Abstract

34

35

Background: Influenza A viruses (IAV) are significant pathogens of humans and other animals. Although endemic in humans and birds, novel IAV strains can emerge, jump species, and cause epidemics, like the latest variant of H5N1. Wastewater-based epidemiology (WBE) has very recently been shown to detect human IAV but whether it can detect avian-origin IAV, and if whole genome sequencing (WGS) can be used to discriminate circulating strains of IAV in wastewater remains unknown.

42

Methods: Using a pan-IAV RT-qPCR assay, six wastewater treatment works (WWTWs)
across Northern Ireland (NI), were screened from August to December 2022. A WGS
approach using Oxford Nanopore technology was employed to sequence positive samples.
Phylogenetic analysis of sequences relative to currently circulating human and avian IAVs
was performed.

48

Findings: We detected a dynamic IAV signal in wastewater from September 2022 onwards across NI. "Meta" whole genome sequences were generated displaying homology to both human and avian IAV strains. The relative proportion of human versus avian-origin IAV reads differed across time and sample site. A diversity in subtypes and lineages was detected (e.g. H1N1, H3N2, and several avian). Avian segment 8 related to those found in recent H5N1 clade 2.3.4.4b was identified.

55

Interpretation: WBE affords a means to monitor circulating human and avian IAV strains
and provide crucial genetic information. As such WBE can provide rapid, cost-effective,
year-round "one-health" IAV surveillance to help control epidemic and pandemic threats.

59

Funding: This study was funded by the Department of Health for Northern Ireland as partof the Northern Ireland Wastewater Surveillance Programme.

63 Highlights

- 64 65
- Dynamic IAV RT-qPCR signal in wastewater detected across NI.
- Nanopore-based WGS reveals presence of both human and avian IAVs in
 wastewater.
- Avian IAV sequence similarity to gull-associated H13/H16 and recent H5N1 isolates.
 - Co-detection of distinct clades of human H1N1 and H3N2 subtypes.
- 70

69

71 Author Summary

- 72 Influenza A virus (IAV) is a major pathogen of humans and other animals and causes regular 73 epidemics and devastating pandemics. Recently, a novel variant of highly-pathogenic H5N1 avian influenza has emerged spreading across the world killing millions of birds and infecting 74 75 mammals, enhancing its pandemic potential. Strengthening global surveillance systems for human and animal IAV is thus a major priority. Wastewater-based epidemiology (WBE) has 76 77 been applied to track SARS-CoV-2 and IAV in humans but whether this approach could work for avian IAV is not known. Here, we develop a "one-health" method to survey pan-IAV 78 79 levels and genetically characterise the viruses. Through this we highlight co-detection of human and avian IAVs in wastewater, with homology to recent H5N1 isolates. Our work 80 81 demonstrates the potential for WBE to help defend against not only human infections but 82 emerging, zoonotic IAVs of pandemic potential.
- 83

84 Graphical Abstract

Introduction

85

86

Influenza A virus (IAV) (Family Orthomyxoviridae: Genus Influenzavirus) is an enveloped 87 virus with a genome comprising 8 segments (named 1-8) of single-stranded negative sense 88 RNA (Krammer et al., 2018). The IAV genome encodes at least 10 proteins, including the 89 hemagglutinin (HA) and neuraminidase (NA) glycoproteins, and the innate immune 90 91 antagonist non-structural protein 1 (NS1). IAV is a major pathogen of humans, livestock, and wildlife, and is the causative agent of several pandemics over the last century following 92 zoonosis from animal reservoirs like pigs and birds. Clinical burden in humans and animals 93 is extensive (1,2,3) but can be managed through prophylactic vaccination focused towards 94 circulating HA and NA sequences (4). 95

96

97 IAV has many subtypes and although some are endemic in humans (e.g., H1N1 and H3N2) and other mammals, wild birds belonging to the orders Anseriformes (e.g., ducks) and 98 99 Charadriiformes (e.g., gulls [5]) are widely acknowledged as the major IAV genetic reservoirs. Most IAVs are considered low pathogenicity avian influenza viruses (LPAIVs) 100 e.g., H13Nx and H16Nx that infect gulls (6,7,8). Others (e.g., H5 and H7) can be high 101 pathogenicity avian influenza viruses (HPAIVs) due to the acquisition of a "multibasic 102 cleavage sequence" in HA (9). A novel strain of H5Nx (clade 2.3.4.4b) HPAIV was first 103 detected in 2016 in Eurasia (10). This variant spread globally killing over 50 million birds and 104 infecting wild and farmed mammal species. Additional evidence suggesting mammal-to-105 mammal transmission (e.g., mink) increases the pandemic potential of such circulating 106 HPAIVs, emphasising the need for heightened, active surveillance in both humans and 107 108 animals (11,12).

109

Current human IAV monitoring usually entails clinical surveillance via primary care (sentinel 110 GP services and in-hospital testing) with onward analysis of positive samples by PCR and 111 112 sequencing. Avian IAV surveillance incorporates active (capture and swabbing of live birds) and passive (dead birds) monitoring. Environmental sampling (e.g., faeces or mud) has 113 114 been explored but has not played a significant role in surveillance efforts globally (13). Complementing established clinical surveillance methods, WBE has recently proven an 115 116 effective approach to track levels and identify variants of SARS-CoV-2 circulating in the human population (14.15.16). Likewise, this method has proven useful for the monitoring of 117 118 enteric pathogens like adenoviruses (17), and other viruses such as respiratory syncytial virus (18,19). WBE studies have also demonstrated the detection of human IAV and 119

influenza B virus (IBV) in wastewater samples, using targeted PCR but with limited
sequencing (20,21,22,23,24,25,26).

122

Whether WBE surveillance can be repurposed as a single sampling approach to monitor both human and animal viral reservoirs and thus help identify and characterise pathogens such as avian influenza with zoonotic potential, remains unknown. Here, we describe an integrated pan-IAV genomic WBE surveillance approach, using an RT-qPCR assay and nanopore WGS to rapidly sequence and subtype influenza positive samples detected and distinguish between human and avian sequences.

Methods

131

132

133 Sample Collection and Processing

Composite (24 hour) wastewater samples comprising primary untreated influent were collected using an Isco Glacier autosampler (Isco; Lincoln, USA) from 6 WWTW covering key population centres from each health trust of NI. Sampling was carried out by Northern Ireland Water Ltd and the Northern Ireland Environment Agency (NIEA). Once received, samples were stored at 4°C before pre-processing the same day. Sample processing, viral concentration, and extraction was carried out as previously described (17).

140

141 Wastewater Screening for IAV - Matrix Protein (MP) segment RT-qPCR

Screening of wastewater for the presence of IAV employed the SVIP-MPv2 assay (27). 142 143 Universal IAV detection was confirmed against avian (H6N1), human (H1N1 and H3N2) and swine (pH1N1 and H1N2) nucleic acid extracts prepared in-house from inactivated virus 144 stocks supplied by the Agri-Food and Biosciences Institute (AFBI, Northern Ireland) and 145 QUB. Raw wastewater samples spiked with cultured human H1N1 virus, inactivated using 146 Triton X (1% w/v), were prepared. These were processed to determine the SVIP-MPv2 147 assays suitability for use against wastewater, to identify any sample matrix effects and to 148 determine if processing methods were applicable for the recovery of IAV. Replicate PCR 149 reactions (comprising 2x 6µl and 2x 3µl purified nucleic acid template volumes) per 150 wastewater sample were performed on a LightCycler 480 II Real-Time PCR System (Roche 151 Diagnostic Limited). RT-PCR was carried out in a reaction volume of 25µL using AgPath-152 153 ID[™] One-Step Reagents (ThermoFisher Scientific) with primers and probe at a final concentration of 1.4µM and 0.4µM respectively, and supplemented with bovine serum 154 albumin (0.2mg/ml. ThermoFisher Scientific) with the following thermo-profile: 50°C for 155 10mins, 95°C for 10mins followed by 45 cycles of 95°C for 10s and 60°C for 30s (Table S1 156 and S2). A standard curve and limit of detection (LOD) were calculated for the SVIP-MPv2 157 158 assay (Figure S1) using synthetic RNA respiratory virus controls H1N1 and H3N2 (103001, 103002, Twist Bioscience) serially diluted in 0.1X TE buffer (ThermoFisher Scientific) 159 160 supplemented with a blocking nucleic acid (0.1µg/µl yeast tRNA, Sigma-Aldrich). IAV MP segment concentrations were normalised using wastewater flow rate and expressed as 161 162 gene copies (g.c.) per 100,000 population equivalents (p.e.) per day as previously described (Revne et al., 2022). Clinical data by epidemiological week covering molecular tests carried 163 164 out for IAV was supplied by the Regional Virus Laboratory (RVL), Belfast Health and Social Care Trust (BHSCT), NI. 165

166 Amplicon Generation for Sequencing - Multi-segment RT-PCR Approach (M-RTPCR)

A M-RTPCR approach to simultaneously amplify all eight segments of the IAV genome from 167 168 IAV MP positive wastewater samples within a single PCR reaction was employed (28). Only those IAV positive WW samples with a Ct value of ≤37 were selected for amplicon 169 170 generation. One step RT-PCR was carried out using SuperScript III One-Step RT-PCR reagents (ThermoFisher Scientific) with final concentrations of primers MBTuni-12 and 171 MBTuni-13 (0.2µM each [Table S1]) in a total volume of 50µl (40µl reaction mix and 10µl of 172 purified nucleic acid). Reactions were run in duplicate on a C1000 Touch thermal cycler 173 (Biorad) using a 96 deep-well reaction module, following thermal cycling conditions as 174 175 previously described (Table S2). Duplicate reaction mixtures were pooled, and amplified 176 DNA purified using a 0.8X ratio of KAPA Pure Beads (Roche Diagnostic Limited). 177 Quantification was carried out using a Qubit high-sensitivity double-stranded DNA kit (Qubit Flex, ThermoFisher Scientific), and amplicons analysed using D5000 ScreenTape assays 178 179 (TapeStation 4200 System, Agilent Technologies) both according to the manufacturers' instructions (Figure S2). As an additional approach to further quantify generated amplicons 180 prior to library preparation, 2 µl of purified amplicon mix was re-tested using the SVIP-MPv2 181 assay. A significant decrease in Ct value versus original screening Ct value was concomitant 182 183 with the presence of increased amounts of matrix protein (segment 7) amplicons signifying successful genomic segment amplification (Table S3). To monitor for potential operator and 184 185 environmental contamination as well as background nucleic acid present in reagents and consumables, negative process controls consisting of DEPC-treated nuclease free water 186 (ThermoFisher Scientific) were included alongside and treated in the same manner. 187

188

189 Nanopore Library Preparation and Sequencing

Samples were prepared for sequencing following the suggested protocol for ligation sequencing of gDNA with the SQK-LSK109 kit (Oxford Nanopore Technologies). To mitigate any problems of cross-barcode contamination samples were not multiplexed, instead a single sample per FLO-MIN106D R9 flow cell was sequenced on a GridION device (Oxford Nanopore Technologies) with sequencing proceeding for 24 hours. Negative process controls were also sequenced in the same way. Flow cells were only used once and not reused for subsequent IAV sequencing runs.

197

198 Genomic Analysis

Nanopore reads were base called using Guppy (version 6.4.2). Reads were taxonomically
classified using Centrifuge (29). A total IAV read number of greater than 20 was arbitrarily

201 chosen as a cut-off for downstream analysis. Identified IAV reads were mapped using 202 Minimap2 (30). For each sample, reference genomes encompassing potential originating 203 viruses were utilised for mapping: human H1N1 (A/California/07/2009), H3N2 204 (A/Barry/3792/2022; EPI_ISL_15391170), H5N1 and avian 205 (A/Mute_Swan/Netherlands/2/2022; EPI_ESL_15364797) and H13N6 (A/black0headed gull/Netherlands/31/2014). Samtools was used for coverage calculations and BCFtools to 206 generate consensus sequences (31). Alignment length and percentage coverage of raw 207 reads was investigated using Basic Local Alignment Search Tool (BLAST+, version 2.13.0) 208 209 against NCBI's available precompiled nucleotide database (32). Generated raw sequences 210 are in the process of being submitted but are available on request.

211

212 Phylogenetic Analyses

213 Generated IAV consensus sequences were used for phylogenetic analysis. Consensus 214 sequence incorporation differed depending on the analysis used with only homogenous consensus sequences used for interrogation of databases and phylogenetics of avian 215 segments 5, 7 and 8, while all consensus sequences available were used for human 216 217 segment 4 and 6 analysis. For human segment 4 and 6 analysis, Nextclade was used to 218 remove low quality consensus sequences. Similarity to known sequences in the GISAID 219 database was determined using their integrated BLAST protocol. All gull H13/16-like 220 sequences since 2013, and H5N1 European sequences (2022) were used (downloaded 221 January 2023). Select human H1N1 and H3N2 segment 4 and 6 sequences were used, including available recent sequences from Northern Ireland. Multiple sequence alignments 222 were performed in MAFFT [https://mafft.cbrc.jp/], and maximum likelihood phylogenies 223 224 inferred (1000 ultrafast bootstrap replicates) using IQ-TREE [http://igtree.cibiv.univie.ac.at/] (33). The best substitution model was identified using IQ-TREE, ranked by BIC and 225 226 implemented. Trees were visualised using FigTree v1.4.4 [http://tree.bio.ed.ac.uk/software/figtree/]. Table S4 provides metadata on the GISAID 227 228 genome sequences used in this study.

232

233 Pan-IAV wastewater screening by RT-qPCR

144 wastewater samples, from 6 WWTW across NI (Figure 1 A), were screened for IAV 234 between 1st August 2022 and 5th December 2022 (epi weeks 31 - 49) using our pan-IAV 235 assay. A consistent IAV signal above the LOD was first detected from the 5th of September 236 237 2022 onwards (epi week 36), corresponding to an average weekly concentration of 5.03 x 10¹² g.c. per 100k p.e. across the WWTW screened (Figure 1 B). IAV positivity and 238 concentrations in wastewater varied across the sites sampled during the period investigated, 239 with three peaks observed during weeks 37, 42 and 48, with an average of 5.74 x 10¹², 8.67 240 x 10¹², and 1.13 x 10¹³ g.c. per 100k p.e. respectively. Clinical data by epi week covering 241 molecular tests carried out for IAV was supplied by the Regional Virus Laboratory, Royal 242 Victoria Hospital. Clinical percentage positivity remained below 1% until week 35 (1.39%) 243 and did not sustain an upwards trajectory until week 42 (1.44%), steadily increasing to 244 3.99% during week 49 before rising markedly from week 50 onwards (6.42%) (Figure 1 B). 245 The peak of the clinical influenza 2022/23 season was during week 52 (14.42% [data not 246 247 shown]) outside of our study period.

 across NI screened for IAV (A). West-to-East: Enniskillen, Derry/Londonderry, Craigavon, Ballymena,
 Belfast, and North Down. Normalised and averaged levels of IAV MP gene copies detected (g.c. per 100k
 p.e.) per epi week across the 6 WWTW sampled (B). Clinical data (black line) represents percentage IAV
 positive PCR and point of care tests carried out by the Regional Virus Laboratory for NI. ★ indicates epi
 weeks where IAV sequence was obtained.

254

255 Meta-whole genome sequencing of human and avian IAV from wastewater

The SVIP-MPv2 assay targets a highly conserved region of the IAV MP segment regardless of subtype and host. To resolve the genomic composition of detected IAV samples, a wholegenome amplification approach was employed. Overall, 12 of 36 IAV positive (<Ct 38) wastewater samples were successfully processed and sequenced (>20 IAV reads) following

260 the full-segment amplicon generation method adopted (Zhou et al., 2009). IAV sequence

261 was generated from samples collected on 12/09/2022, 10/10/2022, 24/10/2022, 31/10/2022,

and 28/11/2022 (epi weeks 37-48 inclusive) covering a range of geographical locations (Fig

- 1A): West-to-East: Enniskillen (ENN), Craigavon (CRG), Ballymena (BYM), Belfast (BEL),
- and North Down (NDN). No sequence data was obtained for Derry/Londonderry.

Table 1. Description of IAV WGS in wastewater. Read number and average percentage coverage
 per segment, per sample. Identity and alignment length of raw reads investigated using Basic Local
 Alignment Search Tool against NCBI's available precompiled nucleotide database.

271 Identified IAV reads in these IAV RT-gPCR-positive samples ranged from 65 to 1,440, with 7,044 sequences detected overall. Reads were generally biased towards the smaller 272 segments (7 and 8) (Table 1). No single sample produced reads for every segment. 273 274 However, across the samples successfully sequenced, reads mapping to all 8 segments 275 were generated and referred to here as "meta"-WGS" to reflect sequencing all segments and to distinguish from true WGS from clinical samples containing single strains. On 276 277 average, percentage coverage of segments varied considerably from 25.7% (PB1) up to 99.6% (NP). Sequences mapping to segments 4 and 6, encoding HA and NA, were 278 279 generated for 9 samples (75%). Average read number and coverage was 203/29.5% and 280 10.2/57.9% for HA and NA segments respectively.

282

283 Fig 2. Taxonomic classification-first interrogation of IAV reads from wastewater. Proportion unique 284 reads from samples (site: BEL = Belfast; BYM = Ballymena; CRG = Craigavon; NDN = North Down) were 285 assigned a similarity to 1 of 7 IAV strains (A/California/07/2009(H1N1); A/Puerto Rico/8/1934(H1N1); A/New York/392/2004(H3N2); A/Korea/426/1968(H2N2); A/Hong Kong/1073/99(H9N2); 286 287 A/goose/Guangdong/1/1996(H5N1); A/Shanghai/02/2013(H7N9)) in the Centrifuge database. These strains were grouped into human-like (H1N1, H3N2 and H2N2; purple shades) and avian-like (H9N2, 288 H5N1 and H7N9; yellow shades) (A). Data from A shown aggregated by human-like and avian-like for 289 each sample with median and range illustrated (B). Fractional proportion of aggregate human-like 290 291 sequences shown sample date only for all sites with links for those for which multidate data is available 292 (BEL in green, BYM in blue and NDN in purple) are shown (C). Graphs generated in Graphpad Prism 293 v9.0.

294

Initial read interrogation using a taxonomic classification first approach suggested the presence of diverse IAV strains, possibly consisting of both human-like and avian-like viruses (**Figure 2 A and B**). The relative abundance of these differed by sampling time and site. At first heterogenous mixes predominated, but the relative abundance of human-like

299 IAV reads increased as the clinical influenza season commenced for Belfast and Ballymena 300 (Figure 2 C). However, North Down showed a more stable mix of human and avian-like 301 sequences. Furthermore, we generated consensus sequences by mapping, focussing our downstream analysis on sequences where the consensus generated by each reference was 302 303 similar to each other. This resulted in 25 consensus sequences spanning all IAV segments (described in Table 2 and found in supplement). Derived consensus sequences were 304 compared to known IAV sequences by BLAST, revealing diverse origins corroborating the 305 original analysis by Centrifuge, including human subtypes (H1N1 and H3N2) but also avian 306 subtypes, which are predominantly circulating in gull populations (H13N6), and even H5N1 307 308 clade 2.3.4.4b (Belfast 10/10/2022) from a Eurasian curlew (a member of the 309 Charadriiformes) (Table 2). Similar to the Centrifuge analysis, we detect here that the proportion of avian-like sequences compared to human-like decreases at later sampling 310 dates. 311

313

Table 2: Similarity of wastewater IAV consensus sequences to known sequences. Table describing BLAST (GISAID) results for consensus sequences from samples sites and dates. Sequences spanned all segments and interrogation of GISAID database allowed low resolution sub-typing by identifying known subtype of the top-ranked similarity hit. For each top hit, the subtype, host species, GISAID ID and name for each sequence is shown. For Belfast 10/10/2022 two hits are shown, including similarity to H5N1.

320

321 Detection of diverse lineages of gull-associated IAV in wastewater

To explore the avian IAV sequences further, we determined the phylogenetic relatedness of our derived consensus sequences relative to the two gull-associated sub-types (H13 and H16 Nx) as well as recent (2022) H5N1 clade 2.3.4.4b viruses found across Europe. Phylogenetic analysis of segment 8 (encoding the virulence factor NS1, and the essential NEP) confirmed clear avian association but disclosed two distinct clades found in our samples (**Figure 3**). One clade (gull 2; sequences found on 12-09-22) was closely related to - but distinct from - H16Nx viruses identified in Europe in 2013/2015 (Netherlands). One

329 of these clades (gull 3; marked by Belfast 10-10-23) was more closely related to recent 330 European H5N1 viruses (clade 2.3.4.4b), which include viruses sequenced from birds and 331 mammals (mink). However, phylogenetically our H5N1-related sequence sat at a basal position to the H5N1 sub-clade along with other gull-associated sequences (found in Europe 332 333 and China in 2020/21), suggesting that it is unlikely to be from an H5N1 viruses but from the ancestor of the lineage that donated its segment 8 to H5N1 clade 2.3.4.4b. No other H5-like 334 sequences were detected. Interrogation of the three segment 5 sequences and the single 335 segment 7 sequence, identified similarity to sequences from Europe (2020/2021), China 336 (2021) and Alaska (2020) (Supplementary Figures 3 and 4). 337

338

- 340

Figure 3. Maximum-likelihood phylogeny of wastewater-derived avian-like segment 8 sequences. Phylogenetic tree of the 4 avian-like segment 8 sequences (in pink) alongside all GISAID gull H13/16like sequences (black), and 2022 H5N1 European sequences (in blue) (accessed January 2023). Three clades are highlighted (gull 1 -3) with presence of NI (pink) and H5 (blue) annotated. Mink H5N1 sequences are highlighted in cyan. For illustrative purposes, several clades are shown collapsed in cartoon form. Relevant bootstrap replicate values are shown on the tree.

347

348 WBE reveals co-circulation of multiple lineages of human associated H1N1 and H3N2

To determine whether our derived sequences might also provide information on the evolution of the human epidemic, derived human segments 4 and 6 consensus sequences were analysed further. To maximise the genomic information available, for this analysis, we included all generated consensus sequences at our disposal, using Nextclade to identify

353 sequences of low quality that were subsequently removed from analysis. This resulted in 11 sequences from 7 samples (available in supplement). Phylogenetic analyses focused on our 354 355 segment 4 and 6 sequences compared to those from recently circulating IAVs from around the world and 2022 Northern Ireland, demonstrated a diversity in WBE sequences, from at 356 357 least one H1N1 clade (6B.1A.5a.2a.1 [5a.2a.1]) and three H3N2 clades (all 'Bangladeshlike' 3C.2a1b.2a.2a.1 [2a.1], 3C.2a1b.2a.2a.3a.1 [2a.3a.1], and 3C.2a1b.2a.2b [2b]) as 358 suggested by our initial analysis with Centrifuge (Figure 4 A - D). Our sequences were 359 similar to recently circulating strains in NI but phylogenetically distinct from those HA 360 sequences incorporated into the utilised vaccines (5a.2 for H1N1 and 3C.2a1b.2a.2 for 361 362 H3N2) for that season.

363

364

365 Figure 4. Maximum-likelihood phylogeny of wastewater-derived human-like segment 4 (HA) and 366 6 (NA) sequences from H1N1 and H3N2. Phylogenetic trees of the 11 human-like segment 4 and 6 sequences (in red) for H1N1 4 (A) and 6 (B) as well as H3N2 4 (C) and 6 (D) alongside select recent 367 worldwide sequences and all available relevant Northern Ireland (NI) clinical sequences (in bold black). 368 H1N1 NI clinical sequences were sampled during the 2022-2023 season, while the H3N2 NI clinical 369 370 sequences were sampled in Spring 2022 during the end of the 2021-2022 season. Established HA sequence clades are shown alongside sequence groupings. Northern Hemisphere 2022/2023 winter 371 372 season vaccine strain sequences highlighted. Bootstrap replicate values >69 are only shown on the tree.

374

Discussion

375

Here we show that WBE, a surveillance approach traditionally focused on monitoring human infections, can also be repurposed and through WGS be used to distinguish between circulating strains of the virus and characterise animal pathogens, in this instance avian IAV (Figure S5).

380

Like others, we detect a clear and dynamic IAV signal in wastewater samples, highlighting 381 the utility of WBE for monitoring influenza (20,21,22,23,24,25,26). However, comparing our 382 wastewater IAV viral load data from the 6 WWTW to the clinical % positivity rate across all 383 of NI did not show a clear positive relationship. Like the rest of the UK (34), NI clinical 384 385 positivity increased over time, while our IAV signal showed several clear peaks and troughs. WGS suggested that earlier in the season more avian IAV dominated before a later shift to 386 human. Thus, considering our genomics findings, a lack of correlation may be expected 387 given the overwhelming non-human avian IAV signal detected. This could potentially reflect 388 dynamics of avian IAVs in wild avian reservoirs. Indeed, comparing peaks in early 389 390 September and early October, distinct avian IAV strains were even identified. Alternatively, the lack of correlation could be explained by the lower % population coverage for the 391 392 wastewater surveillance compared to clinical testing, which covers all NI.

393

Wastewater sequencing of IAV detected diverse avian IAV lineages, notably recent H13 and 394 H16-like viruses, which are LPAIV subtypes infecting gulls and closely related species 395 396 belonging to the order Charadriiformes, poultry and mammals (6,7,35,36,8). Remarkably, we identified one sequence (segment 8 BEL10102022) with close affinity to 397 contemporaneous HPAI H5N1 viruses found across Europe, proven capable of spreading 398 between mammals (12). Although recently in NI, gulls have been confirmed infected with 399 H5N1 (37), it is unlikely that we detected the HPAIV H5N1 clade 2.3.4.4b as H5N1 homology 400 401 was identified only for one segment (8; NS1/NEP), and phylogenetic analysis suggested 402 that they fell outside of the recent H5N1 group. Indeed, we only found non-H5 avian H13 403 segments with no H5 identified. Notably, recent European H5N1 viruses have reassorted 404 with local gull-associated viruses, acquiring segments 3, 5 and 8 (12). Gulls have been 405 shown to be important in spreading HPAIV H5 (38).

406

407 Previous WBE IAV studies, sampling at both the catchment and near source level, and using
408 a variety of processing methods, have proven that molecular detection of IAV/IBV from both

409 solid and liquid WW fractions is possible, highlighting how effective this medium is for tracking influenza dynamics within human communities. However, these studies have 410 411 usually adopted a human-centric screening and sequencing approach, possibly explaining 412 why convincing evidence of avian IAV has not been reported thus far. It is also likely that 413 timing and geography are factors impacting avian IAV detection. The stable mixture of human and avian IAV seen throughout the study period at the North Down WWTW may 414 reflect to the coastal location of this site, which is close to important seabird colonies in 415 Belfast Lough, the Copeland Islands and Strangford Lough (39). The other sampled WWTW 416 sites (with the exception of Derry/Londonderry, from which no sequences were recovered) 417 418 are located much further inland. Regarding the precise origin of our avian influenza 419 sequences, WWTW in general are recognised as providing artificial habitats for birds year-420 round (40,41). However, without in-depth ecological studies at WWTW, other mechanisms 421 must be considered - such as the role of mammal vectors (42) or that true human infection 422 exists. However, we consider these scenarios less likely than direct avian deposition, as no 423 human infections with H13 or H16 subtypes have been noted.

424

Our protocol generated sequence information from the early stages of the human 2022/23 425 IAV epidemic in NI, in particular covering segments 4 (HA) and 6 (NA) that facilitate 426 subtyping and antigenic comparison. Given the dearth of available clinical IAV sequences 427 428 from NI, an accurate comparison between wastewater and the clinical would be challenging, 429 although wastewater-derived sequences generally matched contemporary globally circulating viruses. Comparing our sequences with those of the chosen vaccine strains for 430 2022/2023 showed phylogenetic distinctness, which may impact antigenicity although 431 432 vaccine match was generally considered good for that year (43). This suggests that sensitive 433 and effective real-time WBE IAV sequencing could be as a tool to inform in-season 434 estimates of vaccine effectiveness and clinical burden. However, this would require further in-depth molecular and serological analysis of derived HA and NA sequences, and 435 436 development of more specific RT-qPCR assays

437

We show that "meta" WGS of IAV from WW is possible, despite the unique challenges such complex sample matrices pose. The heterogenous mix of PCR inhibitors, fragmented state of shed virus and variations in viral titres present can negatively impact sequencing workflows. Capturing more virus material, reducing inhibitors, enhancing nucleic acid extraction/purification steps, using more robust enzyme systems, and updated sequencing reagent chemistries/technologies could improve sequencing outcomes. The choice of

bioinformatic workflow, and attendant reference databases, should also be carefully considered to enhance sensitivity and accuracy. Recently developed, influenza focussed bioinformatics tools, such as those provided by "EPI2ME Labs" (44) and "INSaFLU" (45), promise a streamlined approach to deal with primary data, but it remains to be seen how suitable these workflows are for analysing highly complex mixed environmental samples such as those from wastewater.

450

In conclusion, we demonstrate that human-centric WBE can be refocussed as a useful tool for combined avian and human IAV genomic surveillance. WBE may augment established veterinary and clinical testing structures, presenting opportunities to give advance warning on the incidence and spread of IAV and provide a cost-effective means to develop a global and sustained year-round "one health" sentinel service for IAV.
