal drop	Bradburne 1967 (Fig 1)
4.0	5	2	TCID50	HCoV-229E	18-50	Nasal drop	Bradburne 1967 (Fig 1)
15.8	9	6	TCID50	HCoV-229E	18-50	Nasal drop	Bradburne 1967 (Fig 1)
100	15	10	TCID50	HCoV-229E	Unknown	Nasal drop	Callow 1990 (Main text)
17.8	22	7	TCID50	HCoV-229E	18-50	Nasal drop	Reed 1984 (Table V)
31.6	24	12	TCID50	HCoV-229E	18-50	Nasal drop	Reed 1984 (Table V)
15848.9	12	7	TCID50	HCoV-229E	18-50	Nasal drop	Reed 1984 (Table V)
100	55	50	TCID50	HCoV-229E	18-53	Nasal drop	Tyrell 1993 (Table 2)

†TCID50: Median tissue culture infectious dose.

**Table S2.** Human challenge data with SARS-CoV-2.

Dose	Total	Infected	Unit	Pathogen	Age	Inoculation	Reference
10	34	18	TCID50*	SARS-CoV-2†	18-29	Nasal drop	Killingley 2022

\*TCID50: Median tissue culture infectious dose.

†Pre-alpha wild-type virus (Genbank accession number OM294022).

**Table S3.** Description of dose-response models with different distributions for describing the heterogeneity in susceptibility against endemic coronavirus and its estimated parameters.

Susceptibility distribution	Dose-response model	Estimated parameters	Description
Delta	$P_{inf}(d) = 1 - \exp(-ad)$	$a = 1.3 \times 10^{-3}$ [ $6.6 \times 10^{-4}, 2.3 \times 10^{-3}$ ]	All individuals have the same level of susceptibility, and the variance is zero.
Gamma	$P_{inf}(d) = 1 - (1 + \theta d)^{-k}$	$\theta = 1.2$ [ $1.4 \times 10^{-1}, 3.9 \times 10^2$ ] $k = 2.7 \times 10^{-1}$ [ $1.1 \times 10^{-1}, 5.3 \times 10^{-1}$ ]	The level of susceptibility for all individuals follows a gamma distribution.
Two-level	$P_{inf}(d) = 1 - [p_1 \exp(-a_1 d) + (1 - p_1) \exp(-a_2 d)]$	$a_1 = 4.2 \times 10^{-9}$ [ $5.8 \times 10^{-13}, 2.5 \times 10^{-5}$ ] $a_2 = 4.2 \times 10^{-2}$ [ $1.9 \times 10^{-2}, 6.9 \times 10^{-2}$ ] $p_1 = 1.7 \times 10^{-1}$ [ $1.4 \times 10^{-3}, 2.4 \times 10^{-1}$ ]	A population has two levels of susceptibility; a proportion ( $p_1$ ) has a mass at level of susceptibility $a_1$ and the other has another mass at level of susceptibility $a_2$ .
Gamma with point mass	$P_{inf}(d) = 1 - [p_1 \exp(-a_1 d) + (1 - p_1)(1 + \theta d)^{-k}]$	$a_1 = 7.5 \times 10^{-17}$ [ $9.7 \times 10^{-36}, 4.2 \times 10^{-5}$ ] $p_1 = 1.7 \times 10^{-1}$ [ $4.2 \times 10^{-7}, 2.5 \times 10^{-1}$ ] $\theta = 6.2 \times 10^{-7}$ [ $4.9 \times 10^{-8}, 1.0 \times 10^{-1}$ ] $k = 6.8 \times 10^4$ [ $7.4 \times 10^{-1}, 7.7 \times 10^5$ ]	The level of susceptibility for a proportion $1 - p_1$ of population follows gamma distribution, and the other proportion $p_1$ has a level of susceptibility $a_1$ .

**Table S4.** Comparison of estimated dose-response models based on model fit to the observed endemic coronavirus challenge data.

	Delta	Gamma	Two-level	Gamma+point-mass
Log-Likelihood	-393.0	-107.2	-98.3	-98.3
No. of parameters	1	2	3	4
AIC*	787.9	218.5	202.6	204.6
Difference in AIC <sup>†</sup>	585.3	15.9	0	2.0

\*AIC: Akaike Information Criterion. The lowest value indicates the best model in terms of prediction.

<sup>†</sup>Difference of >10 indicates strong evidence [22]. The values here suggest substantial support for the heterogeneity in susceptibility.
