

## SUPPLEMENTARY NOTE

### Study-specific GWAS quality control and imputation

#### *UK Biobank*

Genotyping and imputation for the UK Biobank cohort have been previously described<sup>1</sup>. Briefly, participants were genotyped on the UKB Affymetrix Axiom array (89%) or the UK BiLEVE array (11%) with imputation performed using the Haplotype Reference Consortium (HRC) and the merged UK10K and 1000 Genomes (1000G) phase 3 reference panels. Association analyses in UKB were restricted to individuals of predominantly European ancestry based on self-report and after excluding samples with any of the first two genetic ancestry principal components (PCs) outside of 5 standard deviations (SD) of the population mean, as previously described<sup>2</sup>. We removed samples with discordant self-reported and genetic sex, as well as one sample from each pair of first-degree relatives identified using KING. Using a subset of genotyped autosomal variants with (MAF) $\geq$ 0.01 and call rate  $\geq$ 97%, we filtered samples with call rates  $<$ 97% or heterozygosity  $>$ 5 standard deviations (SD) from the mean. We excluded variants that were out of Hardy-Weinberg equilibrium in cancer-free individuals ( $P_{HWE} < 1 \times 10^{-5}$ ) or had low imputation quality (INFO $<$ 0.30). Analyses were restricted to variants with MAF $\geq$ 0.005.

#### *GERA*

Genotyping, imputation and QC of the GERA cohort has been previously described<sup>3</sup>. Briefly, all men were genotyped for over 650,00 SNPs on four race or ethnicity-specific Affymetrix Axiom arrays that were optimized for individuals who self-reported non-Hispanic white, Latino, East Asian, and African American, respectively<sup>4,5</sup> and QC was performed as previously described<sup>3,6</sup>. Pre-phasing was done by SHAPEIT v2.5<sup>7</sup> and imputation with IMPUTE2 v2.3.1<sup>8</sup> using the 1000 Genomes Project October 2014 release with 2.504 samples. Analyses were restricted to variants with INFO $\geq$ 0.3 and MAF $\geq$ 0.01.

#### *PLCO*

Extensive quality control filtering was performed for subsequent imputation and association analyses. Iterative 80% and 95% sample- and variant-level call rate filters were applied to remove poorly genotyped samples and variants. Samples with greater than 20% estimated contamination based on VerifyIDintensity<sup>9</sup> were also removed. Heterozygosity outliers were detected using absolute values from PLINK method-of-moments F coefficients greater than 0.2. Samples with discordant self-reported and genetically inferred sex were identified by comparing the reported sex with the observed sex based on X chromosome method-of-moments F coefficient from PLINK using 0.5 as the threshold (F coefficients are close to 0.0 for males and 1.0 for females). Discordant samples were further screened for sex chromosome aneuploidies by STR profiling using the Identifier assay. Pairwise genotype concordance for all subjects was assessed to discover unexpected replicates, defined as genotype concordance greater than 95% based on a set of LD-pruned SNPs. Pairwise genotype concordance for all subjects from different datasets within the same platform was also assessed. Cumulatively, samples were filtered to remove abnormal levels of heterozygosity (N=12), sex discordance (N=31), sex-chromosome abnormalities (N=47), unexpected duplicates (N=130), discordant expected duplicates (N=14) and unexpected duplicates (N=126). We also removed one individual in a set of third-degree relatives (N=291).

After QC exclusions, the PLCO Atlas genotyping effort resulted in a total of 112,065 DNA samples genotyped across 110,562 unique individuals on high-density Illumina genotyping arrays. For participants genotyped on multiple genotyping arrays (N=1,192), only genotype data from one array was included following the prioritization of Global Screening Array (GSA) > Oncoarray > Omni2.5M > OmniExpress (OmniX) to ensure non-redundant subject-level genotyping data. The predominant genotyping array was the GSA (N=84,731), followed by the OncoArray (N=16,893), Omni2.5M (N=7,211) and OmniX (N=1,727).

Genetic ancestry for PLCO Atlas participants was determined using GRAF<sup>10</sup> on a set of 10,000 pre-selected fingerprinting variants. GRAF assigned individuals into the following 9 ancestral groups: “African”, “African American”, “East Asian”, “European”, “Hispanic1”, “Hispanic2”, “Other”, “Other Asian”, and “South Asian”. Hispanic1 included individuals of Dominican or Puerto Rican ancestry whereas Hispanic2 included individuals of Mexican or Latin American ancestry. For parsimony we merged “African” and “African American” into a “African American (Combined)” and “East Asian” and “Other Asian” into a “East Asian (Combined)”. The largest ancestral sets in the PLCO Atlas included European (N=100,448), African American (Combined) (N=4,576) and East Asian (Combined) (N=3,528).

Prior to submitting data to the Michigan Imputation Server, we removed variants with minor allele frequency  $\leq 0.01$ , variant-level missingness  $\geq 0.05$ , and Hardy Weinberg equilibrium exact test p-value  $\leq 1 \times 10^{-6}$ . Data from each genotyping platform were then analyzed using a community-recommended script for aligning data to reference datasets (HRC-1000G-check-bim.pl, from <https://www.well.ox.ac.uk/~wrayner/tools/>). The script was modified to support TOPMed 5b as a reference panel using a pre-existing test imputation with 1000 Genomes subjects versus the TOPMed 5b reference panel. Data were uploaded to the MIS in GRCh37/hg19 and lifted over by the MIS. Pre-phasing using phased reference data from TOPMed release 5b was conducted using EAGLE 2.4. Imputation was conducted against the same reference panel using minimac4.

Following MIS imputation, raw imputation data were partitioned into ancestry subpopulations based on GRAF groupings to estimate ancestry-specific imputation quality. After partitioning by ancestry and recomputing imputation quality Rsq values, each platform and ancestry pair was cleaned according to the filtering method described by Kowalski et al<sup>11</sup>. Briefly, all variants with Rsq  $< 0.3$  were removed to be consistent with traditional quality filters. Remaining variants were then partitioned into MAF bins and each bin was filtered, starting at the variant with the lowest Rsq, until the average Rsq of remaining variants within the corresponding MAF bin was at least 0.9.

### *BioVU*

BioVU subjects (n=8,074) were genotyped on Illumina’s Expanded Multi-Ethnic Genotyping Array (MEGA<sup>EX</sup>) platform. First, genetic ancestries were assigned by running principal component analysis using SNPRelate on a set of pruned SNPs (Rsq  $< 0.5$ , MAF  $\geq 0.1$ ). Subjects were classified as being of European ancestry if their first two PCs were within 4 SDs of the median for the subjects reporting “White” as their race. Subjects were classified as being of African ancestry if their first two PCs were within 4 SDs of the median for subjects reporting their race as “Black”. All quality control procedures were performed using PLINK version 1.90. We removed samples with indeterminate genetic sex or discordant self-reported and genetic sex. We removed one randomly selected sample out of each pair of related individuals ( $\pi\text{-hat} \geq 0.2$ ) identified using identity-by-descent. Among subjects passing these initial steps, we removed all palindromic variants and variants with a call rate  $< 3\%$  or MAF  $< 1\%$ . We then excluded subjects with SNP missingness  $> 3\%$  or heterozygosity  $> 5$  SD from the mean. Prior to imputation, data were pre-processed using the HRC-1000G-check tool v4.2.5 (<http://www.well.ox.ac.uk/~wrayner/tools/>) and pre-phased using Eagle v2.4.128. Genetic data was imputed on the Michigan Imputation Server using 1000 Genomes phase 3 version 5 as the reference panel. Final association analyses were performed on imputed variants with MAF  $> 0.005$ , INFO  $> 0.3$ , and HWE v-value  $> 1 \times 10^{-5}$ .

### *MDCS*

4069 individuals from the MDCS were genotyped on various versions of Illumina Omni chips at different times, representing seven different batches total. Data from all of the batches were merged. We noted that some SNPs appeared more than once under different names on the same Illumina chip. For these cases, we kept the SNP with the higher genotyping rate. Ambiguous SNPs (e.g. A/T or C/G alleles), SNPs that were not bimorphic, and variants that were not single nucleotide polymorphisms, were removed. From this, only SNPs that we could unambiguously map to release 1 of the 1000 Genomes project were kept; the final files

from this were aligned to build 37 of the human genome. Individuals with more than 10% missingness were removed. Next, SNPs with a missingness rate greater than 10% or deviation from Hardy-Weinberg equilibrium ( $p < 0.001$ ) were removed. At this stage, the principal components of ancestry were computed. Individuals for whom the inferred sex based on X chromosome heterozygosity was not male, or for whom there were more than two genetic mismatches with 40 SNPs we had previously genotyped in these samples with targeted genotyping<sup>12</sup> were excluded.

To identify genetic ancestry, the SNP chip data was combined with data from HapMap phase 3 for all SNPs in common between the two studies. We then filtered for SNPs with less than 0.01% missingness, and further filtered for SNPs in LD using the `--indep-pairwise 50 5 0.05` command in Plink v1.07. We then ran SMARTPCA on the resulting 18,299 SNPs and kept the top 10 principal components.

To impute these individuals using the TopMed imputation server, a custom Python script using Spark was used to convert the master tped/tfam file to a VCF file for each chromosome. SNPs with missingness greater than 5% or Hardy-Weinberg equilibrium  $P < 1e-05$  were removed. The Plink file was aligned to the build37 reference genome on the basis of chromosome, position and alleles so that the VCF file can properly report genotypes based on the reference and alternate alleles. The resulting build 37VCF files with 847,133 SNPs total were uploaded to the TopMed imputation server for imputation. As the server converts data to build 38, the resulting files were analyzed in build 38.

From the resulting imputed files, only individuals not known to be a case by December 31, 2014, with individual missingness less than 3%, a Z-score less than 5.0 for heterozygosity, with a Z-score on PC1 and PC2 less than 5, and PSA between 0.01 and 10 ng/mL were included. A linear regression model in which the covariates (Supplementary Table 21) were used to predict log(PSA) was fit using robust linear regression with Tukey biweights using the RLM function in the statsmodels Python package, and the residuals were extracted for testing with the individual SNPs.

#### *PCPT and SELECT*

This analysis includes a subset of subjects from PCPT and SELECT who were genotyped on the Illumina Global Screening Array (GSA) 24v2-0. Genotyping calling and quality control were performed at the Center for Inherited Disease Research (CIDR) at Johns Hopkins University using GenomeStudio version 2011.1, genotyping module version 1.9.4, and GenTrain version 1.0. After removal of samples that failed to produce valid output during initial processing and clustering, the completion rate was 0.9951 and 0.9959 in PCPT and SELECT, respectively. A two-stage filter by completion rate threshold of 0.8 for samples and 0.8 for variants, followed by 0.95 for samples and 0.95 for variants was performed. In PCPT no samples were excluded by the initial filter and the subsequent filter excluded 36 samples and 4076 variants, resulting in 6325 samples at 701,852 variants. In SELECT the first stage excluded 4 samples, and 6276 variants. The subsequent filter excluded 81 samples and 3776 variants, resulting in 27,608 samples at 702,137 variants.

Samples that are contaminated during extraction or staging activities can be identified and excluded prior to genotyping via use of an STR fingerprinting (Identifiler<sup>TM</sup>) assay. For samples that became contaminated during array processing, or for those samples not screened by an STR assay prior to array processing, sample contamination is predicted by running the tool VerifyIDintensity<sup>9</sup> on each sample that passes all completion rate filters or has a median raw intensity  $> 6000$ . The tool is run one sample at a time and uses a population frequency file created with the 1000G all population frequencies for the GSA SNPs. Samples with predicted contamination  $> 10\%$  were excluded ( $n=1$  in PCPT and  $n=2$  in SELECT).

Sex of each remaining subject is verified by comparing the reported sex with the observed sex based on X chromosome method-of-moments F coefficient, expected to be close to 0.0 and 1.0 for females and males respectively. Subjects with F coefficients of 0.5 were excluded. Pairwise genotype concordance for all subjects was assessed to discover unexpected replicates. Subjects with genotype concordance  $> 95\%$  at a set of LD-pruned SNPs were considered replicates. Identity-by-descent (IBD) for all subject pairs were using

PLINK and close (1<sup>st</sup> and 2<sup>nd</sup> degree) relatives were identified based on a threshold of 0.20. One randomly selected sample from pair of relatives was retained. Ancestry was estimated using a set of LD-pruned markers and running SNPWEIGHTS<sup>13</sup> with the reference panel provided containing the following populations: European, West African, and East Asian, with a threshold of 0.8 used for imputed ancestry designation. Subjects were assigned to just one ancestry group if the ancestry score fell above this threshold for just one group. ADMIXED populations were designated as ancestry groups with an imputed ancestry score greater than 0.2 and less than 0.8. Autosomal heterozygosity was assessed using the method-of-moments F coefficient ( $[\text{observed hom. count}] - [\text{expected count}] / ([\text{total observations}] - [\text{expected count}])$ ) calculated within each ancestry group. Heterozygosity outliers were identified and excluded using a threshold of 0.10.

Pre-imputation variant-filtering criteria included: minor allele frequency (MAF) > 0.1%, Hardy-Weinberg equilibrium p-value >  $10^{-6}$ , and SNP call rate > 98%. A total of 491,015 genotyped variants remained after these quality control (QC) steps. To prepare the genotype data for the Trans-Omics for Precision Medicine (TOPMed) Imputation, we checked the QC'd plink files against the TOPMed reference SNP list in advance of imputation. For PCPT, a total of 6055 samples and 474,046 variants were submitted to the imputation server. A total 26,365 samples were genotyped on the GSAMD-24v2-0 Illumina genotyping array. The pre-imputation sample-filtering and variant-filtering process followed the same steps as for the PCPT study. After QC, a total of 402,993 variants of 26,297 subjects were input to the TOPMed Imputation Server for imputation.
