Abstract

The dynamics of epidemiological phenomena associated to infectious diseases have long been modelled with different approaches. However, recent pandemic events exposed many areas of opportunity to improve over the existing models. We develop a model based on the idea that transitions between epidemiological stages are alike sampling processes. Such processes may involve more than one subset of the population (e.g. infection), or they may be mostly dependent on time intervals defined by infectious or clinical criteria. The resulting modelling scheme is robust, easy to implement, and can readily lend itself for extensions aimed at answering questions that emerge from close examination of data trends, such as those emerging from the COVID-19 pandemic, and other infectious diseases.

1 Introduction

The urgency to understand the population dynamics during the COVID-19 pandemic propelled new questions in many scientific fields. Some nontrivial aspects of the pandemic have been unravelled and described by analysing clinical or experimental data. In parallel, many modelling efforts have attempted to provide quantitative predictions of the evolution of the pandemic, and some yielded reasonable qualitative explanations. However, the COVID-19 pandemic also unveiled some of the shortcomings of the existing modelling tools, and shed light on the fact that the construction hypotheses for many existing models are simply too limiting to study even the most basic aspects of an epidemic.

We propose a new, simple model for the dynamics of infectious diseases with the idea of being able to answer basic questions and also, provide a basic paradigm from which we can draw more detailed explanations for some other unresolved epidemiological phenomena (for instance, see [Montoya et al. \(2013\)](#)). The model combines ideas from sampling processes with classical approaches from dynamical systems. Of note, restricting some of the construction hypotheses of our model gives the long-established SIR-type models ([Kermack and McKendrick, 1927](#)), and explains, en passage, some important limitations and mathematical impossibilities of the SIR approach.

1.1 Epidemiological dynamics and modelling

The epidemiological dynamics of infectious diseases result from a combination of non-linear and random phenomena occurring in different levels of biological organisation. A variety of theoretical approaches, of which the most notable is the family of SIR-type models ([Brauer et al., 2019](#); [Kermack and McKendrick, 1927](#)) has proven useful to study general aspects of epidemics. However, the existing deterministic and stochastic classes of epidemiological models based on equations, at large, fail to offer reasonable links between the mathematical expressions in the models and the underlying biochemical or biophysical mechanisms they are supposed to capture macroscopically. For instance, there are stochastic models capable of describing different aspects of the dynamics in epidemics. The work of [Greenwood \(1931\)](#) analyses the pertinence of different probabilistic models to explain mechanisms of disease spreading within households. The number of cases of the disease registered in a period of time at each household is used as input for the models, hence having the possibility of measuring the fit of each model to real data. More recently, [Greenwood and Gordillo \(2009\)](#) review compartmental stochastic models, focused on the distribution of the final size of the epidemics, the stochastic periodicity of the number of infectious individuals, and the (random) time that an individual remains infectious after having been infected. The model by [Tuckwell and Williams \(2007\)](#) uses Markovian infection dynamics that occur as binomial processes within a constant population over discrete time. Some surveys about similar stochastic models can be found in the work of [Allen \(2017\)](#) and [Britton \(2010\)](#).

In contrast, deterministic models from the SIR family are, by construction, unable to capture the basic aspects of an epidemic in small populations. SIR-like models also fail to reproduce case-fatality ratios agreeing with data unless the model has multiple stages of infection and deaths occur only at the last epidemiological state. That is, quick deaths can

only happen after an infection reaches its worse stages.

Significant improvements can be made in the study of epidemiological dynamics by replacing one or more of the phenomenological construction postulates of the SIR family (e.g. homogeneous mixing). This can be done by making assumptions and deriving expressions explicitly based on physical, biological, or biochemical principles underlying the infection or disease, however macroscopic. For instance, the infection rate is typically assumed to be proportional to the prevalence of infection (density of infected). Such an assumption may sound reasonable at first and it may even be possible to fit a rational multiple of prevalence to case data after mild corrections. However, the proportionality constant implicit in that assumption depends on factors that include the source of inoculation (e.g. a water or animal reservoir), the collective behavioural patterns of people susceptible to infection and those infected, and the characteristics of the individuals in those populations (e.g. obesity, age, gender).

Another issue that is often ignored is the difference between an infectious process, typically detected by laboratory tests, and the evolution of the disease possibly caused by that infection, which may only be detected if symptoms develop. This is also a problem from an epidemiological standpoint because these two phenomena are usually lumped together in construction hypotheses for models (see [Allen \(2008\)](#)), thus limiting the scope and the resulting dynamics ([Shayak and Sharma, 2021](#)). Also, the clinical manifestations possibly caused by an infection are not necessarily detected or sought for. relevant time window in this regard is the incubation period, which is asymptomatic but possibly infectious. Then number of asymptomatic cases may be the main underlying cause of large epidemic outbreaks ([Gerba, 2009](#)). Examples of communicable diseases of current importance due to their enormous burden on economic, social, and health systems, that can be asymptotically transmitted, and therefore difficult to keep under control include malaria ([Bousema et al., 2014](#)), dengue ([Grange et al., 2014](#)), influenza ([Cohen et al., 2021](#)), COVID-19 ([Gandhi et al., 2020](#)), aids ([Hollingsworth et al., 2008](#)), among many well-documented examples.

The discussion above underscores the necessity of constructing models that explicitly make distinctions between infectious and illness states, or to explicitly distinguish between the exposure of susceptibles and the exposure of infected. It should also be possible to develop models constructed from a macroscopic perspective to explain seemingly paradoxical situations. For instance, infections may cause severe illness or even death in older people and young athletes, but not in children, as has been observed during the COVID-19

pandemic. Of particular interest, there is a lack of computationally simple, mathematically robust models based on pathophysiological considerations that distinguish the clinical outcome from infections taking into account different susceptibility profiles (Butler and Barrientos, 2020; Fakhroo et al., 2020; Fricke-Galindo and Falfán-Valencia, 2021), or explaining different levels of severity in the clinical outcomes of reinfections as a function of the time from the last infection (Katzelnick et al., 2016; Montoya et al., 2013).

As a starting step, in this paper we present a modelling framework based on a simple dynamical principle: individuals in a given epidemiological stage may switch to a different stage through sampling, and all individuals. For instance, at each point in time, people who become infected are sampled from the susceptible population, and they may progress into illness, if they get sampled again. We start by giving basic macroscopic descriptions for transmission of infectious diseases, and make punctual distinctions between the sampling processes involved in the switching through specific epidemiological stages. We then proceed to present a simple model for epidemiological dynamics, hereby called sED. Once the construction of the basic model is explained, we demonstrate a few of its mathematical properties and illustrate some of its advantages over classical epidemiological models, including the possibility of modelling infection spread in small populations with integer state variables. We also show that the sED model recovers different types of deterministic SIR models under particular sets of assumptions, and illustrate the application of the sED model with specific examples. We then show how to extend the proposed modelling framework and we finish the article by presenting some applications and a discussion of the results and some future perspectives.

2 Modelling framework for stochastic epidemiological dynamics

2.1 Working definitions and conceptual distinctions

Susceptible individuals are, by definition, those that can be infected. *Exposed* individuals are those in contact with the pathogen. Exposure may change over time depending on different factors like physical distancing policy, personal mobility, the time of the day, etcetera. Naturally, only susceptible individuals that are *exposed* can become infected, and an individual is *infected* if the pathogen finds a susceptible tissue and starts replicating. After some time in which the pathogen replicates, infected individuals become able to

transmit the pathogen and start contributing to the chain of transmission. The time relative to the (initial) inoculation is a random variable (Fenner et al., 1987). The *incubation* time can be regarded as the time interval between the start of replication and the start of pathological processes associated with pathogen invasion (Li, 2010, p.25). However, since symptoms are usually the way in which pathology is detected, the incubation time is usually referred to in medical epidemiology as the time lapse between the suspected time of infectious contact and the start of symptoms (Dicker C. et al., 2006; He et al., 2020). This is typically a problem since infected people may not be symptomatic (they do not show obvious symptoms), as their infection progresses. In the case that disease ensues, the severity may progress from mild to worse until recovery or death.

The time individuals spend being infected is a random variable that often is modelled as a gamma-distributed random variable (Anderson and Watson, 1980; Feng et al., 2007; Lloyd, 2001; Vazquez, 2021). For practical purposes, the infection time can be thought of as a sum of an initial replication period of the pathogen causing the infection, and a second period during which an individual may have detectable symptoms. The individual may be infectious shortly after the first pathogen invasion, during the incubation period, and before symptoms appear (e.g. COVID-19). This can be modelled by dividing the infectious period into several stages. After the infection period, individuals may develop other phases of the disease that are not necessarily infectious. For instance, in both symptomatic and asymptomatic COVID-19, the initial viral phase might be followed by an inflammatory phase (García, 2020; Manjili et al., 2020) where the probability of infectious virus shedding decreases dramatically (van Kampen et al., 2021). A longitudinal study of people infected with SARS-CoV-2 (Boucau et al., 2022) suggests the possibility of shedding virus for more than 5 days (possibly up to 15 days) after symptom onset. In the best-case scenario, the immune system develops a protection profile against the pathogen and the individual recovers soon after that. In a worse-case scenario, the response of the immune system may be too strong, inflicting damage on different tissues, exacerbating the pathology further, causing severe illness and potential death. Alternatively, it is also possible that individuals are born immune or become immune. This may happen for reasons that include having beneficial mutations in their genome (Allers and Schneider, 2015), having acquired cross-immunity upon exposure to other pathogens (Doolan et al., 2009), or after vaccination (Clem, 2011).

In consideration of the observations made above, and others mentioned further in the perspectives subsection of the discussion, we developed a hierarchy of models for stochas-

tic epidemiological dynamics referred to as sED models from here on, that can be extended depending on the level of detail sought and the questions of interest.

2.2 Modelling rationale

We regard any epidemiological classification of individuals from a population as a dynamical partition into subsets that change in time. The subsets that make up the partition can be represented as nodes in a directed graph with nodes and edges can be respectively weighed according to the size of the population they represent, or alternatively, the probability that an individual changes to the epidemiological stage at the end of the edge (Fig. 1).

The epidemiological dynamics at the population-level can then be based on two simple but powerful concepts.

- First, each infection can be thought of as a *one-way, path* starting at the node representing the susceptible subpopulation, and ending at one of the terminal nodes in the graph representing the recovered state or death due to infection.
- Second, the epidemiological state $s(t)$ of any individual may change during the time interval $[t, t + h]$ with a certain probability $p_s^h(t)$, and remain the same with probability $1 - p_s^h(t)$. Such changes are assumed to occur independently between individuals.

2.2.1 Epidemiological sampling and state switching

The epidemiological state s of an individual at time $t + h$ can be thought of as the result of a *routing* process in which individuals are subjects in *Bernoulli* trials occurring between times t and $t + h$, with probability of success (switch) $p_s^h(t)$. The number of people that change their epidemiological state between times t and $t + h$ is thus the number of successful trials in the *Bernoulli* sample drawn at time t . It is reasonable to assume independence between switching events for different individuals. Within a homogeneous population (e.g. similar co-morbidities), every individual can be assumed to have the same probability of switching between epidemiological states, in which case the number of people who switch can be regarded as a *Binomial random variable* in which the number of trials is the number of individuals initially considered. If there is more than one possible new epidemiological state to switch to, $p_s^h(t)$ can be regarded as a sum of the probabilities of switching to the new different states, and the individuals that switch to the different states can be thought of as a *Multinomial* sample with a number of trials equal to the number

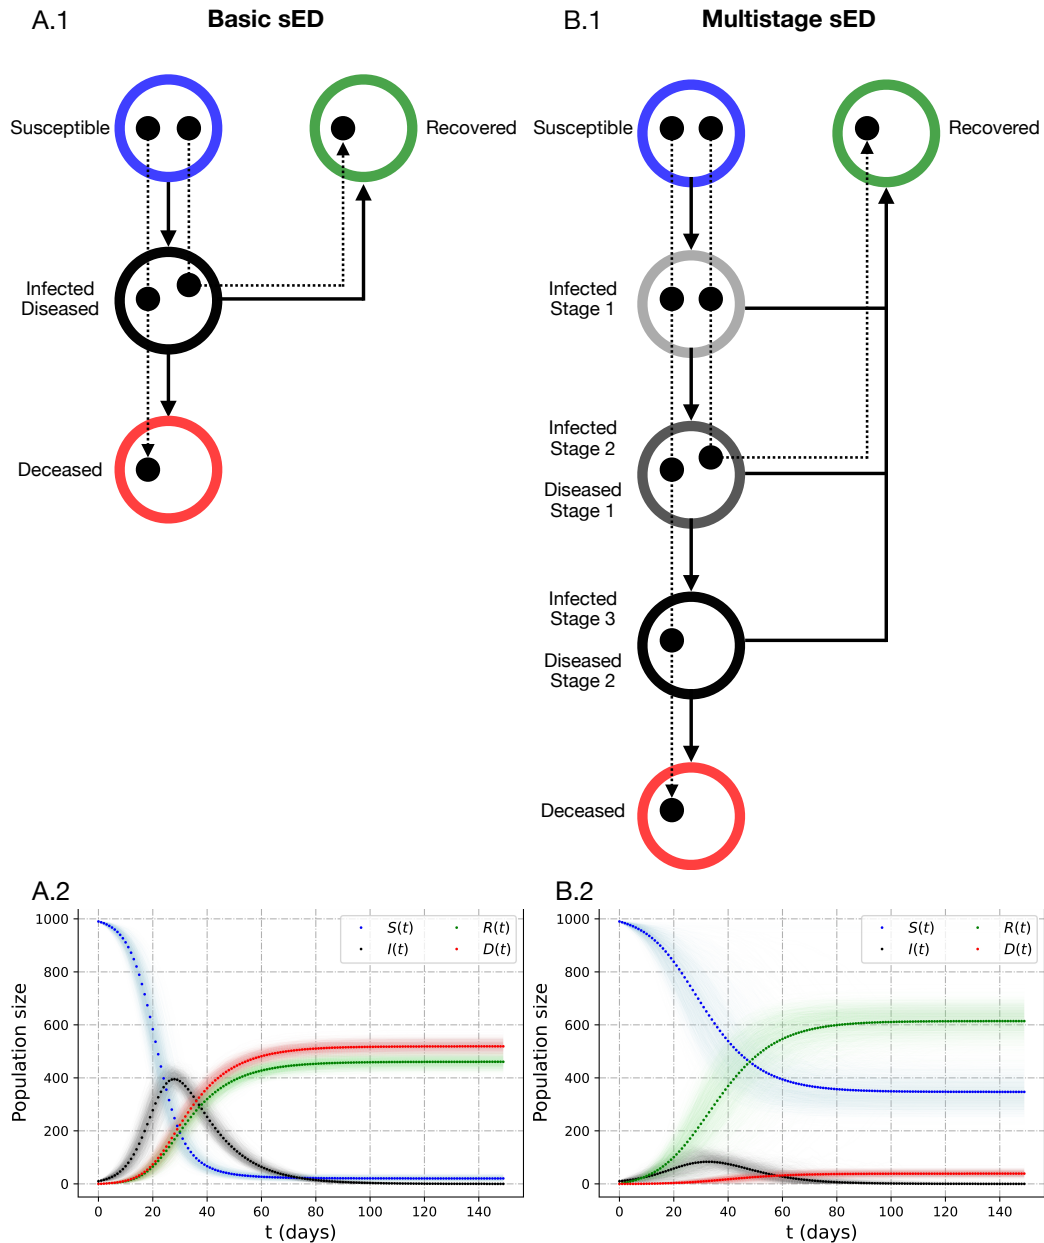

Figure 1: Different dynamical scenarios contemplated by the sED modelling scheme outlined in A1 and B1. The light shades in A2 and B2 represent the confidence bands generated with 2,000 simulations and the solid dots are taken as the average of those simulations. The dynamics in the two models are defined as having the same average time for recovery and death. However, they display different time courses for infection and final outcome. See Tables 1 and 2 for further information.

of people in state s at time t . The epidemiological dynamics of a population formed by different, but relatively homogeneous subpopulations can then be modelled by keeping track the individual changes in epidemiological state, and updating the number of people

in the different stages after each time step.

Reasonable approximations for *populations* formed by heterogeneous groups can then be derived by assuming homogeneity among individuals within a group and tracking the evolution of the different groups. For instance, in some cases it would be reasonable to assume that the (population) average probabilities for switching describe the population dynamics at large, and therefore, sampling for those individuals switching epidemiological states can be done in each subpopulation by performing assuming independent Bernoulli trials, assuming that success occurs with a probability equal to the average probability of switching between epidemiological states for that subpopulation.

The first model we present will be based on this basic assumption which implies two sampling processes on one homogeneous population: one from the susceptible population that depends on contacts between susceptible and infected, and another from the infected that only depends on time from the start of infection (Fig. 1, left column).

2.2.2 Time-dependent switch in epidemiological state

Let τ_s be a random variable representing the waiting time for a switch to a new epidemiological state s . For instance, τ_R represents the expected time for recovery for an individual at some infectious state. The probability of switching within h time units can then be written as $p_s^h(t) = P_s(h)Q_s(t, h)$ where $P_s(h)$ represents the probability that the switch occurs within h time units, and $Q_s(t, h)$ represents the probability that the conditions that are necessary for the switch occur at time t . Assuming that the time τ_s for a switch from the epidemiological state s is an exponential random variable with mean waiting time μ_s ,

$$P_s(h) = P(\tau_s < h) = 1 - \exp(-h/\mu_s). \quad (1)$$

We now proceed to show the derivation for the basic version of the stochastic model for epidemiological dynamics, which is capable of capturing different aspects of epidemiological dynamics, showing some of their properties and advantages over classical models. We do so taking into account the characteristics and data reported for COVID-19.

2.2.3 The start of the chain of transmission: switching from susceptible to infected

Suppose that every member of a population is either susceptible to infection, non-susceptible, or infected by a certain pathogen (e.g. SARS-CoV-2), at any point in time. Let non-negative integers $T(t)$, $S(t)$, and $I(t)$ represent the sizes of the whole population, those

susceptible to infection, and those infected at time t (in days). $T(t) - S(t)$ is the size of the non-susceptible population at time t , *i.e.* those that do not participate in the chain of infections.

Assume that infections are *independent* among individuals, with an average probability of infection $p^h(t, I)$ that depends on factors that include the time of exposure h and the availability inoculum, which can be thought of as a monotonically increasing function of I . In addition, suppose that each of the susceptibles can be infected within h time units with probability $p^h(t, I)$, or remain susceptible with probability $1 - p^h(t, I)$. The number $X_I^h(t)$ of newly infected people (absolute incidence) can then be thought of as a *Binomial* random variable sampled from $S(t)$ individuals. One possibility is to define

$$p^h(t, I) = P_I(h)Q_h(t, I) = P_I(h)\beta\frac{I(t)}{T(t)} \quad (2)$$

where β is the probability that a susceptible person is infected after having an infectious contact with the infectious pathogen, $I(t)/T(t)$ represents the proportion of infected individuals within the population at time t , and $P_I(h)$ represents the probability that the infection occurs within a time window of length h , while being *exposed* to the infectious pathogen. The number of newly infected individuals between times t and $t + h$ can then be thought of as a random variable $X_I^h(t)$ with *Binomial* ($S(t), p^h(t, I)$) distribution, and the expected number of newly infected individuals would then be $p^h(t, I)S(t)$. The number of susceptible people at a time $t + h$ can then be calculated as,

$$S(t + h) = S(t) - X_I^h(t), \quad (3)$$

which means that the expected change between $S(t)$ and $S(t + h)$ is a decreasing function of t , for all $h > 0$. As a working definition, we will consider the start of an epidemic when the expected number of infections, $S(t) \cdot p^h(t, I)$, becomes increasing as a function of time.

We now describe how to take into account the possibility of death due to disease.

2.3 Infections and possibly fatal outcomes

Assume that an initial number of infections $I(0) = I_0$ are caused by a primal source of pathogens, and that those infections are transmissible to the rest of the population. Assume also that infected individuals shed the same (average) inoculum per unit time. For now,

all susceptible and infected individuals are assumed to participate in the chain of infection without restrictions. In a later section, we will explore the effects of extending the model to explicitly include exposure factors for susceptible and infected, separately.

Immunity and death. For this first model, assume that some of the infected individuals die after becoming infected, and the rest recover and become immune from then on, as assumed in the classical SIR formulation. Notice that the assumptions above do not take into consideration any clinical aspects associated to the infection, with only two possible stage switches to become deceased or eventually recover. Let $Y_R^h(t)$ and $Y_D^h(t)$ respectively represent the numbers of people that that recover or die between t and $t + h$. Those that remain infected after that time interval are then

$$I(t + h) = I(t) - Y_D^h(t) - Y_R^h(t). \quad (4)$$

The probabilities that a person is removed from the infected group (i.e. recovers or dies), or that the person remains infected within a small time interval of length h , are assumed to be independent of the state of the epidemics at time t ; thought of as to depend only on the physiological state of the individual facing the infection. Independence between infections enables the possibility of regarding $Y_R^h(t)$ and $Y_D^h(t)$ as outcomes from a *Multinomial* sample from $I(t)$, with respective probabilities p_R^h and p_D^h , for $t \in [t, t + h]$. In other words, the triplet

$$(Y_R^h(t), Y_D^h(t), I(t) - Y_R^h(t) - Y_D^h(t)) \sim \text{Mult}(I(t), p_R^h, p_D^h, 1 - p_R^h - p_D^h),$$

and the dynamics of the infected, recovered, and dead at time $t + h$ can be written as a stochastic dynamical system of the form

$$\begin{aligned} I(t + h) &= I(t) + X_I^h(t) - (Y_R^h(t) + Y_D^h(t)), \\ R(t + h) &= R(t) + Y_R^h(t), \\ D(t + h) &= D(t) + Y_D^h(t). \end{aligned} \quad (5)$$

where $R(t)$ and $D(t)$ are non-negative integers respectively representing the number of recovered or deceased individuals at time t .

2.3.1 Probabilities for recovery and death

Let τ_R and τ_D be positive-valued random variables respectively representing the waiting time for an infected person before recovery or death. Bearing in mind that the distributions of τ_R and τ_D may vary substantially depending on the pathogen (Baron, 1964), assume that infected individuals can either clear a pathogen within an average time μ_R , or alternatively, the individual may die from disease caused by the infection after an average time μ_D . The probabilities that a person is removed from the infected group or that remains infected within a small time interval of length h can be estimated by assuming *Geometrically* distributed times for recovery and death, so that

$$p_s^h \approx h \mu_s^{-1}, s \in \{R, D\}. \quad (6)$$

with $1 - (p_R^h + p_D^h)$ representing the probability of remaining infected within h time units. Large enough values of $I(t)$ yield a *Poisson* approximation of the form

$$p_s^h \approx 1 - e^{-h/\mu_s}, \quad s \in \{R, D\}. \quad (7)$$

Take for instance the epidemiological dynamics of COVID-19 (Fig. 2). Data from the first symptomatic cases of COVID-19 during 2020 in China suggested that deaths in hospitalised individuals occurred between 2 and 3 weeks after start of symptoms (Zhou et al., 2020). In contrast, the hospitalization time for survivors was reported to be between 3 and 4 weeks (Zhou et al., 2020). Also, the average incubation time was reported to be between 4 and 6 days (Quesada et al., 2020), and during this interval of time those infected could shed inoculum while remaining asymptomatic. Taking the above observations into account, we assume values for μ_R and μ_D to be 21 and 28 days, and 28 and 35 days, respectively to construct the basic sED model with dynamics illustrated in Fig. 2.

The joint dynamics of the decreasing size of the susceptible population and the probability of infection result in a sequence of probability mass functions for the newly infected that have many remarkable features (Fig. 3). First, the peak probability has a “U” shape as a function of time, taking the highest values at the beginning and end of the epidemic, and the lowest at the peak of infections. The number of newly infected that corresponds to that peak probability has the opposite behaviour, starting and ending at very low values, and reaching a maximum at the peak of the epidemic. This is in line with the idea that unless the value of β is very large, the probability that a large number of new infections occur is

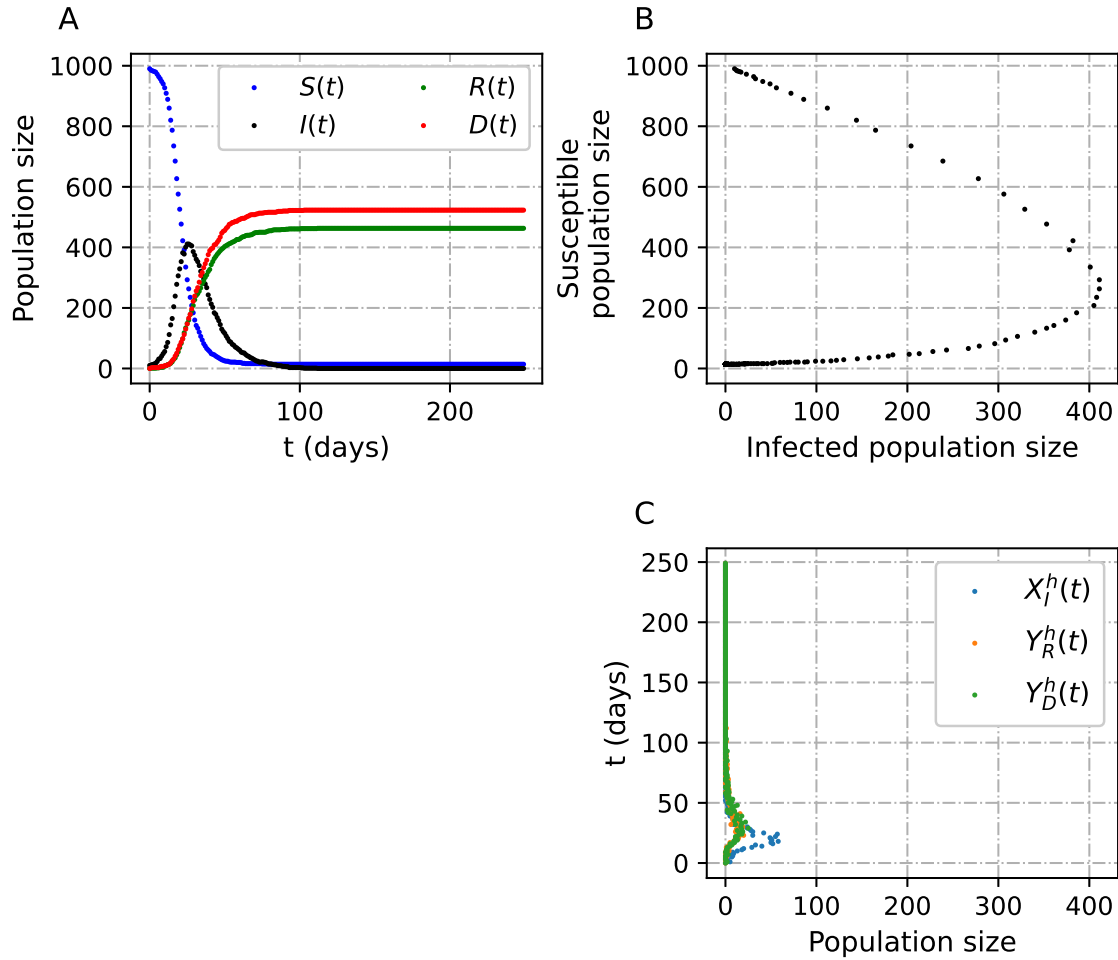

Figure 2: Dynamics and geometry of the sED model. Panel A shows the epidemiological curves obtained with the sED model. Panel B shows the $I - S$ phase plane. Finally, panel C shows the numbers of newly infected individuals and the numbers of people that recover or die over time. The parameters used in this simulation were $\mu_R = 27$, and $\mu_D = 24$. Other parameters can be found in Table 1.

low, at any point in time, regardless of the population size.

Before presenting applications and further extensions of this basic model, we demonstrate some mathematical properties derived directly from equations (3)-(6).

2.3.2 The routing probability and the mean infection time

We first answer a fundamental question: What is the probability that a given infected person recovers?

The multinomial trial with probabilities p_R^h , p_D^h , and $1 - (p_R^h + p_D^h)$ for any time t is independently repeated for time windows of size h , for as long as the population has infected

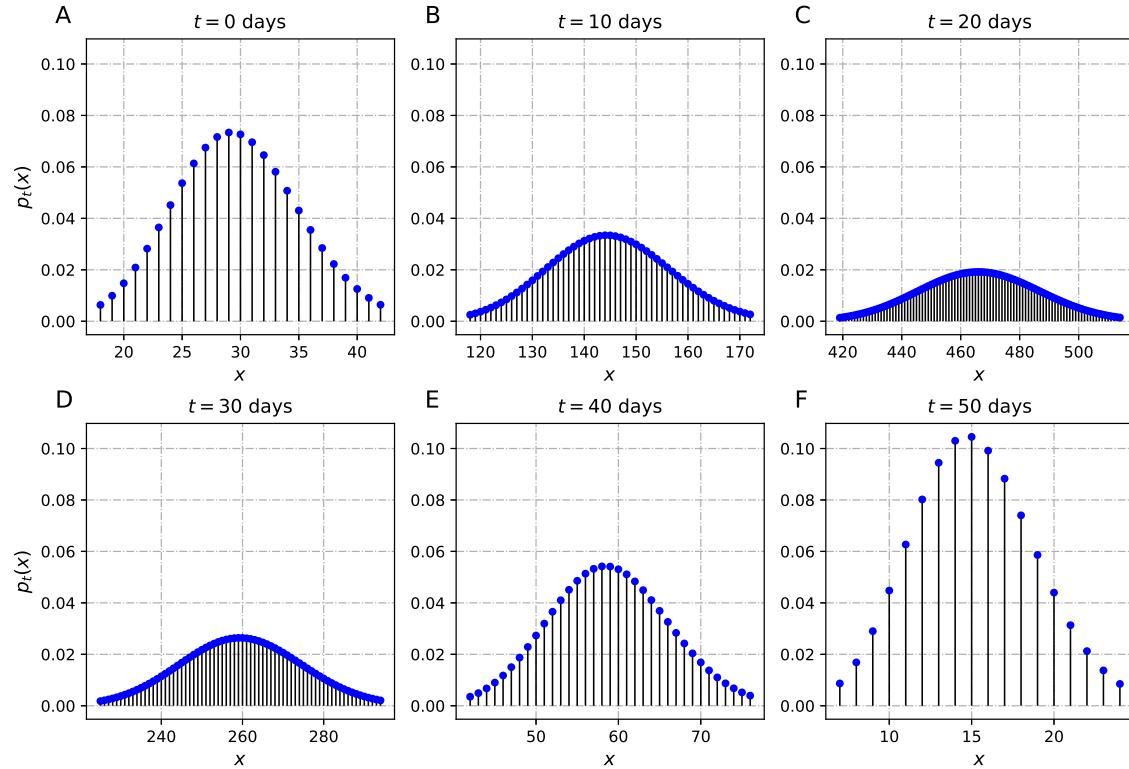

Figure 3: Example of the evolution of the probability mass function $p_t(x)$ of new infections x in the basic sED model as a function of time t . Time progresses through the panels, where panel A represents the beginning of the epidemic, panel B represents day 10, panel C represents day 20, and so on until panel F representing day 50. The parameters used in the simulation were $T_0 = 10,000$, $\beta = 0.3$, $\mu_R = 27$, $\mu_D = 24$ and $h = 1$.

individuals. The event in which an individual *stops being infected* can then be thought of as a sequence of independent trials, each lasting h time units, in which the individual remains infected and in the last trial the person either recovers or dies. The *routing probability* to the recovered state, that is, the probability that an individual eventually recovers, is then given by

$$r_R = \sum_{j=1}^{\infty} \left(1 - p_R^h - p_D^h\right)^{j-1} p_R^h = \frac{p_R^h}{p_R^h + p_D^h} = \frac{\mu_D}{\mu_R + \mu_D}. \quad (8)$$

The probability that an infected individual eventually dies is $r_D = 1 - r_R$. Explicitly,

$$r_D = \frac{\mu_R}{\mu_R + \mu_D}. \quad (9)$$

Note that these two probabilities do *not* depend on the time step h .

The dynamics of the multinomial trials for each infected person can also be thought of as Bernoulli trials with probability of success $p_R + p_D$, and the elapsed time τ_I can then be thought of as a random variable with a mean $\bar{\tau}_I$ given by the inverse of the probability (rate) of leaving the infectious state,

$$\bar{\tau}_I = \frac{1}{h(\mu_R^{-1} + \mu_D^{-1})}. \quad (10)$$

This means that the model can be formulated in terms of the routing probabilities and the mean time spent in the infection stage, $(r_R, r_D, \bar{\tau}_I)$, which could possibly be obtained from hospitalisation data, instead of the mean infection times spent by a person before recovery or death, (μ_R, μ_D) . Using equations (8)-(10) we have

$$p_R^h = \frac{h}{\mu_R} = \frac{r_R}{\bar{\tau}_I}. \quad (11)$$

The inverse of the mean time spent in the infected phase is thus proportional to the probability that within h time units an individual stops being infected, regardless of the outcome.

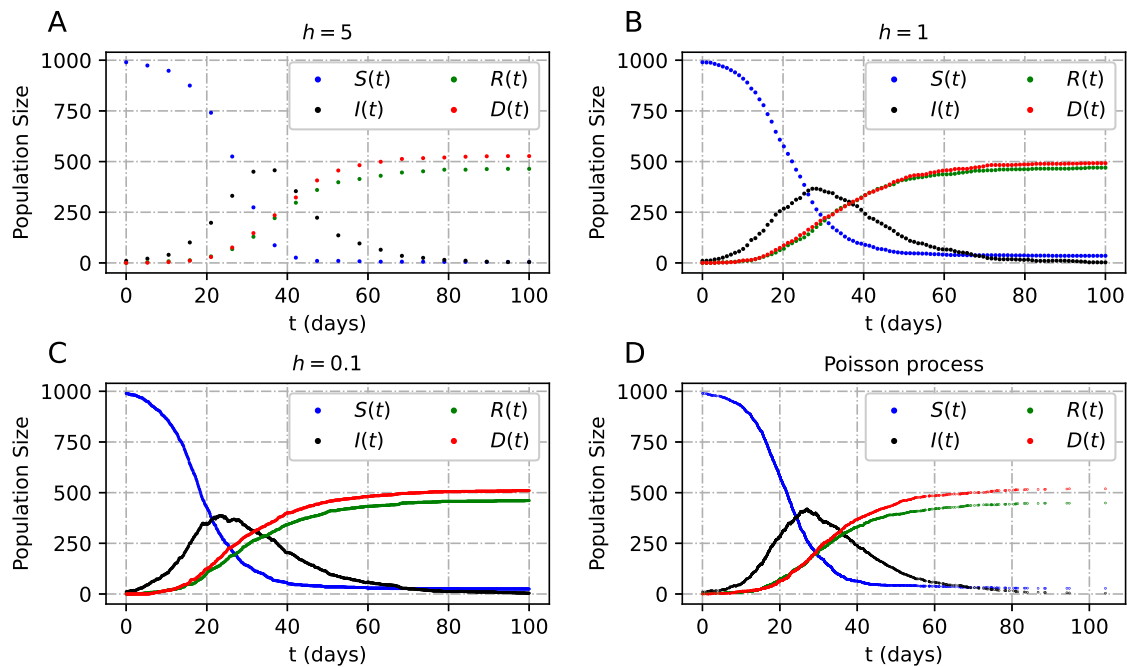

Figure 4: Dynamics of the sED model for decreasing step sizes (h) (A-C), and the approximation of the model using the Poisson process (D). For this simulation $\mu_R = 27$ and $\mu_D = 24$, and the other parameters can be found in Table 1.

2.4 Continuous time Markov chain approximation

Now consider an approximation for the simple sED model, in the case when the step size h (the discrete units of time for the simple sED model) decreases to zero for integer population sizes. The approximation gives insight about the theoretical properties in the limit for small step sizes, and the limit process is relatively easy to simulate since it is a continuous time Markov chain process (Fig. 4).

Recall that a non-homogeneous Poisson process $\{N(t) : t \geq 0\}$ with intensity $\lambda(t)$ and starting at the origin, can be assumed to have independent increments such that,

$$\begin{aligned}\mathbb{P}(N(t+h) - N(h) = 1) &= h\lambda(t) + o(h), \\ \mathbb{P}(N(t+h) - N(h) \geq 2) &= o(h),\end{aligned}\tag{12}$$

for any $t \geq 0$ (see for instance [Basu, 2003](#), p. 142). Consider the sED state vector $\{(S(t), I(t), R(t), D(t)) : t \geq 0\}$ with dynamics given by equations (3)-(5), starting from some initial condition $(S(0), I(0), R(0), D(0))$. Assume that

$$\hat{X}_I^h(0) = \hat{Y}_R^h(0) = \hat{X}_D^h(0) = 0$$

with the super index h emphasising dependence on the size of the time step. After k steps, the cumulative sampling processes can be written as

$$\hat{X}_I^h(kh) = \sum_{i=1}^k X_I^h(ih), \quad \hat{Y}_D^h(kh) = \sum_{i=0}^k Y_D^h(ih), \quad \hat{Y}_R^h(kh) = \sum_{i=0}^k Y_R^h(ih).$$

These processes are defined for a discrete set of times $\{0, h, 2h, \dots\}$, but they can be extended for any positive time as left-continuous step functions on continuous time, taking a discrete set of values. For example, $\hat{X}_I^h(t) := \hat{X}_I^h(kh)$ for any $kh \leq t < (k+1)h$, with $k \in \mathbb{N}$. As a consequence, the limit processes

$$N_I(t) := \lim_{h \rightarrow 0} \hat{X}_I^h(t), \quad N_R(t) := \lim_{h \rightarrow 0} \hat{Y}_R^h(t), \quad N_D(t) := \lim_{h \rightarrow 0} \hat{Y}_D^h(t),$$

are non-homogeneous Poisson processes. We show that in the following lines.

By construction N_I, N_R and N_D start at the origin, and the random variables $\{X_I^h(kh)\}_{k \in \mathbb{N}}$ are independent, which means that the process \hat{X}_I^h has independent increments on disjoint intervals of the form $[n_1h, n_2h]$ where $n_1 < n_2$ are non negative integers. Therefore, the

limit processes N_I , and by a similar argument, N_R and N_D , have independent increments. Further, for $t \in [kh, (k+1)h)$, $S(t) = S(kh)$, $I(t) = I(kh)$, and

$$\mathbb{P}(\hat{X}_I^h(t+h) - \hat{X}_I^h(t) = 1) = \mathbb{P}(X_I^h(kh) = 1).$$

Since $X_I^h(kh)$ has a Binomial distribution with parameters $S(kh)$ and $h\beta I(kh)/T$, respectively, it follows that

$$\begin{aligned} \mathbb{P}(\hat{X}_I^h(t+h) - \hat{X}_I^h(t) = 1) &= S(kh) \left(h\beta \frac{I(kh)}{T(kh)} \right)^1 \left(1 - h\beta \frac{I(kh)}{T(kh)} \right)^{S(kh)-1} \\ &\approx S(t)h\beta \frac{I(t)}{T(t)} + o(h), \end{aligned}$$

for $h > 0$. Also the probability

$$\mathbb{P}(\hat{X}_I^h(t+h) - \hat{X}_I^h(t) \geq 2) = \sum_{i=2}^{S(kh)} \binom{S(kh)}{i} \left(h\beta \frac{I(kh)}{T(kh)} \right)^i \left(1 - h\beta \frac{I(kh)}{T(kh)} \right)^{S(kh)-i},$$

has order $o(h)$, for $h > 0$. In the limit as h goes to zero, the process N_I satisfies equation (12) and \hat{X}_I is thus a non-homogeneous Poisson process with intensity $S(t)\beta I(t)/T(t)$. Since, $(Y_R^h(kh), Y_D^h(kh), I(kh) - Y_R^h(kh) - Y_D^h(kh))$ is Multinomially distributed for kh , we have that $Y_R^h(kh)$ is Binomially distributed with parameters $I(kh)$ and p_R^h . Likewise, $Y_D^h(kh)$ is Binomially distributed with parameters $I(kh)$ and p_D^h . The processes N_R and N_D satisfy (12), which can be proven by following the same reasoning as for N_I .

Taking into account the arguments just presented, as the step size h decreases to zero, the sED system $\{(S(t), I(t), R(t), D(t)) : t \geq 0\}$ based on Binomial samples converges in distribution with order $o(h)$ to the system $\{(\hat{S}(t), \hat{I}(t), \hat{R}(t), \hat{D}(t)) : t \geq 0\}$ based on Poisson sampling, starting from the same initial conditions, with dynamics given by

$$\begin{aligned} \hat{S}(t) &= S(0) - N_I(t), \\ \hat{I}(t) &= I(0) + N_I(t) - (N_R(t) + N_D(t)), \\ \hat{R}(t) &= R(0) + N_R(t), \\ \hat{D}(t) &= D(0) + N_D(t), \end{aligned}$$

where N_I, N_R, N_D are non-homogeneous Poisson processes with corresponding intensity rates $\gamma_S(t) = \hat{S}(t)\beta I(t)/T(t)$, $\gamma_R(t) = \hat{I}(t)\mu_R^{-1}$, and $\gamma_D(t) = \hat{I}(t)\mu_D^{-1}$. Note that the

model dynamics depend on the size of the population $T(t)$ for each time t . In the idealised situation where the total size of the population is constant, $T(t) \equiv T$ (no deaths), the model is greatly simplified because the limit process $(\hat{S}(t), \hat{I}(t), \hat{R}(t))$ boils down to a continuous time Markov chain with state space contained in the set $\{0, 1, \dots, T\}^3$ and infinitesimal generator matrix with transition rates given by

$$\begin{aligned} q((s, i, r), (s - 1, i + 1, r)) &= s\beta \frac{i}{T} 1_{\{1, 2, \dots, T\}}(s), \\ q((s, i, r), (s, i - 1, r + 1)) &= \mu_R^{-1} i 1_{\{1, 2, \dots, T\}}(i), \end{aligned}$$

for $s, i, r \in \{0, 1, \dots, T\}$.

The basic models presented up to this point have some advantages, including the possibility of modelling epidemics in very small populations. However, these basic models have some limitations that can be overcome by extending the basic model. For instance, we will include different stages for the severity of infection to analyse the impact they have in the case-fatality ratios, a quantity often ignored in modelling studies. Importantly, the extensions are constructed following the same rationale used for the basic models.

Table 1: Notation and values used for simulations with the basic sED model.

Symbol	Values	Units	Description
T_0	1000	persons	Initial population size
S_0	10	persons	Initial size of susceptible population
I_0	990	persons	Initial size of infected population
R_0	0	persons	Initial size of recovered population
D_0	0	persons	Initial size of population dead due to disease
X^h	$[0, S]$	persons	Size of newly infected sample (depends on time step)
Y_R^h	$[0, I]$	persons	Size of newly recovered sample (depends on time step)
Y_D^h	$[0, I]$	persons	Size of n sample (depends on time step)
μ_R	$[22, 32]$	days	Expected time between initial infection and death due to disease Li et al. (2020) ; Zhou et al. (2020)
μ_D	$[19, 29]$	days	Expected time between initial infection and death due to disease Li et al. (2020) ; Zhou et al. (2020)
β	0.3	—	Probability of infection given an contact with an infected person Phucharoen et al. (2020)
ε	1	1	Proportion of exposed susceptibles
κ	1	1	Proportion of exposed infected
h	1	days	Time step

3 Applications

3.1 The classical SIR model from the basic sED model

The classical SIR model describes the dynamics of an epidemic in a large population of *constant* size, in terms of three non-overlapping subpopulations representing susceptible, infected, and those that cannot participate in the chain of infections (either formerly infected or immune from the start). One key assumption of the classical SIR model is that individuals that cease being infected do not become susceptible again. In its continuous time and continuous state version, the SIR model can be written as a system of differential equations constructed under the assumption that the population is heterogeneously mixed and of fixed size (no deaths due to infection), with transmission occurring possibly after a contacts between susceptible and infected individuals.

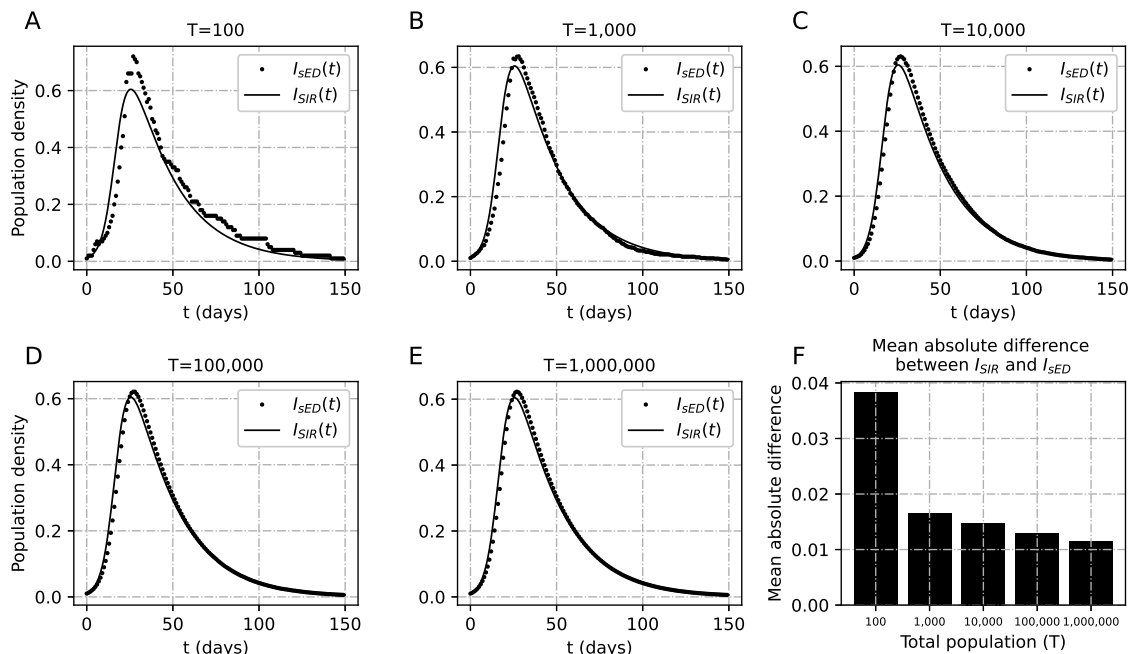

Figure 5: Density of infections for different population sizes of SIR vs sED dynamics obtained by replacing the sampling processes by their mean at each time step (A-E). The bars on panel F indicate the size of the difference between the total infected over time between the two models as a function of the population size. For these realisations, $\mu_R = (27 + 24)/2$ for the sED model without deaths, and $\beta = 0.3$ and $\gamma = 2/(27 + 24)$ for the SIR model.

An analogue of the classical SIR model can be obtained as a particular case of the basic sED model (equations (3)-(5)) by assuming that: (i) there are no deaths due to infections, which makes the population size T a constant; (ii) the samples $X_I^h(t)$ and $Y_R^h(t)$

are replaced by their expected values, which yields a deterministic system of difference equations; (iii) the population size is very large; (iv) the (integer) sizes of the epidemiological classes are replaced by subpopulation densities, thus enabling the possibility of thinking about state variables as continuous; and (v) the time step can be arbitrarily small to replace the difference equations with differential equations where the densities are continuous variables changing with respect (continuous) time.

Briefly and explicitly, the expected number of new infected between times t and $t + h$ is $h \beta S(t) I(t)/T(t)$, which means that, on average, the absolute incidence (new cases) between t and $t + h$ can be written as

$$S(t + h) - S(t) = -h\beta S(t)I(t)/T(t). \quad (13)$$

Similarly, the number of people expected to stop being infected between t and $t + h$ is $p_R^h I(t) = \mu_R^{-1}$, and the average change in a window of h time units is thus

$$I(t + h) - I(t) = h \left[\beta \frac{S(t)}{T} - \frac{1}{\mu_R} \right] I(t). \quad (14)$$

Then, if the (initial) population size T is large enough, we can let $x(t) = S(t)/T$, $y(t) = I(t)/T$, and $z(t) = 1 - (x(t) + y(t))$, and then write differential equations from equations (13)-(14) describing the dynamics of (x, y, z) by taking the limit as h tends to 0. If we let ∂_t denote the instantaneous rate of change with respect to time, then the dynamics for x and y can be described by differential equations of the form

$$\partial_t x = -\beta xy, \quad (15)$$

$$\partial_t y = (\beta x - \gamma) y, \quad (16)$$

with $\partial_t z = -(\partial_t x + \partial_t y) = \gamma y$ representing the time-dependent change in the density of the population that is immune to the disease (*i.e.* does not participate in the chain of transmission), and $\gamma = 1/\mu_R$.

3.1.1 Is it possible to write a simple and well posed extension for the continuous SIR to account for deaths?

Can we change equation (16) to include the possibility of death due to disease? One way to do that would be to split γ as a sum of two rates, one representing recovery, the other death, respectively. As a consequence, $z(t)$ would be now a sum of population densities

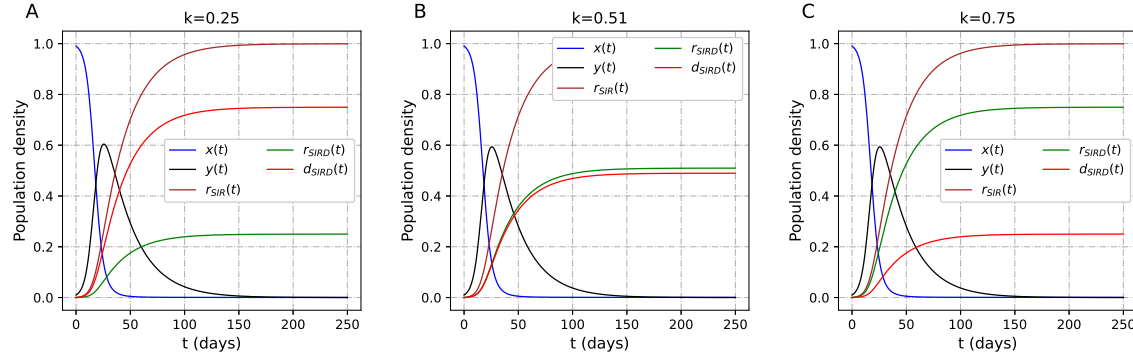

Figure 6: Systematic comparison between the dynamics of the SIR and SIRD models. The comparison was made assuming that $\gamma = \gamma_d + \gamma_r$ with $\gamma_d = k\gamma$, and $\gamma_r = (1 - k)\gamma$ and $k \in \{0.25, 0.51, 0.75\}$ (A, B, and C respectively), with $\gamma = 2/(27 + 24)$.

$d(t) + r(t)$ where $d(t) = D(t)/T(t)$ represents the proportion of people dying at time t , and $r(t) = R(t)/T(t)$ represents the proportion of people that do not participate in the chain of transmission at time t (either because they recovered or because they were immune to infection from the start). A typical setup for this would be to extend the system (15)-(16) to include

$$\partial_t r(t) = \frac{y(t)}{\mu_R}, \quad \partial_t d(t) = \frac{y(t)}{\mu_D}, \quad (17)$$

which could, in principle, be solved numerically to obtain approximations for the dynamics of the state vector (x, y, r, d) , for each time t (Fig. 6). However, the total population size at time t is $T(t) = S(t) + I(t) + R(t)$, so that $1 = x(t) + y(t) + r(t)$ for all $t \geq 0$, and

$$\partial_t r = -\partial_t(x + y) = \gamma y.$$

But $\gamma y = \partial_t z = \partial_t r + \partial_t d$, which means that $\partial_t d \approx 0$ for all $t \geq 0$. As a consequence, adding dynamics for deaths due to infection would add an inconsistency in the way the model is posed.

3.2 Limiting the exposure of the susceptible vs. limiting the exposure of the infected

Assume that a certain proportion ε of the susceptible are exposed to inoculation, and also, that only a proportion κ of those infected actively sheds inoculum.

Suppose that at any time t (days), non-negative integers $T(t)$ and $S(t)$ represent the size of the whole population and those susceptible to infection at time t . Let $\varepsilon(t)$ and $\kappa(t)$

respectively represent the proportion of the susceptible population that are exposed to the pathogen at any time t , and the proportion of infected people that shed inoculum. The values of $\varepsilon(t)$ and $\kappa(t)$ depend on factors that include the mobility of the population and other behavioural patterns.

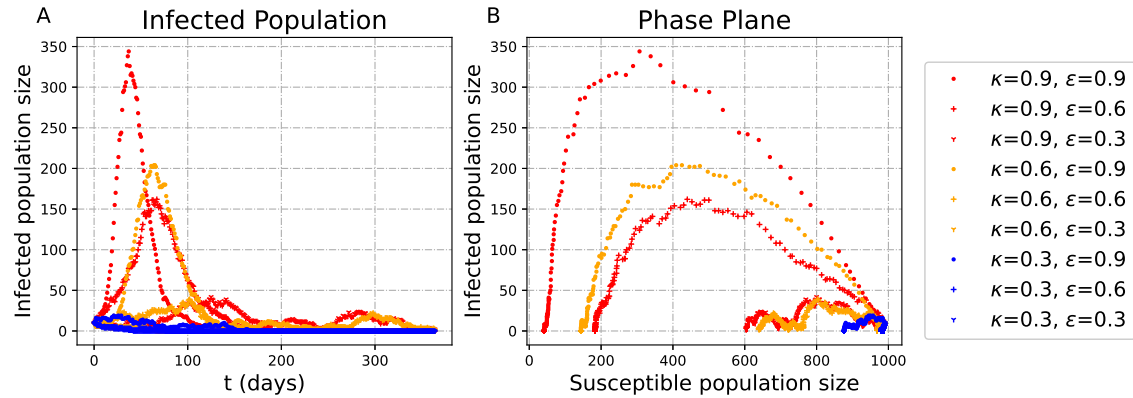

Figure 7: (A) Infection processes varying the exposure for susceptible and infected (ε and κ). (B) The $S - I$ phase plane for different values of p . Realisations were calculated using $\mu_R = 27$, and $\mu_D = 24$.

The number $X_I^h(t)$ of newly infected people (absolute incidence) can then be thought of as a *Binomial* random variable sampled from $\lfloor \varepsilon(t)S(t) \rfloor$ individuals. Assuming homogeneous mixing between the exposed susceptibles and the exposed infected, define

$$p^h(t, I) = P_I(h)Q_h(t, I) = P_I(h)\beta\frac{\kappa(t)I(t)}{T(t)} \quad (18)$$

where β , $\kappa(t)$ and $I(t)/T(t)$, respectively represent the probability that a susceptible person is infected after having an infectious contact (contact with the pathogen), the proportion of infected individuals shedding inoculum, and the proportion of infected individuals within the population at time t . $P_I(h)$ represents the probability that the infection occurs within a time window of length h , while being *exposed* to the pathogen causing the disease of interest. As a consequence, the number of newly infected individuals between times t and $t + h$ can be thought of as a random variable $X_I^h(t) \sim \text{Bin}(\lfloor \varepsilon(t)S(t) \rfloor, p^h(t, I))$, and the expected number of newly infected individuals would then be $p^h(t, I)\lfloor \varepsilon(t)S(t) \rfloor$.

Recall that a Binomial random variable with parameters n and p converges to a *Poisson* random variable with parameter np as n tends to infinity. In this way if $\lfloor \varepsilon(t)S(t) \rfloor \geq 10$ a Poisson random variable with parameter $\lfloor \varepsilon(t)S(t) \rfloor \cdot P_I(h)\beta\frac{\kappa(t)I(t)}{T(t)}$, has a probability distribution very close to the one of $X_I^h(t)$ (Poor, 1991). Observe that $\varepsilon(t)$ and $\kappa(t)$ appear as a product in the parameter of the Poisson approximation. Therefore, some degree of

symmetry can be expected for large enough populations in the behaviour of $I(t)$], and other quantities depending on $I(t)$ as a function of the exposures for susceptible and infected for large enough populations (Figure 8).

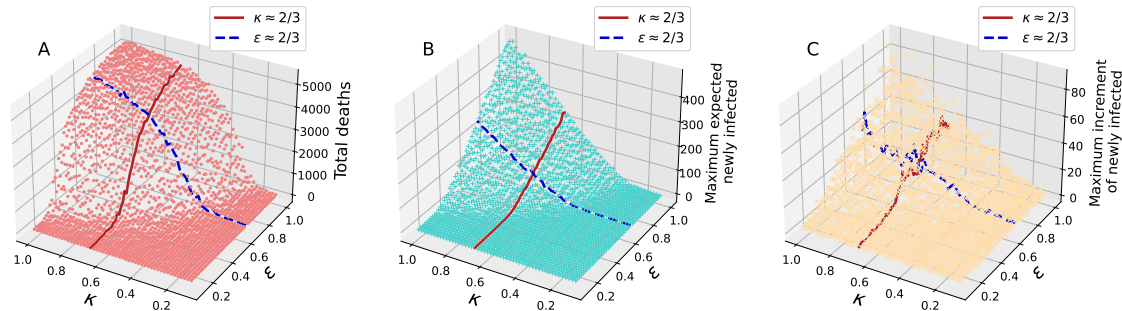

Figure 8: Quantities of interest that directly depend on $I(t)$, as a result of varying the exposure for susceptible and infected (ϵ and κ) in the basic sED model. The solid line in red corresponds to the case $\kappa = 2/3$, and the dashed line in blue corresponds to the case $\epsilon = 2/3$. (A) Total deaths, (B) maximum expected value of the newly infected individuals, and (C) maximum increment of the newly infected individuals between t and $t + h$.

In principle, it is possible to estimate the value of $p^h(t, I)\epsilon(t)$, if data of new infections is available. For infectious diseases like COVID-19, or Ebola, if time is in minutes, or larger, and h is only a few seconds ($h \ll 1$), then $p_I(h) \approx 1$, and the probability of infection given a contact with an infected individual is approximately $\beta \kappa(t)I(t)/T(t)$, as it has been proposed for models like the classical SIR.

3.3 Case fatality ratios and the necessity of considering infections with different severity stages

The probability that an individual recovers eventually (equation (8)) depends on two quantities mainly statistical in nature, μ_R and μ_D , respectively representing the mean time spent by an individual in the infectious state and the mean time spent infected before death. However, equation (8) does not capture the complexity of the relation between epidemiological waiting times like μ_R and μ_D , and the probability of having a good or a bad outcome. For example, the incubation time (the time between the initial inoculation and the emergence of symptoms) for some individuals may be very small, as they quickly develop an increasingly severe disease, significantly increasing the probability of death in comparison to other cases in which the disease is not as severe (Salinas-Escudero et al., 2020). Also, for some diseases the probability of recovery may decrease as individuals spend more days in a hospital (Faes et al., 2020; Salinas-Escudero et al., 2020). For

instance, during the first months of the COVID-19 pandemic, there were several studies reporting shorter hospitalization times with fatal outcomes in comparison to recovery times (Alimohamadi et al., 2021; Porcheddu et al., 2020).

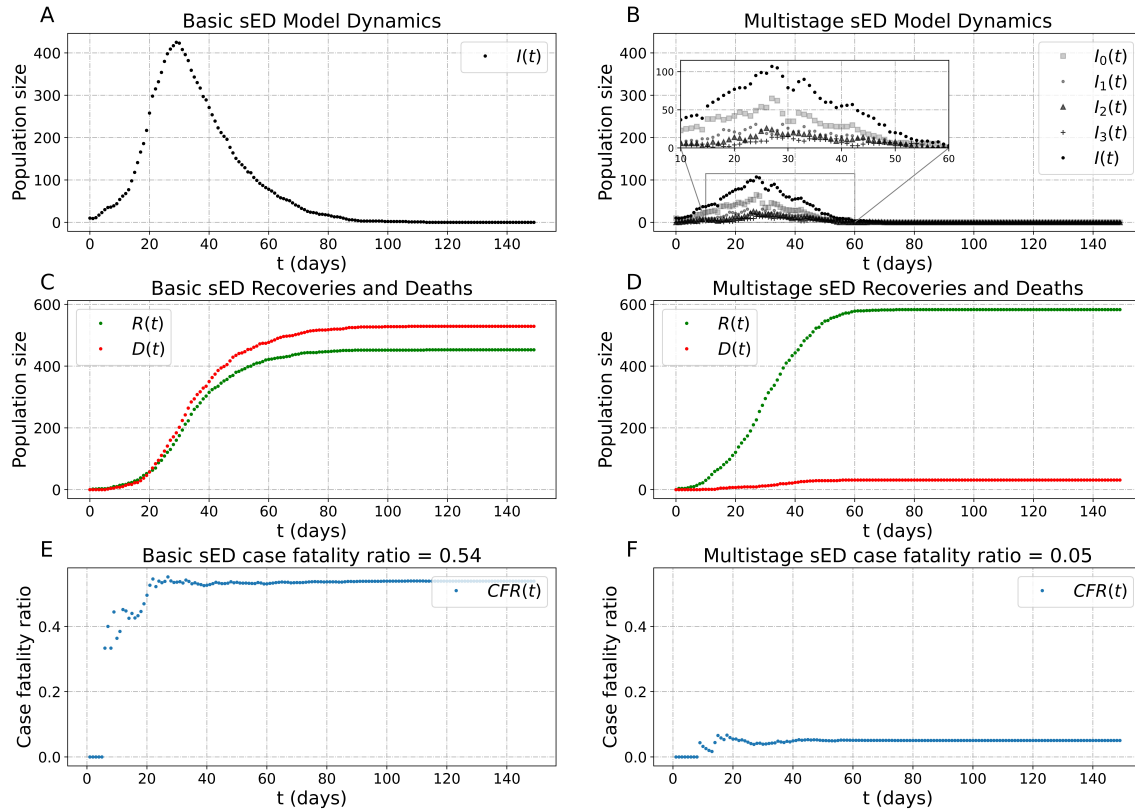

Figure 9: Case fatality ratios can be adjusted by assuming multiple infection-related epidemiological stages. Epidemiological dynamics of for multiple infection-related stages (A, C, E, respectively) versus a single infectious stage (B, D, F, respectively). Realisations in both cases were simulated assuming the same total expected infection time with $\mu_R = 27$ and $\mu_D = 24$ for the basic sED and $\mu_R^0 = 5, \mu_R^1 = 6, \mu_R^2 = 12, \mu_R^3 = 4$, and $\mu_D^0 = 5, \mu_D^1 = 5, \mu_D^2 = 5, \mu_D^3 = 9$ for the multistage sED. As before, the initial population size for these simulations is 1000.

Naturally, assuming $\mu_R > \mu_D$ for the basic sED model (and the SIR model) yields case-fatality ratios $D/(D + R) > 1/2$ (Figure 9 A, C, E), which does not necessarily happen for most infectious diseases. In particular, for COVID-19 $\mu_R < \mu_D$ and the CFR has been considerably smaller than 0.1 for all variants and all age groups (Bendavid et al., 2021; Cao et al., 2020; Luo et al., 2021). Thus, the most simple form of the sED model cannot yield small case-fatality ratios and simultaneously capture the macroscopic trends in the time course of $I(t)$. By extension, the same happens with the SIR model. To address this issue, we propose an adaptation of the basic model that takes a more realistic description of the disease history of individuals into account, thereby allowing the possibility of

reproducing both the macroscopic infection dynamics and the more detailed evolution of the recovered and deceased subpopulations.

3.3.1 Infections with multiple states

Before developing the extension model, it is important to remark that the time period in which an individual is capable of transmitting the infection does not necessarily coincide with the manifestation of clinical symptoms. For instance, shedding of viable inoculum occurs during the incubation period for many infectious diseases. Alternatively, it is also possible that an infected person stops transmitting viable virions or other infection-causing pathogens before recovering (Li, 2010). These events depend strongly on the disease (Baron, 1964). Of interest, it could also be the case that individuals in advanced stages of infection do not participate in the chain of transmission because of being spatially isolated; *e.g.* due to hospitalisation, self isolation, or because of losing the ability to move.

To get a better epidemiological description of the initial infection and possibly the subsequent clinical stages, we model the increase in the severity of infection assuming that the time course of infection is divided in different stages that progress toward more severe illness, until possibly reaching the death state in the absence of recovery. In other words, at each infectious stage the individual either recovers, or advances to a more severe state. At the last infectious stage, the only possibilities are either recovery or death.

Assume that the sizes of the infected or ill populations are represented by k state variables $\{I_0, \dots, I_{k-1}\}$, with indices increasing according to the severity of the disease. The states do not necessarily represent clinical states. The size of the infected population is therefore $I = I_0 + \dots + I_{k-1}$. It is assumed here that a person may recover from any infection stage, and cannot become part of the subpopulation in an infection state without having been through all the infection states of less severity. By extension, an infected individual cannot die without having been through all the infection states. For instance, for COVID-19 it is reasonable to assume that there are at least four possible infectious states labelled as 0, 1, 2, and 3, with population sizes I_0, I_1, I_2, I_3 , respectively representing an incubation period, followed by symptomatic stages I_1, I_2 , and I_3 of mild, middle, and severe stages, after which they could die (Figure 9 B).

Let $h\beta_i\kappa_i(t)$ be the probability of having an effective transmission within a time window of size h , given a contact between a susceptible person and an individual in the stage I_i . Then, by using the law of total probability counting over the partition on the different possible infectious subpopulations, the probability that a susceptible person becomes

infected in a time window of size h is given by

$$p^h(I_0, \dots, I_{k-1}, t) = h \sum_{i=0}^{k-1} \beta_i \kappa_i(t) \frac{I_i(t)}{T(t)}. \quad (19)$$

which generalises (18).

For the subsequent stages, in analogy with the Subsection 2.3.2, we can derive geometrically distributed times for advancing or recovering to the next stage for each individual. The probabilities that a person in the i th infectious stage advances to the next stage or recovers, within a small time interval of length h are estimated by

$$p_R^{(i)} \approx \frac{h}{\mu_R^{(i)}}, \quad p_I^{(i)} \approx \frac{h}{\mu_I^{(i)}}, \quad (20)$$

for $i \in \{0, \dots, k-1\}$, where $\mu_R^{(i)}$ is the mean time that a patient spends in the i th infectious stage before recovering and $\mu_I^{(i)}$ is the mean elapsed time that a patient spends in the i th infectious stage before moving forward to the next infectious stage. Accordingly, an individual remains infected in the i th stage with probability $1 - (p_I^{(i)} + p_R^{(i)})$. For computational and notational purposes, we can think the death stage as a stage labeled k with size I_k , and use this extra index in equation (20). Therefore, a Multinomial approach can be derived in each stage, to compute the number of individual that advances or recover in each state to give a complete description of the dynamics for this extension. A system that extends equations (3)-(5) taking into account the different infectious stages can thus be written as

$$S(t+h) = S(t) - X_0^h(t) \quad (21)$$

$$I_j(t+h) = I_j(t) + X_{j-1}^h(t) - (X_j^h(t) + Y_j^h(t)), \quad (22)$$

$$R_j(t+h) = R_j(t) + Y_j^h(t), \quad (23)$$

for $j \in \{0, \dots, k\}$, with total counts for recovered and dead given by

$$R(t+h) = \sum_{j=0}^{k-1} R_j^h(t+h), \quad (24)$$

$$D(t+h) = D(t) + X_k^h(t), \quad (25)$$

where $S(t)$, $I(t) = I_0(t) + \dots + I_{k-1}(t)$, $R(t)$, and $D(t)$ respectively represent the numbers of susceptible, infected, recovered, and dead individuals at time t . The sampling

underlying the evolution is given by

$$X_0^h(t) \sim \text{Bin}(\lfloor \varepsilon(t)S(t) \rfloor, p^h(t)),$$

$$(X_j^h(t), Y_j^h(t), I_j(t) - X_j^h(t) - Y_j^h(t)) \sim \text{Mult}\left(I_j(t), p_I^{(j)}, p_R^{(j)}, 1 - p_I^{(j)} - p_R^{(j)}\right),$$

for $j \in \{0, 1, \dots, k\}$, assuming that all samples are independent. The X 's represent the quantity of people advancing through infectious stages, the last one being death, and the Y 's represent the number of people recovering from the disease, at some given time.

The dynamics from this extension of the basic sED can be such that the total expected time before recovery is larger than the total expected time before death due to disease (Fig. 9), but such that the case fatality ratio is much smaller than 1/2 depending on the parameters of the model.

3.3.2 Probability distribution of the final stage reached by an individual

In this section we illustrate some mathematical properties of the multistage extension of the sED model just presented. We focus on the maximal stage of infection or disease that a given individual may reach before recovering. The reason is that the last stage and the final clinical outcome is of interest for clinical and epidemiological purposes (Roger, 2011).

Consider the sED model with multiple infection stages $S, I_0, \dots, I_{k-1}, R, D$ (equations (21)-(25)). Assume that one individual has been initially infected at some time t . By construction, the time spent infected and the maximal stage reached before recovering or dying will not depend on the (random) individual evolution.

First, using the same rationale as in the basic sED model, if an individual is in the i th stage of infection, the probability that the individual goes to the recovery state without passing to the next stage (without getting worse) is given by the routing probability of recovery $\mu_I^{(i)} \left(\mu_R^{(i)} + \mu_I^{(i)} \right)^{-1}$ (see Subsection 2.3.2).

By considering the equations for each stage, assuming independence between the sampling processes at different stages, and considering only the expected times for each stage of infection, the probability that the infected individual reaches the stage I_l ($l \leq k$) as maximal stage of infection or disease before recovering is given by

$$\left(\prod_{i=1}^{l-1} \frac{\mu_R^{(i)}}{\mu_R^{(i)} + \mu_I^{(i)}} \right) \left(\frac{\mu_I^{(l)}}{\mu_R^{(l)} + \mu_I^{(l)}} \right). \quad (26)$$

Using the same reasoning, the probability that a person dies is

$$\prod_{i=1}^k \frac{\mu_R^{(i)}}{\mu_R^{(i)} + \mu_I^{(i)}}. \quad (27)$$

Table 2: Notation and values used in the multistage extension of the sED model (Li et al., 2020; Zhou et al., 2020).

Symbol	Value	Units	Description
μ_R^0	[4.1,7.0]	days	Expected recovery time for asymptomatic people.
μ_R^1	[4.3,7.5]	days	Expected recovery time after first symptomatic stage.
μ_R^2	[9.0,15.0]	days	Expected recovery time spent after the second (mild) symptomatic stage.
μ_R^3	[2.0,9.0]	days	Expected recovery time spent in the third (severe) symptomatic stage.
μ_I^0	[4.1,7.0]	days	Expected incubation time.
μ_I^1	[4.3,7.5]	days	Expected time spent between the first and second symptomatic stages.
μ_I^2	[5.0,11.0]	days	Expected time spent in the second and third symptomatic stages.
$\mu_D = \mu_I^3$	[4.0,12.0]	days	Expected time spent in the third (severe) symptomatic stage before death.

4 Discussion

We have presented a derivation of a model for the epidemiological dynamics of infectious diseases based on simple assumption: at any given time, individuals in any epidemiological stage are the subjects of a random sampling process in which they either remain in their epidemiological stage, or move to a different stage. Then we have distinguished two different types of sampling. In the first sampling type, individuals are chosen depending on an interaction with another subpopulation, as is the case during the infection process. In the second sampling type, sampling depends on waiting times. As a result, we have obtained a simple, easy to implement model derived from common sense rules, that takes into account different sources of randomness in the evolution of infectious diseases. The model works for small and large populations as well, and also, allows extensions to study the effects of specific factors that may become important determinants of the epidemics (e.g. exposure of infected vs. exposure of susceptible, single vs. multiple disease stages). *En passage*, we explain how to derive a continuous time, continuously valued SIR model

from the sED model, and in what circumstances do the classical SIR models work, and expose some of the problems that arise in extensions of the SIR models intended take into account deaths due to disease. We also show a few mathematical properties related to the expected times spent by an individual in different epidemiological stages. Of particular interest, we show how case fatality ratios in models with only one infectious stage would be larger than or equal to $1/2$ unless the expected time for recovery is shorter than the expected time for death due to disease. We also show that realistic values for the CFR can be only be obtained in models with more than one infectious (or clinical) stage that allows percolation of the population through different infectious stages and recovery before reaching the last stage and dying.

4.1 Why do we need a different model than the SIR model?

One issue of interest is the theoretical and practical impossibilities of using the SIR model for small populations (equations (15)-(16)). However, there are many epidemics in which the populations of interest are small (e.g. small villages in Liberia during Ebola outbreaks). For large enough populations the dynamics of the deterministic SIR model can be compared to simulations of the dynamics obtained with the sED model after dividing the sED state variables by the population size (Fig. 5). In doing so, we show that simply adding another variable to the regular SIR deterministic dynamics to account for deceases leads to a contradiction, thereby showing that such a model would be conceptually ill-posed. Further, we illustrate the similarity between the dynamics of the continuous state, deterministic model obtained from the sED model, and the sED model. To do so, we show that the distance between the normalized 3-dimensional vector $(S(t), I(t), R(t))/T(t)$ and its deterministic counterpart $(x(t), y(t), z(t))$ decreases robustly as the population size T increases (Fig. 5).

There are many possible extensions that could be implemented from the sED model. For instance, the assumption of having a homogeneous population can be easily dropped by allowing different probabilities of infection for more than one subpopulation. One easy way to do this is to use object oriented programming to create a generic class with sED dynamics for a single homogeneous population. Then it is possible to simulate the joint dynamics of more than one homogeneous population by setting a meta-class that allows the interactions of several instances of the class for a single population (Supplementary Material 1). The need for better understanding of the epidemiology and immunology underlying different co-morbidities for COVID-19 and other infectious diseases has been

repeatedly suggested by surveillance data, genetic profiling data (Velavan et al., 2021), CT-value readings in RT-PCR tests (Waudby-West et al., 2021), and serological testing (Toulis, 2020). The modelling scheme presented here could also be extended to take into account populations with different susceptibilities. For instance, it became clear very early during the COVID-19 pandemic that overweight or obese people were at a larger risk of having a severe or lethal outcomes upon infection (Busetto et al., 2020; Hamer et al., 2020; Popkin et al., 2020). Another possible extension could aim to model epidemics with different mechanisms of infection.

The modelling scheme presented here allows the construction of extensions of the basic sED model to address these and other issues using data, which opens the possibility of adding a layer of knowledge and understanding that would potentially have a positive impact on decision making policies, and help health care providers.

4.2 The effects of exposure of susceptible and infected on the epidemic dynamics

Infection processes occurring between pairs of individuals depend at least in three aspects: the potential effectiveness of the infected individuals in transmitting the infection, the vulnerability to infection of the susceptible individuals, and the physical exposure between them, typically occurring through physical contact. These aspects are very difficult to measure precisely, but they can be thought of as independent, and different indirect statistical measures can be used to produce estimations for them. Examples of these include viral load as an indicator of infectivity potential (Jones et al., 2021; Marc et al., 2021); existence of comorbidities to measure vulnerability (MK et al., 2021); presence of antibodies in an individual as indicators of infection severity and history of infections (Legros et al., 2021); mobility in cities as a proxy of physical exposure (Lu and Gan, 2022), especially in consideration of lock downs and social distance and public health measures (Wu et al., 2021). The sED model allows us to explicitly separate exposition of the susceptible population and the exposure of people with the potential to infect others. This allows us to observe explicitly the different dynamics resulting from having drastic reductions in each factor, opening the possibility of establishing or discarding the efficacy of public health measures directed to the reduction of such factors. To model one specific scenario that can be thought of in the context of the COVID-19 pandemic, we chose values for the exposures of infected people, $\kappa \approx 2/3$, to produce a conservative simulation of a scenario in which the proportion of asymptomatic infected people was similar to that observed for

COVID-19 (red curves, Figure 8, He et al. (2021)). From those simulations, it can be appreciated that the strategy to mitigate the epidemics by reducing the exposure of people in general could fail if the values of ε are not small enough. That is, the strategy does not work unless the reduction in exposure for susceptible individuals decreases dramatically. For instance, for $\kappa = 2/3$, at most 1/3 of the susceptible individuals or less should be exposed in order to have a drastic reduction of in prevalence, incidence, and the resulting deaths. The strategy in this case was estimated so that death cases did not enter the parts of the curve with larger slopes (Figure 8). Note that the strategy for health care providers and health system decision makers could be focused on the rate of change of the incidence instead using the same analysis.

Sadly, our model also confirms empirical observations that can be obtained from data of cases produced by the different SARS-CoV-2 variants around the world, showing that reduction of cases by limiting exposure could be nearly impossible for epidemics in which the asymptomatic infected and contagious population is largely exposed, and uncontrolled by direct epidemiological tracing measures (e.g. surveillance in public transportation stations and hubs). Our model complements previously well known results and demonstrates in a very simple way why consideration of transmission mitigation strategies based on lock-downs and limited mobility (Arino and Van den Driessche, 2003, 2006) should not be taken lightly, at least in the absence of effective surveillance (Bendavid et al., 2021; Sood et al., 2020) aimed at reducing the exposure of infected people to the general population. The results we show also make a case for the consideration of other mitigation strategies based on non-massive isolation and focused protection (Bhattacharya et al., 2021; Kullforff et al., 2021) that would also avoid economical and sociological harm imposed by lock-downs (Foster, 2020).

4.3 Infection vs infectivity

The sED model can describe some aspects concerning the infectivity and lethality of a disease that cannot be directly explained by the force of infection and the basic reproduction number. For a fact, but also for epidemiological purposes, the infection time may not necessarily be equal to the time interval in which a person is infectious. For instance, an infected person during the incubation period, or already in the process of clearing the virus, may have a sufficiently low viral load such that the person is effectively not infectious (Folgueira et al., 2021). Similarly, the infection time may include a period of symptoms that may be severe enough to reduce the exposure of the infected person (e.g. hospital-

isation or self isolation), potentially decreasing the availability of inoculum shedding for other people to get infected. The sED model can be easily adjusted to study the case in which infectivity periods last less than the (clinical)infection time (and viceversa). Further, it is also possible to include decreased levels of exposure by the infected; we study those cases in a companion paper dedicated to study COVID-19.

Of note, hypothesis in the sED model that infection depends on the exposure of those infected in environments where susceptibles may be inoculated applies also to infections that depend on non-human vectors like dengue. This is justified by recent data from dengue outbreaks and endemicity in densely populated urban areas (Falcón-Lezama et al., 2017; Villabona-Arenas et al., 2016). Consider the case in which there is one female mosquito per building in an apartment complex. The radius of interaction of the mosquito can easily be 25 meters, without taking into account vertical interactions. This means that one case of dengue in one building could result in many more cases, without the need of an abundant population of mosquitoes. The sED model uses simple parameters that can, nevertheless, capture such complex infection processes. Those parameters can be calibrated using the statistical information available. Then the model can be used to analyse qualitatively different scenarios depending on those parameters. In particular, the multistage sED model allows to divide the process of infection using different layers related to different possible mechanisms of infection and transmission of the diseased studied.

4.3.1 Multiple stages for infection and illness progression

As pointed out earlier, an adequate scheme to model the evolution of many diseases, should be one in which classification of infection states is constructed according to the physiological changes of the individual, whether or not they depend on clinical assessment. The clinical stages associated with infections and disease due to such infections can then also be considered. Note, however, that only taking clinical considerations into account may result in very inaccurate assessments with possibly undesired consequences. For instance, infections with SARS-CoV-2 cause a large percentage of asymptomatic cases (non-clinically detected), that in turn, has resulted in large increases in the incidence of cases that in some cities have overwhelmed the local health systems (Zhao et al., 2020). This is at large our motivation for thinking about the pathophysiological states of an individual during an infection as the base for our modelling scheme.

Constructing a model by taking the physiology related to the infection as a basis to classify different subpopulations may result in an inability to estimate parameters in an

statistically meaningful way. However, the sED model is simple enough and easy to expand so that anyone could use it to explore qualitatively different outcomes of an epidemic, and identify underlying mechanisms guided by fitting real data (e.g. prevalence and incidence curves). That was the case leading to the extension of the basic sED model into the multistage model (Section 3.3), with which we show how CFRs with very low values can be obtained by simply introducing multiple, subsequent infection stages with the condition that individuals who die from the infection must go through all disease stages before dying. By means of exploration, the multistage sED model thus provided some insight about why it would not be possible to obtain low CFRs with shorter recovery intervals in comparison to hospitalisation times, as documented during the first months of the COVID-19 pandemic. *En passage*, that analysis also shows that it would not be possible to model COVID-19 with classical SIR dynamics unless the model is modified by stratifying the disease stages before death.

4.4 Future perspectives and concluding remarks

One important factor to consider for possible extensions of the model is the variation in the behaviour of an individual's immune system in the presence of microbes, and after an infection (Glück et al., 2005). The overall physiological state of the individual (Bryant and Curtis, 2013), and other genetic or epigenetic factors (Zhang and Cao, 2019) are important during the initial contact and the subsequent phases of infection.

For instance, recent evidence from the COVID-19 pandemic shows that clinical outcomes can be defined by factors such as the body fat ratio, which has been correlated to the capacity of an individual to produce inflammatory responses (Brojakowska et al., 2021). As a consequence, the individual profile that possibly includes details related to his/her immune status is essential to define possible courses of disease evolution. The hierarchy of models presented here can be used to model disease spread in small and large populations that may include individuals with different levels of susceptibility (work in progress).

It is worth mentioning that the concept of immunity, by name, is relatively ill posed, as large enough inoculations will almost surely result in symptomatic or even severe disease for people that already had contact with the infectious pathogen. In other words, reinfection is always a possibility for large enough inoculations, and possibly not so large ones, as shown by the massive number of COVID-19 reinfections. The severity of disease for reinfections can, in principle, be assumed to be mild or nonexistent. However, the recent COVID-19 pandemic provided with several counter-examples to that. In this regard,

we are particularly interested in developing extensions addressing the study of epidemiological dynamics with reinfection, possibly involving different levels of severity in the reinfection outcomes (Montoya et al., 2013).

In this article we presented a new mathematical model to describe epidemiological dynamics. Its purpose is to describe some crucial aspects observed in the evolution of pandemics often not taken into account in the existing modelling literature, while simultaneously being intuitive, based on common sense arguments, and robust enough to be easily adapted to different particular features of diseases.

Disclosures. Some of the work contained in this article is part of the thesis written by CINH (Herrera-Nolasco, 2020) to obtain a Bachelor's degree in Mathematics at Facultad de Ciencias, UNAM. MAHV's contribution was supported by DGAPA-PAPIIT-UNAM grant IN-228820. SIL's contribution was supported by DGAPA-PAPIIT-UNAM grant IN-102822.
