59 Supplementary information S2: Anthropometric data cleaning and growth curve fitting

60 For all anthropometric variables, we set values that were biologically implausible to missing. Biological implausibility 61 was determined by manual examination of the distribution of weight, height, BMI and ponderal index at each age 62 and, where relevant, by comparison of values to those at earlier and later timepoints. Implausible weight and height 63 values were excluded prior to calculation of BMI and ponderal index.

We analysed the children's mother-reported BMI at age 6 months and 1, 2, 3, 5, and 8 years. Analyses involving mother-reported BMI measurements had different sample sizes for each age due to missing data (either for whole questionnaires or for individual questions within questionnaires). Furthermore, analyses involving mother-reported BMI measurements made inefficient use of the available data, because each mother-reported measurement was considered in isolation without accounting for the child's other measurements, and sometimes children had multiple measurements available at similar ages, of which only one was used. In order to maximise statistical efficiency we 70 therefore used all available offspring BMI measurements to fit a growth curve, from which we predicted offspring BMI at 1 year intervals between age 1 and 8 years. These fitted BMI values, which we refer to as "predicted BMI", were used as outcomes as a supplement to the mother-reported BMI measures described above, enabling comparison of linear regression and MCoTS results from an identical (and larger) sample across different ages.

74 Children with at least one BMI measurement taken between 1 and 8 years of age were included in the sample used 75 to fit the growth curve. BMI across childhood has a complex shape; there is a steep increase from birth to around 9 76 months of age (which is referred to as the adiposity peak), then a decline until around 6 years of age (the adiposity 77 rebound) before increasing through puberty. Due to this complex shape, measurements taken before age one were

78 not used as several repeated measures in the first year of life are required to accurately model the adiposity peak 79 (1). In total, 323,372 measurements from 80,805 individual children (48.8% female) were used, and the mean 80 number of measurements per child was 4.00. We did not natural log transform BMI measurements prior to fitting the growth curve because BMI was only slightly skewed from age five onwards. We fit a linear mixed model, 81 82 separately in males and females with linear, quadratic and cubic terms for age in both the fixed and random effects to account for nonlinearity of BMI change over time, using the R package nlme (2, 3). The random effects allow the 83 84 intercept and slope to vary around the population mean for each individual, and appropriately account for clustering 85 of BMI measurements within individual children. Prior to model fitting, age was centered at four years (the mean 86 age in the data). To ensure we had the best fitting model, we varied both the fixed and random effects and the 87 correlation structure for the residuals then compared the models using the Akaike Information Criterion (AIC), Bayesian Information Criterion (BIC) and likelihood ratio tests. We established that (i) linear, quadratic and cubic 88 89 fixed and random effects were required to adequately describe the growth curve, and (ii) a first order continuous autoregressive (AR1) correlation structure for the residuals gave better fit than a compound symmetry structure or 90 unstructured residuals. Therefore, the final model for the BMI of the i^{th} individual at the t^{th} time point (age) was: 91

$$BMI_{it} = \beta 0 + u0_i + \beta 1age_{it} + u1_i age_{it} + \beta 2age_{it}^2 + u2_i age_{it}^2 + \beta 3age_{it}^3 + u3_i age_{it}^3 + e_{it}$$

93 where $\beta 0$, $\beta 1$, $\beta 2$ and $\beta 3$ are the fixed coefficients representing the average intercept and linear, quadratic and 94 cubic age effects respectively. $u0_i$, $u1_i$, $u2_i$ and $u3_i$ are the random coefficients representing the deviation for 95 individual *i* from the average intercept and linear, quadratic and cubic age effects respectively, with $u_i \sim N(\mathbf{0}, \mathbf{G})$ 96 where \mathbf{G} is the variance-covariance matrix of the random effects. e_{it} is a normally distributed residual capturing the 97 deviation of the i^{th} individual at the t^{th} time point from the individual growth curve, $e_{it} \sim N(\mathbf{0}, \mathbf{\Sigma})$ where $\mathbf{\Sigma}$ is the 98 residual correlation matrix and a first order continuous autoregressive (AR1) correlation structure was assumed. The 99 model accounts for missing data on the assumption that data are missing at random.

We used the growth curve to calculate predicted BMI (i.e. the fitted values from the linear mixed model) at one year age intervals between one and eight years, separately for male and female offspring, for children with at least three BMI measurements available. From age five onwards, predicted BMI variables were slightly skewed so were natural log transformed prior to subsequent analysis.

104

105 Supplementary information S3: Covariate data

MoBa mothers and fathers each completed a questionnaire at around 17 weeks of gestation (which are referred to here as "Questionnaire 1", and "Father Questionnaire"). MoBa questionnaire data were linked to the Medical Birth Registry of Norway (MBRN) version 2017Q4 (4), which contained data from the birth notification forms (99.9% of pregnancies), or notification forms related to termination of pregnancy (0.1% of pregnancies). The questionnaireand MBRN-derived variables used in the present study are detailed in the table below.

Variable	Data source	Categories	Notes
Maternal parity	MBRN	"zero", "one", "two", "three", "four or more"	The highest value of the separate variables "parity registered by MBRN" and "parity reported by the mother" was used
Maternal smoking during pregnancy	Questionnaire 1	"yes, "no"	
Paternal smoking during pregnancy	Paternal questionnaire, Questionnaire 1	"yes, "no"	Maternal report was substituted for missing paternal report data for 23.9% of fathers
Maternal educational attainment	Questionnaire 1	"Incomplete 9-year secondary school", "9-year secondary school", "1-2 year high school", "vocational high school", "3-year high school general studies/junior college", regional technical college/4- year university degree", "university/technical college, more than 4 years", "other"	
Paternal educational attainment	Paternal questionnaire, Questionnaire 1	"Incomplete 9-year secondary school", "9-year secondary school", "1-2 year high school", "vocational high school", "3-year high school general studies/junior college", regional technical college/4- year university degree", "university/technical college, more than 4 years", "other"	Maternal report was substituted for missing paternal report data for 23.6% of fathers
Parental language	Questionnaire 1	"Norwegian", "other"	
Grandparental language	Questionnaire 1	"Norwegian", "other"	
Maternal income	Questionnaire 1	"no income", <150,000 NOK", "150,000-199,999 NOK", "200,000-299,999 NOK", "300,000-399,999 NOK", "400,000-499,999 NOK", >500,000 NOK "	
Paternal income	Paternal questionnaire, Questionnaire 1	"no income", <150,000 NOK", "150,000-199,999 NOK", "200,000-299,999 NOK", "300,000-399,999 NOK", "400,000-499,999 NOK", >500,000 NOK "	Maternal report was substituted for missing paternal report data for 64.3% of fathers
Maternal age at childbirth	MBRN	"≤17 years", 18-19 years", "20-24 years", "20-25 years", "25-29 years", "30-34 years", "35-39 years", "40-44 years", 45+ years"	
Paternal age at childbirth	MBRN	"≤19 years", 20-24 years", "25-29 years", "30-34 years", "35-39 years", "40-44 years", "45-49 years", 50+ years"	
Offspring gestational age at birth	MBRN	NA	Based on ultrasound estimation. If ultrasound was not available, the gestational age was calculated from the last menstrual period
Liveborn status	MBRN	"liveborn", "stillborn/termination"	pre en
Offspring sex	MBRN	"female", "male"	

Supplementary information S4: Linear mixed model to account for non-independence between siblings 112

- In MoBa there are a large number of siblings in the offspring generation (if siblings were excluded, the sample would 113
- be around 17% smaller). In order to maximise power we included siblings in the sample used for linear regression 114
- 115 analyses, and used a linear mixed model with a random intercept at the family level to appropriately account for
- non-independence between siblings: 116

 $Y_{ij} = \beta 0 + u 0_j + \beta 1 \times maternal BMI_{ij} + \beta 2 \times paternal BMI_{ij} + \sum_l \beta_l \times covariate_{lij} + e_{ij}$ 117 (1)

where Y_{ij} is the phenotype for the i^{th} individual in the j^{th} family, $\beta 0$, $\beta 1$, $\beta 2$ and β_l are the fixed coefficients for the 118 intercept, maternal BMI, paternal BMI and the l^{th} covariate respectively, $u0_i$ is a random intercept for the 119

 j^{th} family, $u_i \sim N(0, \sigma_u^2)$, and e_{ij} is a residual, $e_{ij} \sim N(\mathbf{0}, \mathbf{\Sigma})$. $\mathbf{\Sigma} = I\sigma_e^2$ is the residual variance-covariance matrix, where 120 I is an identity matrix and σ_e^2 is the residual variance. Linear mixed models were fitted using the R package nlme (1, 121 2).

122

Supplementary information S5: z-test for the difference in maternal and paternal associations 123

- For each offspring outcome we used a z-test to test whether associations with maternal and paternal BMI differed in 124
- magnitude. We calculated the *z* statistic as $z = \delta / \sqrt{Var(\beta 1) + Var(\beta 2) 2Cov(\beta 1, \beta 2)}$, where δ is the difference 125
- between the coefficients for maternal BMI and paternal BMI ($\beta 1$ and $\beta 2$ respectively in equation 1), and 126
- 127 $Cov(\beta 1, \beta 2)$ is from the estimated covariance matrix for the fixed effects in equation 1.

128 Supplementary information S6: Summary statistics for transformed and untransformed exposure and outcome

130 a: variable was used in genetically informed structural equation modelling (MCoTS) analyses (variables used in linear regression

analyses were identical, with the exception that unlogged parental BMI was used as the exposure, and for models involving

weight/BMI/PI, age and sex were included as covariates rather than using age/sex standardized z-scores), b: CEBQ variables
 were regressed on age and sex prior to inverse normalization of the residuals within sex strata

135 Supplementary information S7: Tests for non-linear associations between exposures and outcomes

Our MCoTS structural equation models partitioned the covariance, which is a measure of linear association, between 136 137 the natural logarithm of the exposure, and the outcome (which was logged when necessary). To assess whether a 138 linear association adequately described the relationship between each logged exposure and outcome we (i) explored 139 whether there was evidence for a quadratic association, (ii) fitted a LOWESS smoother, and (iii) regressed the 140 outcome on categories of log parental BMI equivalent to the World Health Organization obesity classification (<18.5 kg/m², 18.5–24.9 kg/m², 25–29.9 kg/m², 30–34.9 kg/m², 35–39.9 kg/m², ≥40 kg/m²). Results are shown in the plots 141 below, with vertical grey lines indicating the log BMI categories used for the categorical fit. Variables were treated as 142 143 per the MCoTS analyses, i.e. exposures were logged and outcomes were logged when necessary. INT: inverse normal transformation. 144

Although there was some evidence for a non-linear association between log maternal BMI and offspring outcomes at younger ages (birth to three years), such that the association plateaued at higher maternal BMI, these departures from linearity were relatively mild, as demonstrated by the LOWESS and categorical fits. For log offspring BMI from age five onwards the associations with log maternal BMI were approximately linear. For log paternal BMI there was also evidence for a slight plateauing of the association with birth weight at higher paternal BMI, but associations with offspring BMI at ages beyond birth were approximately linear.

CEBQ emotional overeating (INT) vs. log maternal bmi, both sexes

2yr predicted BMI vs. log paternal bmi, both sexes

Log 8yr predicted BMI vs. log paternal bmi, both sexes

196 Supplementary information S8: Multiple Children of Twins and Siblings (MCoTS) model

To quantify the extent to which exposure-outcome associations were due to genetic confounding, we fitted a genetically informed structural equation model (SEM) in a subset of the MoBa sample. This SEM is an extension of the classic twin design (CTD) which has been widely used to estimate heritability (i.e. the proportion of phenotypic variance that is due to genetic effects). Because monozygotic (MZ) twins are genetically identical but dizygotic (DZ) twins are on average only 50% genetically similar, the expected phenotypic similarity of a heritable trait will be greater for MZ versus DZ twins. Building on the CTD, a Children of Twins design exploits the fact that such patterns of genetic and phenotypic similarity are mirrored in relatives of twins (5). This enables estimation of the extent to

which phenotypic similarity between parents and offspring is due to genetic similarity (i.e. genetic confounding). For example, an MZ twin is 50% genetically similar to the child of their co-twin, but a DZ twin will be on average only

206 25% genetically similar to the child of their co-twin. If these relatedness coefficients are reflected by patterns of

phenotypic similarity this provides evidence for genetic confounding. We fit an extended children of twins SEM (the
 Multiple Children of Twins and Siblings [MCoTS] model, described in the path diagrams below and elsewhere (5)).

211

212

Sibling 1 and sibling 2 are full siblings, half siblings, dizygotic twins or monozygotic twins, in the parent generation. 213 Outcomes are included for up to two children of each parental sibling, and parental BMI is allowed to vary between 214 pregnancies via the correlation rE. Genetic correlations are set according to quantitative genetic theory (6). Additive 215 genetic correlations between sibling pairs (Sibling rA) are set at 1.0, 0.5 or 0.25 for monozygotic twins, dizygotic 216 217 twins/full siblings and half siblings respectively. Additive genetic correlations between cousin pairs (Cousin rA) are set at 0.25, 0.125 or 0.0625 for cousins related via monozygotic twins, dizygotic twins/full siblings and half siblings 218 respectively. Dominance genetic correlations between sibling pairs (Sibling rD) are set at 1.0 or 0.25 for monozygotic 219 220 twins and dizygotic twins/full siblings respectively and are zero for half siblings. Latent (unmeasured) variables are shown in circles, measured variables are shown in rectangles, single headed arrows denote causal paths, and double 221 headed arrows denote covariances. A1: additive genetic effects on parental BMI, D1: dominance genetic effects on 222 223 parental BMI, E1: nonshared environmental effects on parental BMI, A1': genetic effects common to parental BMI and offspring outcome, C1: extended family effects, A2: additive genetic effects specific to the offspring outcome, 224 C2: shared environmental effects on offspring outcome, E2: nonshared environmental effect son offspring outcome, 225 p: "phenotypic" effect, including any causal effect of parental BMI on the offspring outcome, as well as residual (non-226 genetic) confounding, rE: within-parent correlation between E1 for parenting child 1 and child 2. The path between 227 228 A1 and A1' is fixed to 0.5, because parents share 50% of their genome identical by descent with their children. For 229 simplicity, variance paths have been omitted, but variance was 1 for all latent variables. Consequently, for A1' residual variance after accounting for the path between A1' and A1 is 0.75. MCoTS SEM were fit in R version 4.0.3 230 231 (OpenMx package version 2.18.1) (7, 8). A full description of the MCoTS model is given in McAdams et al. (5).

233 Supplementary information S9: MCoTS model with ACE partition of parental exposure

234

Sibling 1 and sibling 2 are full siblings, half siblings, dizygotic twins or monozygotic twins, in the parent generation. 235 Outcomes are included for up to two children of each parental sibling, and parental BMI is allowed to vary between 236 pregnancies via the correlation rE. Genetic correlations are set according to quantitative genetic theory (6). Additive 237 238 genetic correlations between sibling pairs (Sibling rA) are set at 1.0, 0.5 or 0.25 for monozygotic twins, dizygotic 239 twins/full siblings and half siblings respectively. Additive genetic correlations between cousin pairs (Cousin rA) are 240 set at 0.25, 0.125 or 0.0625 for cousins related via monozygotic twins, dizygotic twins/full siblings and half siblings respectively. Latent (unmeasured) variables are shown in circles, measured variables are shown in rectangles, single 241 headed arrows denote causal paths, and double headed arrows denote covariances. A1: additive genetic effects on 242 parental BMI, C1: shared environmental effects on parental BMI, E1: nonshared environmental effects on parental 243 BMI, A1': genetic effects common to parental BMI and offspring outcome, C1: extended family effects, A2: additive 244 genetic effects specific to the offspring outcome, C2: shared environmental effects on offspring outcome, E2: 245 246 nonshared environmental effect son offspring outcome, p: "phenotypic" effect, including any causal effect of 247 parental BMI on the offspring outcome, as well as residual (non-genetic) confounding, rE: within-parent correlation between E1 for parenting child 1 and child 2. The path between A1 and A1' is fixed to 0.5, because parents share 248 50% of their genome identical by descent with their children. For simplicity, variance paths have been omitted, but 249 variance was 1 for all latent variables. Consequently, for A1' residual variance after accounting for the path between 250 A1' and A1 is 0.75. MCoTS SEM were fit in R version 4.0.3 (OpenMx package version 2.18.1) (7, 8). A full description 251 252 of the MCoTS model is given in McAdams et al. (5).

253 Supplementary information S10: MCoTS model with AE partition of parental exposure

254

Sibling 1 and sibling 2 are full siblings, half siblings, dizygotic twins or monozygotic twins, in the parent generation. 255 Outcomes are included for up to two children of each parental sibling, and parental BMI is allowed to vary between 256 pregnancies via the correlation rE. Genetic correlations are set according to quantitative genetic theory (6). Additive 257 258 genetic correlations between sibling pairs (Sibling rA) are set at 1.0, 0.5 or 0.25 for monozygotic twins, dizygotic 259 twins/full siblings and half siblings respectively. Additive genetic correlations between cousin pairs (Cousin rA) are 260 set at 0.25, 0.125 or 0.0625 for cousins related via monozygotic twins, dizygotic twins/full siblings and half siblings respectively. Latent (unmeasured) variables are shown in circles, measured variables are shown in rectangles, single 261 headed arrows denote causal paths, and double headed arrows denote covariances. A1: additive genetic effects on 262 parental BMI, E1: nonshared environmental effects on parental BMI, A1': genetic effects common to parental BMI 263 and offspring outcome, C1: extended family effects, A2: additive genetic effects specific to the offspring outcome, 264 C2: shared environmental effects on offspring outcome, E2: nonshared environmental effect son offspring outcome, 265 266 p: "phenotypic" effect, including any causal effect of parental BMI on the offspring outcome, as well as residual (nongenetic) confounding, rE: within-parent correlation between E1 for parenting child 1 and child 2. The path between 267 A1 and A1' is fixed to 0.5, because parents share 50% of their genome identical by descent with their children. For 268 simplicity, variance paths have been omitted, but variance was 1 for all latent variables. Consequently, for A1' 269 residual variance after accounting for the path between A1' and A1 is 0.75. MCoTS SEM were fit in R version 4.0.3 270 (OpenMx package version 2.18.1) (7, 8). A full description of the MCoTS model is given in McAdams et al. (5). 271

273 Supplementary information S11: Liability threshold model for untransformed CEBQ outcomes

Because several CEBQ outcomes were severely skewed, for the primary MCoTS analysis we regressed all CEBQ outcome variables on age and sex then applied a rank-based inverse normal transformation to the residuals. As a sensitivity analysis we instead applied a liability threshold MCoTS model to CEBQ outcomes that were recoded into three equally sized categories. Liability threshold models assume that a continuous, normally distributed liability captures all latent genetic and environmental determinants of the trait. The observed categorical outcome (*Y*) is

related to the continuous liability (*Z*) by thresholds τ_1 and τ_2 , such that

280
$$Y = \begin{cases} 2 \text{ if } Z \ge \tau_2\\ 1 \text{ if } \tau_2 < Z \ge \tau_1.\\ 0 \text{ otherwise} \end{cases}$$

Liability threshold MCoTS SEM were fit in R version 4.0.3, similarly to the MCoTS models for continuous outcomes (OpenMx package version 2.18.1) (7, 8). The means vectors for offspring outcomes were fixed to zero and the outcome phenotypic variance was constrained to one, with τ_1 and τ_2 being freely estimated.

285 Supplementary information S12: Differences in participant characteristics between baseline and 8 year old sample

Variable	Baseline	sample	8 year sample		0	
		Mean	%	Mean	%	Pdifference
Parental characteristics

Covariance between parental BMI (SD) and offspring outcome (SD)

322 Supplementary table S1:

Full linear regression results for associations between exposures and outcomes (see separate excel file sup_tables.xlsx).

325

326 **Supplementary table S2:**

Full MCoTS results including model fit statistics and estimated variance components for parental and offspring phenotypes (see separate excel file sup_tables.xlsx).
