15 **Highlights**

- 16 • A novel stochastic matching pursuit algorithm called microstructure-informed
17 myelin mapping (MIMM) is developed to quantify Myelin Volume Fraction (MVF)
18 using Magnetic Resonance Imaging (MRI) and microstructural modeling.
- 19 • MIMM utilizes a detailed biophysical model to capture the susceptibility effects on
20 both magnitude and phase to quantify myelin and iron.
- 21 • White matter fiber orientation effects are considered for the improved MVF
22 quantification in the major fiber tracts.
- 23 • The acquired myelin and iron maps may be utilized to monitor longitudinal disease
24 progress.

25 **Abstract**

26 Quantification of the myelin content of the white matter is important for studying
27 demyelination in neurodegenerative diseases such as Multiple Sclerosis (MS),
28 particularly for longitudinal monitoring. A novel noninvasive MRI method, called
29 Microstructure-Informed Myelin Mapping (MIMM), is developed to quantify the myelin
30 volume fraction (MVF) by utilizing a multi gradient echo sequence (mGRE) and a detailed
31 biophysical model of tissue microstructure. Myelin is modeled as anisotropic negative
32 susceptibility source based on the Hollow Cylindrical Fiber Model (HCFM), and iron as
33 isotropic positive susceptibility source in the extracellular region. Voxels with a range of
34 biophysical parameters are simulated to create a dictionary of MR echo time magnitude
35 signals and total susceptibility values. MRI signals measured using a mGRE sequence
36 are then matched voxel-by-voxel to the created dictionary to obtain the spatial
37 distributions of myelin and iron. Three different MIMM versions are presented to deal with
38 the fiber orientation dependent susceptibility effects of the myelin sheaths: a basic
39 variation, which assumes fiber orientation is an unknown to fit, two orientation informed
40 variations, which assume the fiber orientation distribution is available either from a
41 separate diffusion tensor imaging (DTI) acquisition or from a DTI atlas based fiber
42 orientation map. While all showed a significant linear correlation with the reference
43 method based on T2-relaxometry ($p < 0.0001$), DTI orientation informed and atlas
44 orientation informed variations reduced overestimation at white matter tracts compared
45 to the basic variation. Finally, the implications and usefulness of attaining an additional
46 iron susceptibility distribution map are discussed.

47 **Keywords:** Myelin volume fraction; Stochastic matching pursuit; Hollow cylindrical fiber
48 model; Quantitative susceptibility mapping; Multi gradient echo

49 **1. Introduction**

50 The myelin sheath is a multilamellar structure of lipid bilayers formed by glial cells around
51 the nerve fibers, which allows rapid electrical conduction between neurons and provides
52 trophic support to the axons (Bean, 2007; Brady, Siegel, Albers, R.W., & Price, 2005).
53 Myelination is an essential process in the development and maturation of the central
54 nervous system, and loss of myelin (demyelination) has been implicated in normal aging
55 as well as in neuroinflammatory and neurodegenerative diseases such as multiple
56 sclerosis (MS) (Dobson & Giovannoni, 2019). Therefore, the development of a non-
57 invasive myelin-specific quantitative biomarker is highly important for the diagnosis,
58 monitoring, and therapeutic management of these diseases.

59 Myelin water fraction (MWF) mapping is a magnetic resonance imaging (MRI) method
60 that aims to quantify the ratio of the myelin water to the total water content of each voxel
61 (Lazari & Lipp, 2021; J. Lee et al., 2021; A. MacKay et al., 2006; Mackay et al., 1994; A.
62 L. MacKay & Laule, 2016; Mancini et al., 2020; van der Weijden et al., 2021). Traditionally,
63 MWF has been measured by applying multi-component T2-relaxometry to the multi-echo
64 data acquired with a slow 2D multi-echo spin echo (MESE) sequence. More efficient 3D
65 acquisition schemes including the gradient and spin echo (GRASE) (Prasloski et al.,
66 2012) and fast acquisition with spiral trajectory and adiabatic T2prep (FAST-T2) (Nguyen
67 et al., 2016; Nguyen, Spincemaille, Gauthier, & Wang, 2017; Nguyen et al., 2012) have
68 been proposed to reduce the acquisition time for clinical translation. Due to the ill-posed
69 nature of the inverse Laplace transform, these approaches are highly sensitive to noise,
70 which necessitates acquisitions with a large voxel size to improve SNR. Furthermore,
71 MWF measurements obtained by T2-based methods can be confounded by fiber

72 orientations and the presence of iron (Bartels et al., 2022; Birkl et al., 2019; Birkl et al.,
73 2020; Birkl, Doucette, Fan, Hernández-Torres, & Rauscher, 2021).

74 More recently, there has been a great interest in myelin mapping using the multi-echo
75 gradient echo (mGRE) sequence as it is widely available on clinical scanners and can
76 provide whole-brain isotropic coverage in a short acquisition time with much lower specific
77 absorption rate than spin echo sequences (Haacke, Xu, Cheng, & Reichenbach, 2004;
78 Markl & Leupold, 2012). MWF can be calculated by performing three-compartment T2*
79 relaxometry of the magnitude (Du et al., 2007; Hwang, Kim, & Du, 2010) or the 3 pool
80 complex fitting (3PCF) (H. Lee et al., 2018; Nam, Lee, Hwang, & Kim, 2015) of mGRE
81 signal, with the latter approach considered more sensitive by utilizing the frequency
82 offsets created by the white matter fiber bundles (Sukstanskii & Yablonskiy, 2014;
83 Wharton & Bowtell, 2012). This approach showed that the mGRE phase is an additional
84 source of information regarding tissue myelin content. Nevertheless, the 3PCF approach
85 requires the non-linear iterative fitting of 10 parameters per voxel, which is slow and
86 sensitive to the choice of parameter initialization and stopping criteria (Chan & Marques,
87 2020; Nam et al., 2015). Furthermore, this approach overestimates the myelin content in
88 iron-rich brain regions such as basal ganglia since iron also causes rapid signal decay
89 and frequency shifts (Dong et al., 2021; Hédouin et al., 2021; Jung, Yun, Kim, & Kim,
90 2022).

91 To improve the performance of mGRE-based MWF imaging, Chan and Marques (Chan,
92 Chamberland, & Marques, 2023; Chan & Marques, 2020) proposed two algorithms that
93 incorporate either diffusion or multi flip angle mGRE measurements on top of the regular
94 mGRE acquisition. Although these algorithms improve myelin quantification, they require

95 long scan times (> 20 min). Recently, Hédouin et al. (Hédouin et al., 2021) proposed to
96 generate a dictionary of complex signal evolutions based on an HCFM simulation of the
97 WM fibers (Wharton & Bowtell, 2012, 2013), which was then utilized to train a neural
98 network for fast parameter extraction. However, this method does not model
99 heterogeneous background susceptibility due to iron and requires multiple orientations in
100 data acquisition that is not feasible in clinical practice.

101 In this study, inspired by the dictionary generation strategy in (Hédouin et al., 2021) and
102 matching pursuit approaches (Bergeaud & Mallat, 1995; Chen, 2011; Mallat & Zhang,
103 1992; Tropp & Gilbert, 2007), we propose a novel myelin quantification method to
104 estimate the MVF from a single 6-min mGRE scan (Sisman, Nguyen, et al., 2023; Sisman,
105 Romano, et al., 2023). The central element of this approach is a detailed signal model
106 which connects the macroscopic mGRE signals (T_2^* magnitude decay and magnetic
107 susceptibility derived from quantitative susceptibility mapping (QSM) (Azuma et al., 2016;
108 A.V. Dimov et al., 2018; T. Liu et al., 2010; Wang & Liu, 2015)) measured on the voxel
109 level to the micro-scale myelin network and iron distribution. Further, we propose a
110 stochastic matching pursuit algorithm for fast and effective dictionary matching. We
111 performed in vivo evaluation of the developed MIMM method by comparing it with the
112 3PCF algorithm and also with MWF measurements obtained by the FAST-T2 method in
113 healthy volunteers.

114 2. Theory

115 2.1. MIMM Dictionary Generation

116 Similar to previous approaches, the hollow cylindrical geometries are initially assumed to
 117 extend to infinity such that the field perturbations created by these cylinders do not change
 118 along their main direction. However, in MIMM, the computed fields are only considered in
 119 a 3D grid with fixed orientations, obtained by resampling the replicated 2D fields to the
 120 laboratory frame of reference. The 2D field perturbations produced by the hollow cylinders
 121 are (Wharton & Bowtell, 2012):

$$122 \quad f_{iso} = \chi_{iso} \times \begin{cases} 0, & \text{if } r < r_i \\ \frac{1}{2} \left(\cos^2 \theta - \frac{1}{3} - \sin^2 \theta \cos 2\phi \left(\frac{r_i^2}{r^2} \right) \right), & r_i < r < r_o \\ \frac{1}{2} \left(\sin^2 \theta \cos 2\phi \left(\frac{r_o^2 - r_i^2}{r^2} \right) \right) & r > r_o \end{cases} \quad (1)$$

$$123 \quad f_{ani} = \chi_{ani} \times \begin{cases} \frac{3}{4} \sin^2 \theta \ln \left(\frac{r_o}{r} \right), & \text{if } r < r_i \\ \sin^2 \theta \left(-\frac{5}{12} - \frac{\cos 2\phi}{8} \left(1 + \frac{r_i^2}{r^2} \right) + \frac{3}{4} \ln \left(\frac{r_o}{r} \right) \right) - \cos^2 \theta, & r_i < r < r_o \\ \frac{1}{8} \left(\sin^2 \theta \cos 2\phi \left(\frac{r_o^2 - r_i^2}{r^2} \right) \right) & r > r_o \end{cases} \quad (2)$$

124 Here, χ_{iso} and χ_{ani} are isotropic and anisotropic volume susceptibilities of the myelin
 125 sheath, respectively. f_{iso} and f_{ani} are the field perturbations corresponding to these two
 126 susceptibility components. θ is the angle between the principal fiber axis and the main
 127 magnetic field direction of the MR scanner. r_i , and r_o are the inner and outer radii of fibers
 128 excluding and including myelin sheath, respectively. ϕ and r are the cylindrical
 129 coordinates in the fiber frame of reference.

130 In the classical mGRE based MWI approaches, an overestimated level of myelin water in
 131 basal ganglia is observed as a systematic artifact (Hédouin et al., 2021; Jung et al., 2022)
 132 mainly because of the high iron concentration in these regions. In order to tackle this
 133 problem, randomly distributed iron inclusions in the extracellular region are also included
 134 in the simulated volume as a second major susceptibility source. Considering that brain
 135 iron mainly exists in ferritin form (Wang & Liu, 2015) which is much smaller ($\sim 8 - 12 \text{ nm}$)
 136 (Clemente-León et al., 2006) than the WM fibers ($\sim 1 \mu\text{m}$) (Graf von Keyserlingk &
 137 Schramm, 1984), iron inclusions are represented by single sub-voxels in the extracellular
 138 space. The iron-based field perturbation (f_{iron}) is computed by convolution with the dipole
 139 kernel using Fourier transform for computational efficiency. In order to avoid wrapping
 140 artifacts, the simulated volume is padded with zeros in each direction before convolution,
 141 and the padded regions are cropped afterward. Consequently, the total field perturbation
 142 in sub-voxel j is:

$$143 \quad f_T(j) = f_{iso}(j) + f_{ani}(j) + f_{iron}(j) \quad (3)$$

144 The complex signals corresponding to each sub-voxel for each echo (TE) time are
 145 computed and the total signal coming from the whole volume at each TE is computed as:

$$146 \quad S_D(TE) = \rho^{IEW} \sum_{j \in \text{Intra-Extracellular}} e^{-\frac{TE}{T_2^{IEW}}} e^{-i\gamma B_0 f_T(j)TE} + \rho^{MW} \sum_{j \in \text{Myelin Sheath}} e^{-\frac{TE}{T_2^{MW}}} e^{-i\gamma B_0 f_T(j)TE}$$

147 (4)

148 with T_2^{IEW} , and T_2^{MW} are the transversal relaxation time constants of the intra-extracellular
 149 and myelin water compartments, respectively. Similarly, ρ^{IEW} and ρ^{MW} are the relative
 150 proton density of the intra-extracellular and myelin water compartments. γ is the
 151 gyromagnetic ratio of water proton and B_0 is the strength of the static magnetic field of

152 the MR scanner. While some parameters are varied in certain ranges to create the
153 dictionary, some of the parameters are kept constant to decrease the dictionary size and
154 computation time since both increase exponentially with the number of variable
155 parameters. Moreover, it also makes the matching pursuit process more robust
156 considering the fact that fitting for coupled parameters (such as volume susceptibilities
157 and volume fractions) can be a more ill-posed inverse problem. The varying and constant
158 parameters and the corresponding ranges are given in Table 1. The dictionary signal S_D
159 was computed for a TE range of $[0, 60]$ ms with 3 ms step size (21 echoes). In summary,
160 4 varying input parameters are chosen as:

161 (1) 2D Fiber Density (2DFD): The ratio of the hollow circles' area to the whole 2D grid
162 area.

163 (2) g-ratio: The geometric ratio of the inner radius of the fiber axon to the outer radius
164 (r_i/r_o) .

165 (3) Extracellular Iron Density (EID): The ratio of the extracellular sub-voxels that are
166 iron inclusions to all extracellular sub-voxels.

167 (4) Fiber Orientation (θ).

168 The steps of the simulation of one dictionary element are summarized in Figure 1a. First,
169 a random distribution of 2D fibers in a circular region is created with varying radii but a
170 fixed g-ratio (Danz, 2020). Then, the field perturbations of each myelin source are
171 computed using Equations 1 and 2 at each sub-voxel. The computed field distribution is
172 extended to a 3D grid by simple replication and resampling based on the fiber orientation.
173 A smaller region of interest (ROI) at the center of the 3D grid is extracted to imitate an
174 imaging voxel where susceptibility sources exist both inside and outside. The fiber volume

175 fraction (FVF) and iron volume fraction (IVF) of the simulated volume are computed as
176 the relative volumes covered by the fibers and iron inclusions within this ROI.

177 It is important to note here that even though FVF and g-ratio are required to be decoupled
178 for the simulation of the dictionary, however, the fitted values for them are not expected
179 to be correct considering the mGRE signal is sensitive to total myelin content rather than
180 fiber density and myelin thickness separately. Therefore, it is more convenient to claim a
181 measure of the total myelin volume within each voxel. Consequently, the MVF value for
182 each dictionary element can be computed as (Campbell et al., 2018):

$$183 \quad MVF = FVF (1 - (g - \text{ratio})^2) \quad (5)$$

184 Furthermore, a bulk susceptibility value is also estimated for each dictionary element
185 based on the volumetric myelin and iron susceptibility values and volume fractions. The
186 voxel susceptibility originating from myelin content is calculated using the isotropic
187 component as $\chi^{myelin} = \chi_{iso} \times MVF$ assuming that single orientation QSM measures the
188 mean susceptibility of the susceptibility tensor; mean susceptibility is defined as the
189 average of the eigenvalues of the susceptibility tensor (or 1/3 of the trace) (C. Wisnieff et
190 al., 2013). Then, voxel myelin and iron susceptibilities are defined as $\chi^{myelin} =$
191 $\chi_{myelin} \times MVF$ and $\chi^{iron} = \chi_{iron} \times IVF$. Here, superscripts are utilized to refer to voxel
192 quantities, whereas subscripts are reserved for volumetric quantities. Finally, the total
193 susceptibility of each dictionary element is computed as:

$$194 \quad \chi^{total} = \chi^{myelin} + \chi^{iron} \quad (6)$$

195 To create the overall dictionary that will be employed for MIMM, two approaches are
196 adopted. First, as done in the conventional MR fingerprinting (Ma et al., 2013), the input

197 parameters of the dictionary generation process are selected so that they will cover the
198 parameter space uniformly. For instance, g-ratio is swept between 0.5 to 1 with a 0.05
199 step size. Secondly, the parameter space coverage is driven by a random sampling
200 approach using a uniform distribution function again using the same range of parameters
201 (Chen, 2011). Only the 2DFD is kept uniformly sampled to ensure comprehensive
202 coverage of the parameter space while keeping the overall computation time short. After
203 choosing the input parameters, the remaining steps are the same for both approaches.
204 In this paper, the dictionaries generated with the explained approaches are referred to as
205 the deterministic pursuit dictionary and the stochastic pursuit dictionary, respectively.

206 **2.2. Stochastic Matching Pursuit of the Solution**

207 To match the dictionary and the acquisition echo times, the magnitude signal evolution of
208 each element is resampled to the acquisition echo times using a 5th-order polynomial
209 interpolation of the natural logarithm of the dictionary signals. Then, the interpolated
210 magnitude signals are normalized to have a unit Euclidian norm.

211 **2.2.1. Basic MIMM**

212 The microstructural properties of each voxel are determined by an exhaustive search in
213 the dictionary based on a novel similarity metric which is a linear combination of the
214 traditional linear correlation between the dictionary and measured magnitude signal
215 evolutions and the absolute difference between χ^{total} of the dictionary elements and
216 tissue susceptibilities (χ^{QSM}) of the measurements. Linear correlation is widely used in
217 MR fingerprinting for quantitative MR studies (Ma et al., 2013). χ^{QSM} is the quantitative
218 susceptibility value of each voxel estimated from the mGRE phase data. The idea to
219 combine the magnitude signal evolution and QSM for quantitative imaging has previously

220 been employed for MRI based oxygen extraction fraction (OEF) mapping (Cho,
221 Spincemille, Nguyen, Gupta, & Wang, 2021). The dictionary element that minimizes the
222 following cost function is determined for each voxel k .

$$223 \quad \hat{d} = \underset{d \in D}{\operatorname{argmin}} (1 - \langle |S_D|, |S| \rangle) + \lambda_\chi |\chi_D^{total} - \chi^{QSM}| \quad (7)$$

224 Here, $|S_D|$ and $|S|$ are the normalized magnitude signal evolutions of the dictionary
225 elements and the imaging voxel, respectively. λ_χ is a weighting parameter that determines
226 the relative weighting of the two terms. D is the dictionary and \hat{d} is the dictionary element
227 that minimizes the cost function. The corresponding MVF , θ , and χ^{iron} values of \hat{d} are
228 then assigned to the voxel that is being processed to assemble the corresponding
229 biophysical parameter maps.

230 **2.2.2. DTI Orientation Informed MIMM**

231 Even though basic MIMM tries to tackle the fiber orientation dependence of the HCFM
232 based MIMM by assuming θ is an unknown, it is known that in order to estimate the fiber
233 orientation from mGRE measurements, data with at least 3 different sampling orientations
234 is required (Wharton & Bowtell, 2013). Therefore, the θ values provided by the basic
235 MIMM are expected to have high error, thereby also inducing errors in the estimated MVF.
236 MIMM is improved here by incorporating a fiber orientation map obtained from a separate
237 Diffusion Tensor Imaging (DTI) scan as:

$$238 \quad \hat{d} = \underset{d \in D}{\operatorname{argmin}} (1 - \langle |S_D|, |S| \rangle) + \lambda_\chi |\chi_D^{total} - \chi^{QSM}| \quad \text{given } \theta = \theta_{DTI} \quad (8)$$

239 Here, the exhaustive search procedure to find the best matching element is limited to the
240 dictionary elements whose orientation values (θ) match with the DTI fiber orientation
241 (θ_{DTI}). Before this procedure, the dictionary orientation values and the orientation values

242 obtained from DTI are rounded to the nearest multiple of 5° . Moreover, orientation
243 informed MIMM is applied only at the voxels where the fractional anisotropy (FA) value
244 computed from the diffusion tensor (DT) is larger than 0.25 and the QSM value is lower
245 than 0.1 ppm. This prevented using unreliable orientation values in the cortical gray
246 matter where highly organized fiber tracts do not exist, and in basal ganglia, where DTI
247 measurements can be erroneous due to the existence of high levels of iron.

248 **2.2.3. Atlas Orientation Informed MIMM**

249 In the case that subject-specific WM fiber orientation is not available, we propose to use
250 the orientation map obtained from a DTI brain atlas such as The International Consortium
251 of Brain Mapping (ICBM) DTI-81 normative atlas (Mazziotta, Toga, Evans, Fox, &
252 Lancaster, 1995; Mori et al., 2008). In this work, the atlas diffusion tensor was warped
253 from the MNI ICBM-152 space to the subject mGRE space.

254 The MIMM algorithm is summarized in Figure 1a. Examples of dictionary magnitude
255 signal evolution as a function of fiber orientation and g-ratio are shown in Figure 1(c-d).

256 **3. Methods**

257 Different aspects of the MIMM algorithm are evaluated utilizing Monte Carlo simulations,
258 and experimental data from healthy subjects. The experimental myelin volume fraction
259 maps are compared with myelin water fraction maps obtained with conventional T2-
260 relaxometry (Nguyen et al., 2016; Nguyen et al., 2017). Furthermore, 3PCF is also
261 implemented as described in (Nam et al., 2015) and the obtained MWF maps are
262 compared with the MVF maps both quantitatively and qualitatively.

263 **3.1. Simulation Grid Resolution and Size Optimization**

264 As described in Section 2.1, in order to obtain the magnitude signal evolution of a
265 dictionary element, a finite-size simulation volume needs to be created and the
266 corresponding field perturbation distribution needs to be calculated. Considering the fact
267 that an imaging voxel generally contains thousands of fibers, simulating a realistic voxel
268 requires extremely high computation power and time. On the other hand, if we employ a
269 relatively larger grid size of simulation than a single fiber, the resulting magnitude signal
270 evolution may approximate the signal of a voxel that is substantially larger. In order to
271 assess this idea, simulation volumes with varying resolutions and sizes were created
272 (assuming the largest fiber radius is $10 \mu\text{m}$ (Graf von Keyserlingk & Schramm, 1984)) and
273 the corresponding magnitude signal evolutions were computed. In Figures 2a and 2d, the
274 created simulation volumes with varying grid resolution and sizes are shown, respectively.
275 Figures 2b and 2e demonstrate the corresponding magnitude signal evolutions, and
276 Figures 2c and 2f depict the corresponding computation time for each case. Figures 2b
277 and 2c suggest that there is minimal change in the magnitude signal evolution between
278 grid resolutions 256 and 512 even though the required computation time to obtain these

279 signal curves is almost 5 times larger for the latter. Similar observations were made for
280 grid sizes $50 \mu m$ and $100 \mu m$. Therefore, for the rest of this study, all the dictionary
281 elements are computed utilizing a 256^3 grid at $50 \mu m$ resolution.

282 **3.2. Monte Carlo Simulations**

283 In order to evaluate the sensitivity of the MIMM approach to MRI signal noise, a separate
284 set of data ($N = 10000$) was computed with random simulation parameters while keeping
285 the constant parameters in Table 1 the same. For a given Signal-to-noise ratio (SNR)
286 level, all the dictionary elements were corrupted with noise. Independent identically
287 distributed (i.i.d.) Gaussian noise with standard deviation (s.t.d.) $\frac{1}{SNR}$ were added to both
288 the real and imaginary parts of the signal evolutions before normalization (Note that the
289 first echo magnitude is 1 before normalization). Moreover, Gaussian noise with s.t.d.
290 $\frac{0.3}{SNR}$ ppm was also added to the χ^{total} values. Then, the noise corrupted signals and
291 χ^{total} values were matched with the original dictionary as if it was a real measurement
292 using various echo times and λ_χ values. The mean absolute error of the estimated MVF
293 values $MVF_{j,E}$ was computed as:

$$294 \quad \epsilon_{MVF} = \frac{1}{N} \sum_{j=1}^N |MVF_{j,T} - MVF_{j,E}| \quad (9)$$

295 were $MVF_{j,T}$ were the true MVF value of the j^{th} simulated data point. This was computed
296 for the basic and the orientation informed MIMM strategies under different levels of noise.
297 Moreover, it is also used to investigate the effect of the weighting factor λ_χ in Equations
298 7 and 8 and of the dictionary size.

299 **3.3. MR Data Acquisition**

300 Healthy subject data were acquired on a 3T MRI scanner (Prisma^{fit}, Siemens
301 Healthineers, Erlangen, Germany) using a 64-channel array head coil in ten volunteers
302 (7 males, 3 females, age range: 25–51) following an IRB-approved protocol. Informed
303 consent was obtained from each subject. The protocol for each scan was as follows:

304 (1) Whole-brain T1-weighted (T1w) scan using Magnetization Prepared Rapid
305 Acquisition Gradient Echo (MPRAGE) with acquisition parameters: axial field of
306 view FOV = 25.6 cm, phase FOV factor 100%, repetition time TR = 2300 ms, echo
307 time TE = 2.26 ms, voxel size = 1 mm³ isotropic, readout bandwidth RBW = 200
308 Hz/pixel, flip angle FA = 8°, GRAPPA acceleration factor = 2, acquisition time =
309 5:21 min (176 slices).

310 (2) Monopolar 3D mGRE with acquisition parameters: FOV = 25.6 cm, phase FOV
311 factor = 81.3%, TR = 41 ms, TE₁/ΔTE = 2.2/3.25 ms, number of TEs = 7, voxel
312 size = 1×1×2 mm³ (interpolated to 1 mm³ isotropic), RBW = 260 Hz/pixel, FA = 15°,
313 slice partial Fourier factor = 0.875, GRAPPA acceleration factor = 2, acquisition
314 time = 6:05 min (160 slices).

315 (3) FAST-T2 with acquisition parameters: 3-dimensional spiral acquisition with TR/TE
316 = 7.6/0.5 ms, FOV = 25.6 cm, phase FOV factor=100%, sequence TR = 2000 ms;
317 T2prep TEs = 0 (T2prep pulse turned off), 7.5, 17.5, 67.5, 147.5, and 307.5 ms,
318 voxel size = 1.3×1.3×2 mm³ (interpolated to 1×1×2 mm³), RBW = 1042 Hz/pixel,
319 FA = 10°, number of spiral leaves per stack = 32, acquisition time = 8 min (80
320 slices).

321 (4) 2D Spin Echo Echo Planar Imaging (SE-EPI) Diffusion Weighted Imaging
322 (DWI) with acquisition parameters: number of diffusion encoding directions = 30,
323 b-value = 1000 s/mm², FOV = 24 cm, phase FOV factor = 100%, TR = 10000 ms,
324 TE= 70 ms, voxel size = 1.9×1.9×2.5 mm³, RBW =1562 Hz/pixel, slice partial
325 Fourier factor = 0.75, GRAPPA acceleration factor = 2, acquisition time = 5:40 min
326 (60 slices).

327 **3.4. Data Processing**

328 **3.4.1. ROI Segmentations**

329 For regional MWF and MVF analysis, a total of 15 ROIs were selected for each subject:
330 5 subcortical GM ROIs (Globus Pallidus, Putamen, Caudate, Thalamus, Hippocampus)
331 were extracted from T_1w images using FreeSurfer(Fischl, 2012); and 10 WM ROIs (Genu,
332 Splenium, and Body of Corpus Callosum, External Capsule, Anterior Limb of Internal
333 Capsule, Optic Radiation, Superior Longitudinal Fasciculus, Superior Corona Radiata,
334 Cingulate Gyrus, and Cerebro Spinal Tract) were chosen from the WM parcellation map
335 provided by the DTI-81 atlas (Mori et al., 2008).

336 **3.4.2. DTI Image Reconstruction**

337 First, the susceptibility induced B_0 off-resonance map is estimated from mGRE phase
338 data using a nonlinear fitting algorithm (T. Liu et al., 2013) and spatially unwrapped
339 (Cusack & Papadakis, 2002). Then, DWI images were corrected for geometric distortions
340 using the estimated off-resonance map and FSL FEAT algorithm (Jenkinson, Beckmann,
341 Behrens, Woolrich, & Smith, 2012; Woolrich, Ripley, Brady, & Smith, 2001). Finally,
342 Diffusion Tensor images were reconstructed using the FSL DTIFIT algorithm (Behrens et
343 al., 2003).

344 **3.4.3. QSM Image Reconstruction**

345 QSM images were reconstructed from the same field used for DTI image correction. The
346 background field is removed using the projection onto dipole fields (PDF) algorithm (T.
347 Liu et al., 2011) and QSM is reconstructed using Morphology-Enabled Dipole Inversion
348 (MEDI) with global cerebrospinal fluid (CSF) referencing (A.V. Dimov et al., 2022; J. Liu
349 et al., 2012; Z. Liu, Spincemaille, Yao, Zhang, & Wang, 2018).

350 **3.4.4. Myelin Content Image Reconstructions**

351 The macroscopic field inhomogeneity effects in the mGRE magnitude data are corrected
352 using the library-driven voxel spread function approach (Y. Liu et al., 2021; Yablonskiy,
353 Sukstanskii, Luo, & Wang, 2013). The MIMM algorithm was implemented in MATLAB
354 R2020a (Mathworks, Natick, Massachusetts, USA), and all the in vivo data were
355 processed using the same implementation. Furthermore, the 3PCF algorithm proposed
356 by Nam et al. (Nam et al., 2015) was also implemented to estimate the MWF map using
357 the mGRE data. The implementation details provided in (Nam et al., 2015) were followed
358 in addition to some additional smoothing introduced before fitting to suppress noise, due
359 to the lower number of echoes available. Finally, MWF from FAST-T2 was extracted as
360 described in (Nguyen et al., 2016).

361 For the in vivo data, λ_χ was determined using L-curve analysis (Hansen, 1992) by
362 balancing the two error terms in Equations 7 and 8 in a representative subject. It was also
363 found this balancing can be limited to a subset of the data in a subject: In this work, λ_χ
364 was determined by averaging the two error terms obtained within all the voxels in the 10
365 central slices.

366 Selecting the dictionary size poses a tradeoff between the goodness of the match (it is
367 possible to find a better match in the dictionary with a larger size) and the time required
368 for the matching pursuit process. In a representative subject, the MVF map was obtained
369 with different dictionary sizes and the average minimum matching error together with the
370 image entropy (Pal & Pal, 1991) were computed over the whole brain white matter. Image
371 entropy level was employed to quantify the detail in the image features.

372 **3.4.5. Image Registrations**

373 Several registrations between different subject image spaces and to/from ICBM-152
374 space were required during data processing. All the registrations can be summarized
375 here:

376 (1) A linear transformation (affine transform) from subject DTI space to mGRE space
377 was estimated using FSL Linear Image Registration Tool (FLIRT) (Jenkinson,
378 Bannister, Brady, & Smith, 2002), the b-value = 0 image from DTI dataset and
379 combined T2*-weighted (T2*w) magnitude image of the mGRE and the FA map
380 was brought to mGRE space. The first principal eigenvector of the reconstructed
381 DTI images (V_1) was registered to the mGRE space using the estimated linear
382 transformation and FSL *vecreg* command to estimate θ maps.

383 (2) Nonlinear transformation (affine transform and warp field) was estimated from
384 ICBM-152 space to individual subject T1 space using ANTs SyN algorithm
385 (Avants, Tustison, & Song, 2009). Then, a linear transformation from subject T1
386 space to mGRE space was estimated again using ANTs. The ICBM-81 DTI atlas
387 was brought to the mGRE space using the computed transformations as a single-

388 step transformation. The first principal eigenvector (V_1) of the registered ICBM-81
389 DTI atlas and then the corresponding θ maps were calculated.

390 (3) The linear transformation from subject FAST-T2 space to mGRE space was
391 estimated using FSL FLIRT to bring the estimated reference MWF maps to mGRE
392 space.

393 (4) Finally, ROI segmentation masks that reside on subject T1 and ICBM-81 DTI atlas
394 spaces were brought to subject mGRE space with FSL FLIRT and ANTs using the
395 computed linear and nonlinear transformations, respectively.

396 A desktop PC (CPU: Intel i7-5820k, 3.3 GHz; 64 GB RAM) was used for all the data
397 processing steps.

398 4. Results

399 Figure 3a shows example MVF maps obtained using the basic matching pursuit with both
400 the deterministic and stochastic versions, as well as using two dictionary sizes. MVF
401 maps obtained with stochastic matching are visibly smoother and present less “salt-and-
402 pepper-noise” compared to those obtained using deterministic matching. No obvious
403 improvement with the increased dictionary size was observed, even though the larger
404 dictionary increases the computational cost of matching by a factor of 4. To visualize the
405 source of this significant difference in the results, we projected the input parameters of 2
406 example dictionaries (deterministic pursuit dictionary with size 12540 and stochastic
407 pursuit dictionary with size 12000) onto the (g-ratio, θ) plane (Figure 3b). Even though
408 the total number of dictionary elements is similar, the parameter coverage of the
409 stochastic pursuit dictionary is improved in certain subspaces. Furthermore, in Figure 3c
410 all the dictionary elements are shown g-ratio – θ – IVF parameter space to visualize the
411 3D space coverage. Even though it is difficult to see the difference between the two
412 dictionaries as in the 2D case, it can be seen that the total number of elements is similar.

413 Figure 4a shows two L-curve results for different subjects. $\lambda_\chi = 0.015$ was approximately
414 located at the corner of the L-curve for both subjects and then used for all the further
415 results. Example MVF maps using both the basic and orientation informed MIMM for 3
416 different values of λ_χ are demonstrated in Figure 4b. Additionally, Figure S1 presents the
417 results of the Monte Carlo experiments to evaluate the performance of the MIMM based
418 quantification of the microstructural properties with different λ_χ values. It demonstrates
419 the mean absolute errors of the 3 output parameters of the MIMM algorithm for both basic
420 and orientation informed MIMM strategies with both deterministic pursuit and stochastic

421 pursuit dictionaries. The plots show that mean absolute errors increase with decreased
422 SNR levels as expected. Furthermore, for most of the results, the accuracy is higher when
423 orientation informed MIMM strategy is utilized. The error levels are relatively constant for
424 a large range of λ_χ values except between 10^{-4} and 10^2 , where an optimal value of λ_χ
425 maximizes the accuracy of the fitting. However, this value is SNR-dependent.

426 Figure 5a shows a comparison between various dictionary sizes. From dictionary size
427 20000 to 80000, the minimum matching error decreases by 6%, and the image entropy
428 increases by only 1%. These results suggest that the increase in the matching
429 performance and the change in the image features are subtle after a dictionary size of
430 20000 even though the dictionary size and consequently the matching time increases by
431 a factor of 400%. Hence, a dictionary size of 20000 was employed for all the results
432 hereafter unless otherwise stated. Example MVF results using both the basic and
433 orientation informed MIMM for 3 different dictionary sizes are shown in Figure 5b. Figure
434 S2 shows the Monte Carlo simulation results regarding the dependence of the accuracy
435 of the MIMM algorithm on the dictionary size. It is seen that after an approximate
436 dictionary size of 10000, changes in the accuracy are below 4%.

437 Four axial slices of the obtained MVF maps in a single subject using the basic MIMM
438 strategy, DTI orientation informed strategy, and atlas orientation informed strategy are
439 shown in Figure 6 and Figure S4 along with the corresponding T1w images, QSM maps,
440 MWF maps obtained with 3PCF from the mGRE data, MWF maps obtained with T2-
441 relaxometry from the FAST-T2 data and FA maps. All MVF maps correlated well visually
442 with the reference FAST-T2 MWF maps. Compared to 3PCF MWF maps, MVF maps
443 display a lower level of noise and image artifacts. The globus pallidus is visibly

444 overestimated in the 3PCF MWF maps compared to the MVF maps (red arrows).
445 Orientation informed MIMM reduces some of the visible overestimations in the main fiber
446 tracts compared to basic MIMM (green arrows). However, overestimation is still present
447 in certain tracts like the posterior limb of the internal capsule (yellow arrows) that
448 correspond to the fiber tracts oriented in the superior-inferior direction (blue/purple
449 regions in the FA map).

450 Figure 7 shows the results from the ROI based linear correlation analysis between the
451 MVF maps obtained with all 3 MIMM strategies and the FAST-T2 MWF maps, as well as
452 that between 3PCF MWF and FAST-T2 MWF for comparison. All 3 MVF maps show a
453 significant correlation with FAST-T2 MWF with a correlation of $r \approx 0.73-0.75$ whereas the
454 3PCF MWF map shows a significant correlation with $r = 0.34$. Subject-specific linear
455 correlation analysis results for each method are presented in Figures S4-S8.

456 A comparison of the orientation maps in a single subject between the ICBM DTI-81 atlas
457 based approach and the subject DTI orientation based map is presented in Figure 8. The
458 two orientation estimates as well as the corresponding MVF maps are compared using
459 linear regression and Bland-Altman analysis of the ROI averages in Figure 8b.

460 Figure 9a presents example iron susceptibility distribution maps obtained with 3 MIMM
461 strategies for an example subject. Average χ^{iron} values across all the subjects within
462 different cortical gray matter parcellations are shown in Figure 9b. The voxel-wise
463 distribution of the MVF and χ^{iron} for all 10 subjects are presented in Figure 10 as violin
464 plots for three major brain regions (cerebral white matter, cortical gray matter, and deep
465 gray matter). In order to suppress voxel-wise noise effects in this plot, the parameter
466 maps were blurred with a Gaussian kernel of size $5 \times 5 \times 5$ beforehand.

467 In order to evaluate the reproducibility capability of the results with MIMM, the MVF maps
468 of the same subject are computed 8 times independently with 8 different dictionaries with
469 dictionary size 10000 and $\lambda_{\chi} = 0.015$ utilizing orientation informed MIMM. The
470 reconstructed maps and the voxel-wise mean and standard deviation images are
471 depicted in Figure S3.

472 **5. Discussion**

473 In this study, we have demonstrated the feasibility of using an HCFM based modeling of
474 the myelin sheaths and the inclusion of iron sources for the quantification of myelin in
475 brain tissue. Better correlation with the reference MWF maps and better visual quality
476 were obtained using the MIMM algorithm compared to the prior 3PCF. Fiber orientation
477 helps myelin mapping accuracy at white matter tracts, and atlas information seems
478 sufficient, providing similar results as subject-specific DTI orientation maps. Finally,
479 paramagnetic iron-specific susceptibility distributions are demonstrated as an additional
480 output of the MIMM algorithm.

481 MIMM improves myelin mapping by better modeling the mGRE signal of white matter in
482 the following aspects compared to prior methods, which is consistent with findings from
483 improving QSM biophysics modeling (A. V. Dimov et al., 2015; A. V. Dimov et al., 2018;
484 Kee et al., 2017; Wen et al., 2021). First, realistic HCFM is used to model the field
485 perturbation distribution due to the myelin content of tissues and the corresponding
486 magnitude decay curves. Second, the brain iron is modeled as an additional susceptibility
487 source that was not explicitly accounted for in the previous methods. Finally, local QSM
488 values are utilized for voxel-wise myelin and iron quantification rather than the non-local
489 phase.

490 Stochastic matching pursuit provides effective filtering of signals not modeled in the
491 dictionary. This study considers 2 effective water pools (intra-extracellular and myelin):
492 myelin water as a bound water pool that is trapped between the lipid bilayers of the myelin
493 sheath demonstrates much faster decay and the water pools inside and outside the cells.
494 The CSF water pool that is included in a lot of the previous MWF works (Mackay et al.,

495 1994; A. L. MacKay & Laule, 2016; Nguyen et al., 2016) demonstrates negligible decay
496 in most of the mGRE acquisitions with relatively short echo times ($T_{2CSF} > 600$ ms)
497 (Meyers, Kolind, & MacKay, 2017). Therefore, the CSF water pool can be effectively
498 ignored in constructing the dictionary.

499 The use of random grid sampling of the dictionaries in stochastic matching pursuit is very
500 useful for accurate myelin mapping at a given SNR level, as shown in simulations (Figure
501 S1). In vivo, smoother MVF maps with lower apparent noise (Figure 3a) were obtained
502 using the stochastic pursuit dictionary. Stochastic pursuit reduces the quantization
503 mismatching errors due to the large gaps in the sampled parameter locations in the
504 deterministic pursuit dictionary as seen in Figure 3(b-c). Particularly, the stochastic pursuit
505 dictionary projected onto the g-ratio – θ plane provides smaller gaps or much denser
506 parameter distribution although the dictionary sizes are similar. Figure 3b shows an
507 almost continuous sampling of the g-ratio with the stochastic pursuit dictionary whereas
508 a fixed quantization level of 0.05 in the deterministic pursuit grid dictionary is responsible
509 for the apparent quantization errors in Figure 3a. Another benefit of the random sampling
510 strategy for dictionary generation is the fact that the dictionary size can be increased in
511 any desired fashion instead of the exponential growth of a conventional dictionary that
512 arises by increasing sampling density in each parameter direction. This provides the
513 flexibility that an optimum dictionary size can be determined more easily from a linearly
514 increasing dictionary size search range as illustrated in Figure 5 and Figure S2. One
515 drawback of the utilization of stochastic pursuit dictionaries is the intrinsic uncertainty
516 introduced in the results by the different randomness of the dictionary. This can be
517 observed in Figure S3 as a certain level of variation is observed in the results

518 reconstructed with different dictionaries of the same size. Even though the visual
519 differences are minimal between different results, there is a voxel-wise standard deviation
520 that goes as high as 2% in the white matter. This can be an issue for reproducibility unless
521 the same dictionary is used for the reconstruction of different cases, or a fixed random
522 seed is utilized for the dictionary generation. This observation requires further
523 investigation in the future.

524 The L-curves shown in Figure 4a demonstrate well the behaved selection of the weighting
525 strength. Significant changes in the image contrast and artifacts were observed in Figure
526 4b as λ_χ increased. First of all, for low λ_χ , the magnitude term in Equations 7 and 8
527 dominates during the matching pursuit process which diminishes the ability to separate
528 myelin and iron. The basal ganglia, especially globus pallidus, are assigned very high
529 MVF values. High λ_χ values, on the contrary, lead to overestimated MVF values in the
530 fiber tracts where the QSM values are very low (negative and high in magnitude) even
531 with orientation informed MIMM and noisy texture in the remaining areas. MVF
532 overestimation cannot be addressed in this case since orientation information is
533 employed in the magnitude term. The intermediate values provide a balance between the
534 two terms and reduce the errors using the complementing information arising from the
535 two terms.

536 The MIMM algorithm addresses two major disadvantages in the prior 3PCF approach for
537 MWF mapping: the lack of information regarding the separation of myelin and iron and
538 the high number of model parameters. The former creates an artificial overestimation of
539 the myelin content in regions with high iron deposition such as basal ganglia while the
540 latter causes noisy parameter maps due to the intrinsic ill-posedness of the fitting process

541 with a high number of fitting parameters. The inclusion of iron in the biophysical model
542 and QSM in the matching provides a framework to separate the magnitude decay due to
543 myelin and iron. Additionally, the 3PCF approach also requires a much longer
544 computation time which can be a detrimental factor in clinical settings. For instance, the
545 fitting of a single subject took ~3 hours with our computation setting whereas the MIMM
546 algorithm took approximately 4 mins. Moreover, utilization of the HCFM further accounts
547 for the orientation effects in the white matter fiber tracts. The matching pursuit process
548 with the biophysical modeling provides MVF maps with higher visual quality since the
549 effective number of parameters that are solved is lower.

550 In Figure 7, the linear correlation with the reference FAST-T2 MWF obtained with all of
551 the three MVF quantification methods was higher compared to that of the 3PCF MWF
552 maps. This is in line with the improved qualitative performance shown in Figure 6. The
553 surprising result here is that utilization of the orientation informed MIMM seems to provide
554 no quantitative improvement over the basic MIMM. This is in contrast to the lower mean
555 absolute errors observed in the simulation (Figure S1) and the better visual consistency
556 with the FAST-T2 MWF map in Figure 6. Here, it should be noted that when orientation
557 informed MIMM is utilized, not only does the vertical dispersion in the data points in Figure
558 7 decrease but the slope of the best-fitting line also decreases. These two parallel
559 decreases both in the slope and data dispersion probably cancel each other out and
560 produce a similar correlation coefficient. This can be explained considering most of the
561 ROIs chosen in this study belong to the major white matter fiber tracts and the MVF values
562 in these tracts decrease consistently when the orientation informed MIMM is utilized. A
563 similar correlation does not mean similar accuracy since the correlation coefficient

564 between two vectors will stay the same if one vector is scaled by a constant whereas the
565 accuracy will change. Even though we showed that orientation informed MIMM provides
566 better estimates of the MVF, basic MIMM has its practical advantage where it does not
567 require any orientation map and still provides decent MVF distributions except for the
568 overestimated values in the major fiber tracts. The promising result in Figure 8 is that
569 almost identical MVF can be obtained using an atlas based fiber orientation distribution
570 that is registered to the mGRE space rather than the orientation maps obtained from a
571 separate DTI acquisition. The availability of a T1 weighted scan, which is often acquired
572 in clinical protocols, can enhance image registration that is required for the atlas
573 orientation informed MIMM. In a scenario where it is not available, direct registration of
574 the atlas based diffusion tensor to the mGRE space can be realized but the accuracy
575 might get lower. The MVF made available from standard mGRE using MIMM processing
576 described in this work would allow routine study of myelin in various neurological
577 disorders, including multiple sclerosis (Dobson & Giovannoni, 2019; Eskreis-Winkler et
578 al., 2015; Cynthia Wisnieff et al., 2015) and amyotrophic lateral sclerosis (S. Kolind et al.,
579 2013; Schweitzer et al., 2015).

580 A natural byproduct of the MIMM method is the χ^{iron} distribution that demonstrates the
581 concentration of iron in different brain regions. Even though this was not the main focus
582 of this study, mapping the susceptibility distribution due to iron is also a clinically relevant
583 task. Some examples of clinical interest in iron susceptibility mapping are the
584 paramagnetic rim lesion detection in MS patients (Marcille et al., 2022) and motor cortex
585 iron quantification in Amyotrophic Lateral Sclerosis (ALS) patients (Adachi et al., 2015).
586 In Figure 9a, the χ^{iron} maps of the healthy subject are almost identical for the three

587 matching strategies. This shows that orientation informed MIMM does not substantially
588 impact the χ^{iron} distribution. This is likely due to the isotropic nature of the iron-related
589 susceptibility sources. Figure 9b shows the non-uniform iron concentration in different
590 gray matter regions of healthy subjects. Interestingly, in cortical gray matter, the motor
591 cortex shows slightly higher iron concentrations compared to other regions, consistent
592 with the literature (Kwan et al., 2012). After the separation of the myelin and iron content
593 in the voxels, it is possible to evaluate their individual distributions in different regions of
594 the brain. The violin plots in Figure 10 are provided as an example visualization of this
595 kind of evaluation. MVF values have higher mean values in the white matter compared to
596 cortical gray matter and deep gray matter as expected. Deep gray matter regions seem
597 to have significant myelin content as well. In terms of iron, on the other hand, deep gray
598 matter regions seem to have the highest content. The mean iron content in white matter
599 and cortical gray matter regions seem to be close whereas the median iron content in
600 white matter seems to be higher than cortical gray matter. The highest positive
601 susceptibility source content in the cortical regions was observed to exist in the superficial
602 white matter in the previous studies (S. Lee, Shin, Kim, & Lee, 2023) which can explain
603 the current results. The results with different MIMM strategies, however, do not
604 demonstrate an obvious difference in the distributions.

605 Though the use of an orientation prior in MIMM improves the myelin quantification in most
606 of the white matter fiber tracts such as corpus callosum and optic radiation (green arrows
607 in Figure 6), it fails to correct the overestimation in some fiber tracts such as the posterior
608 limb of the internal capsule (yellow arrows in Figure 6). The main reason for the
609 overestimation in those areas in the first place is the strong negative susceptibility effects

610 in these fiber tracts that can be seen in the QSM images. With the utilization of the QSM
611 term during the matching pursuit process, these strong negative values translate into high
612 MVF. The HCFM predicts strong magnetic field perturbations in the extracellular space if
613 the fibers are approximately perpendicular to the main magnetic field (red and green
614 fibers in the FA map). Therefore, the amount of decay in those areas can be explained
615 by the existence of a moderate amount of myelin. In this way, orientation informed MIMM
616 corrects for those overestimations in the fiber tracts oriented left-to-right or anterior-to-
617 posterior. However, the fiber tracts oriented superior-to-inferior do not follow the HCFM
618 prediction since they still manifest highly negative QSM values. This means that even
619 though the field perturbation due to myelin is very small, the material susceptibility of the
620 existing myelin sheaths is substantial as captured by QSM. A possible explanation of this
621 situation can be the existence of fiber crossings in those areas that are not covered by
622 the current model. This remains to be a limitation of this study that needs to be
623 investigated in future studies.

624 Another limitation of this study is the utilization of the fixed T2 values for the myelin and
625 intra-extracellular water pools. This was done to decrease the number of free variables
626 to solve for and make the matching pursuit process more well-posed. Another limitation
627 is that the fibers inside the voxels are assumed to have the same orientation. This
628 assumption will break in voxels with fiber crossings. In future studies, the model can be
629 improved by including multi orientation fibers and multi T2 water pools. The stability of the
630 fitting can then be improved using spatial regularization.

631 **6. Conclusion**

632 A novel microstructure informed matching pursuit method called MIMM is developed to
633 measure MVF based on detailed biophysical modeling of the human brain using HCFM
634 and distinct susceptibility source inclusions. The MIMM method is superior to previously
635 developed 3PCF based myelin quantification using mGRE signals in terms of accuracy,
636 visual quality, and processing time. A significant linear correlation with the reference T2-
637 relaxometry method is observed ($r = 0.75$, $p < 0.0001$) whereas a significant correlation
638 is observed with the 3PCF with lower correlation ($r = 0.34$, $p < 0.0001$). Furthermore, the
639 feasibility of utilizing an atlas-based fiber orientation map was also investigated instead
640 of a subject-specific fiber orientation map acquired using DTI since it may not be available
641 in routine clinical scans. MIMM has the potential to be used as a myelin and iron
642 quantification tool for longitudinal studies.

676 **FIGURES**

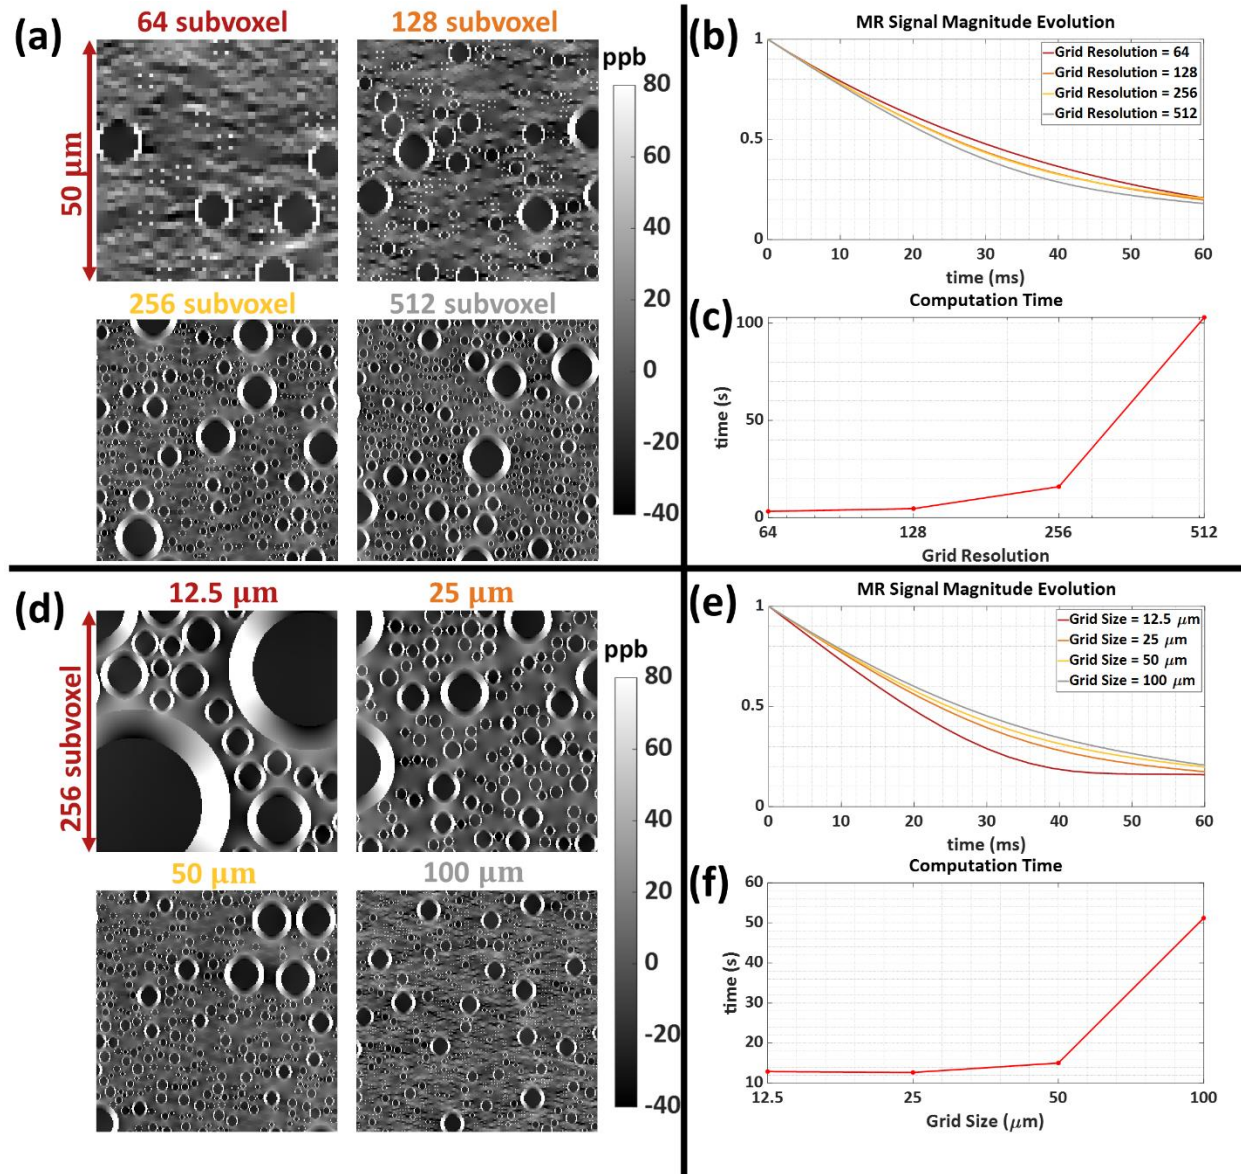

*Required only with the Orientation Informed Matching.

677

678 Figure 1. a) A detailed description of the dictionary generation and matching pursuit

679 process. b) Example dictionary elements showing how the magnitude signal evolutions

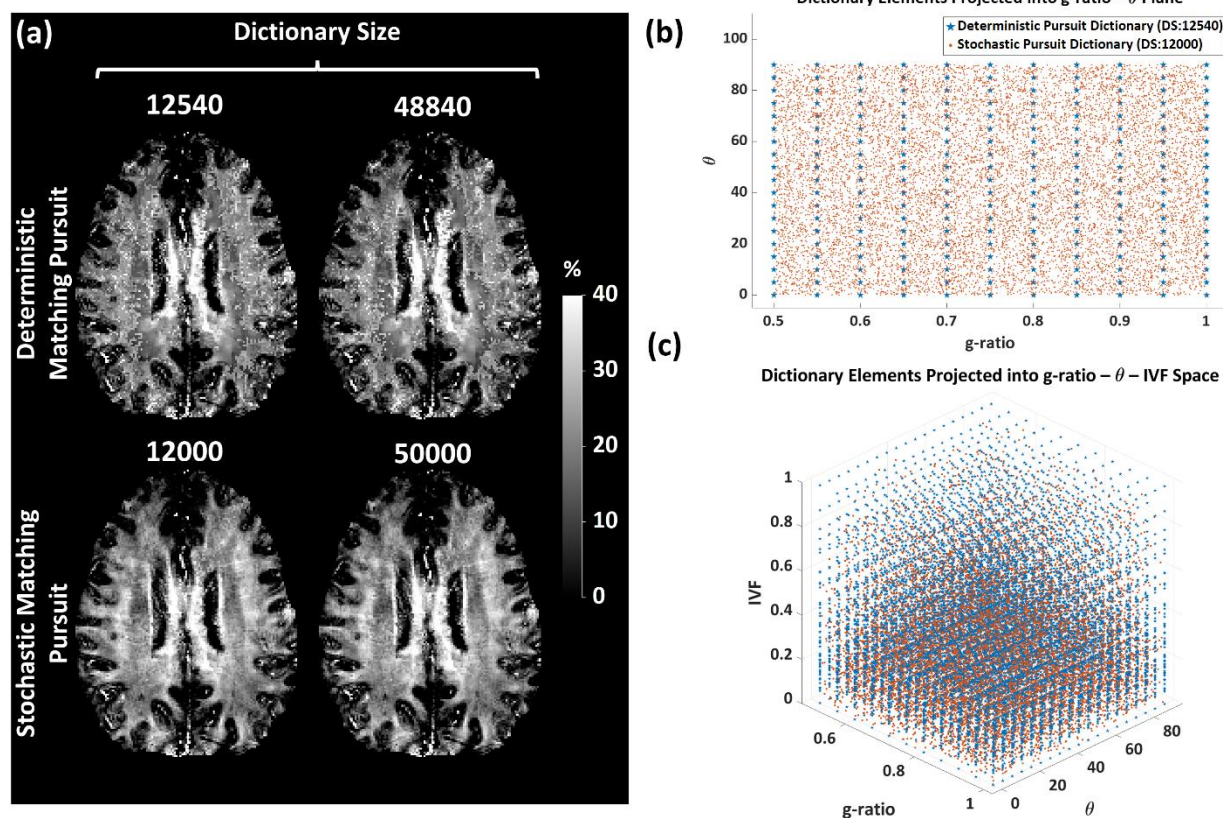

680 depend on the g-ratio and θ values.

681

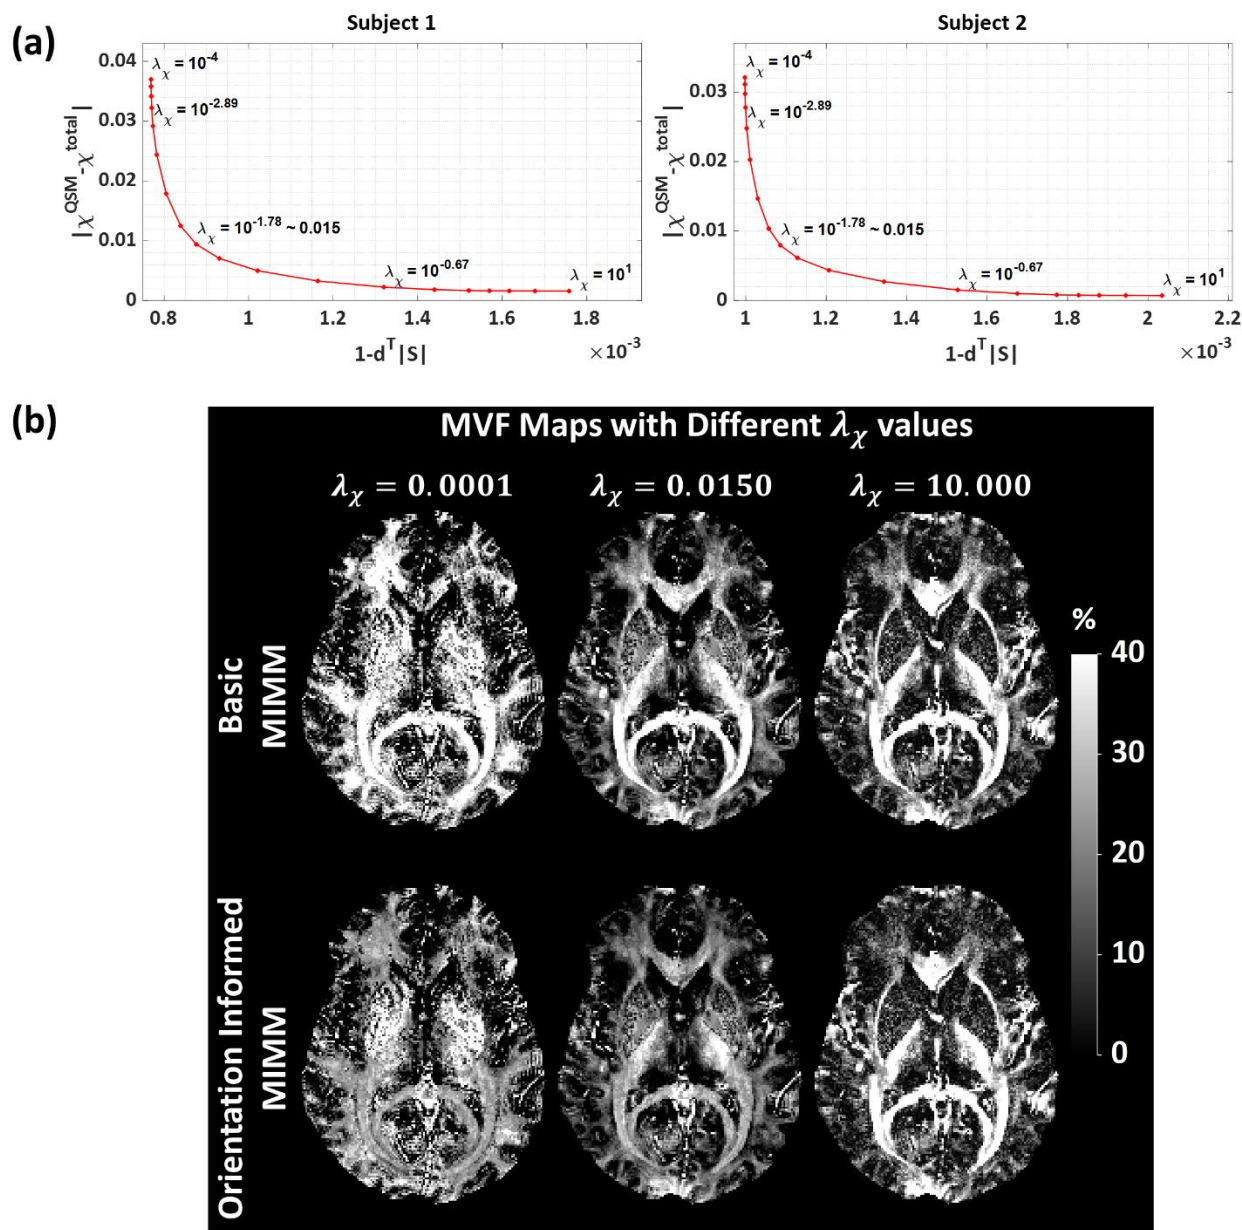

682 Figure 2. Comparison of different grid resolutions and grid sizes for the MR magnitude
 683 signal evolution simulations. a) Field perturbation distributions in 4 different resolution
 684 levels where the grid size is the same (50μ). b) Signal magnitude evolutions
 685 corresponding to 4 different resolutions. c) The time spent computing each signal
 686 magnitude evolution for each resolution. d) Field perturbation distributions in 4 different
 687 grid sizes where the grid resolution is the same (256 sub-voxel). e) Signal magnitude

688 evolutions corresponding to 4 different grid sizes. f) The time spent computing each signal
689 magnitude evolution for each grid size.

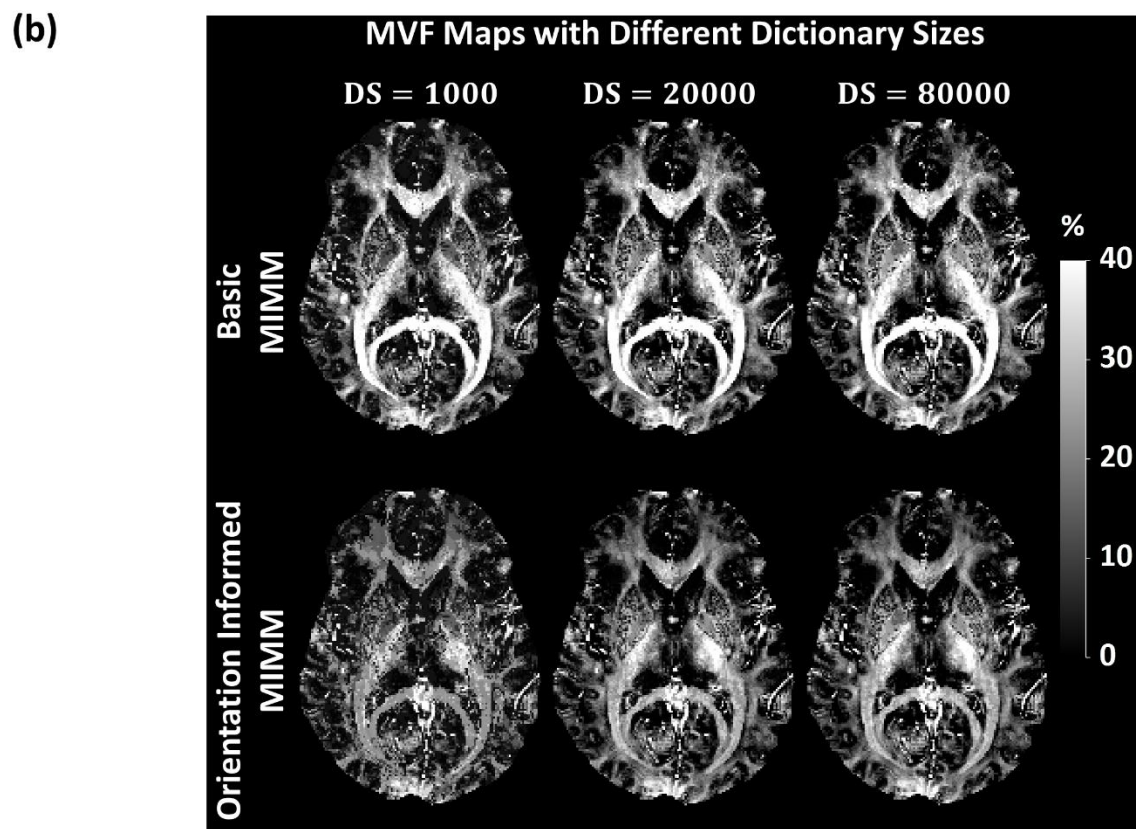

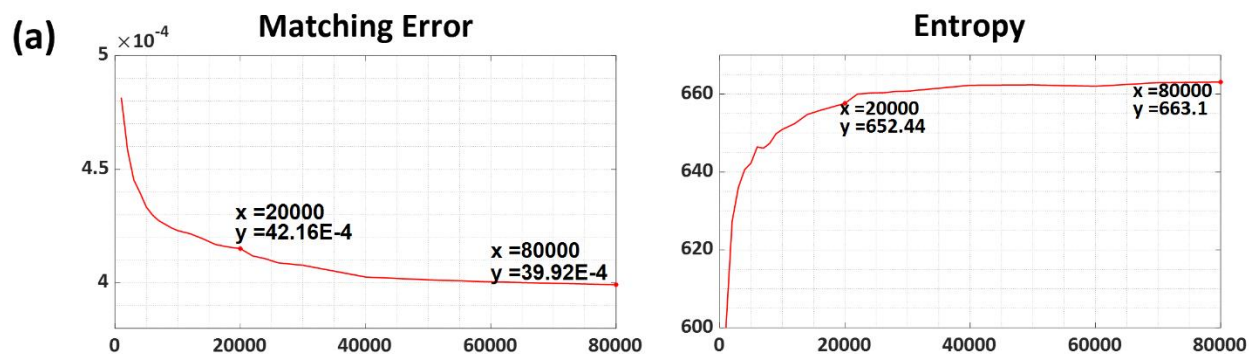

690
691 Figure 3. Comparison of the deterministic and stochastic matching pursuit (MIMM)
692 results. a) Example MVF maps obtained with deterministic matching pursuit and MIMM
693 with different dictionary sizes. Basic MIMM is utilized in this example. b) Projection of all
694 the dictionary elements utilized for the two pursuits onto the g-ratio - θ plane. c)
695 Projection of all the dictionary elements onto g-ratio - θ - IVF parameter space.

696

697

698 Figure 4. Analysis regarding the choice of the optimal weighting parameter λ_χ . a) L-curve
 699 analysis results for 2 different subjects using basic MIMM. The values demonstrated in
 700 the plots are obtained by averaging the errors obtained with the given λ_χ among all the
 701 voxels in 10 central slices. b) MVF maps obtained using basic and orientation informed
 702 MIMM using DTI and the dictionary of size 20000 with different λ_χ values.

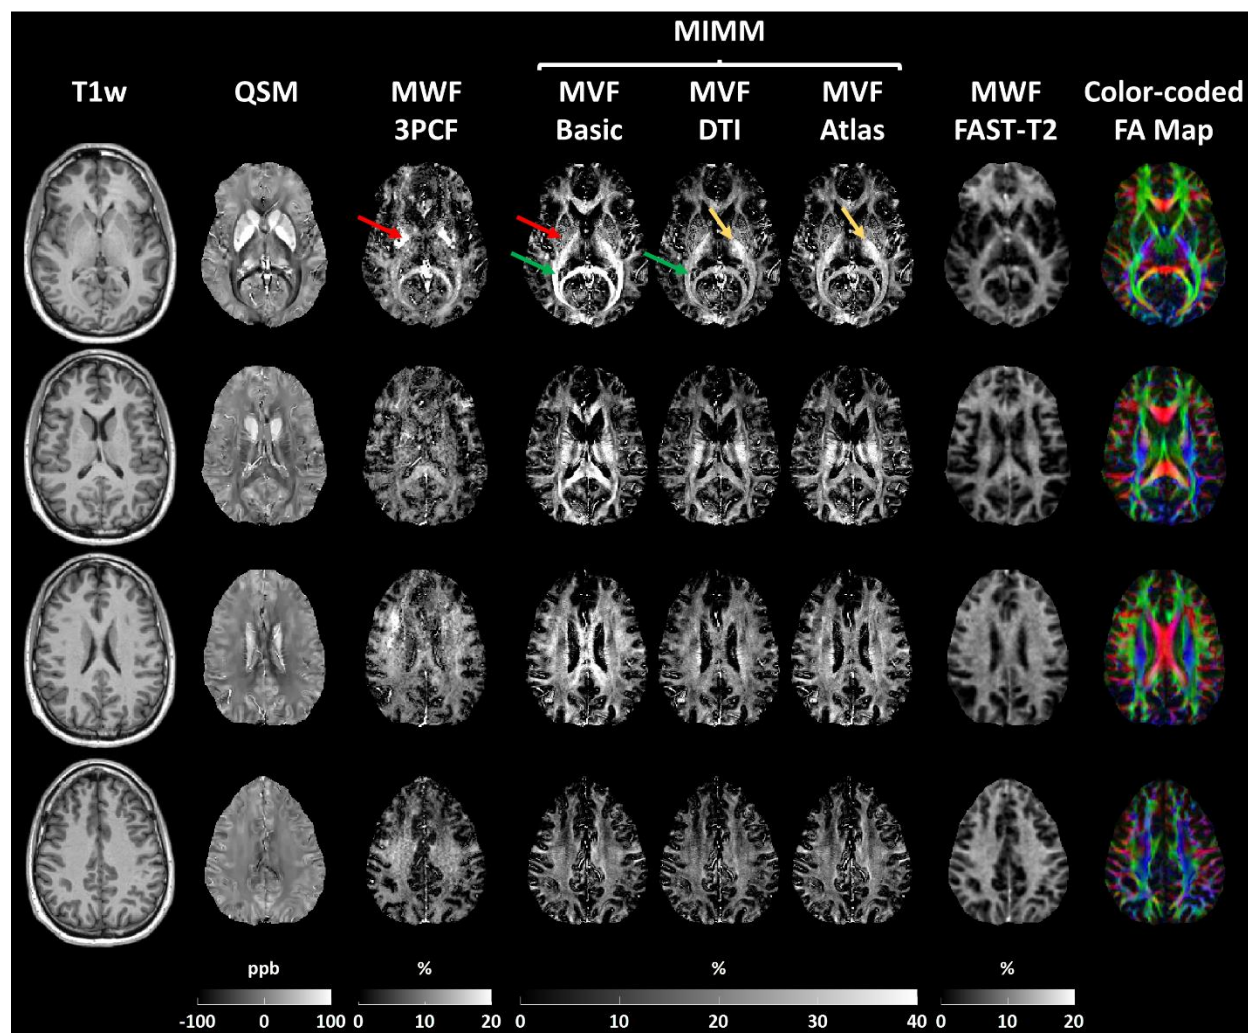

703

704 Figure 5. Analysis regarding the choice of the optimal dictionary size. a) Average

705 minimum fitting error and image entropy values computed over the white matter for an

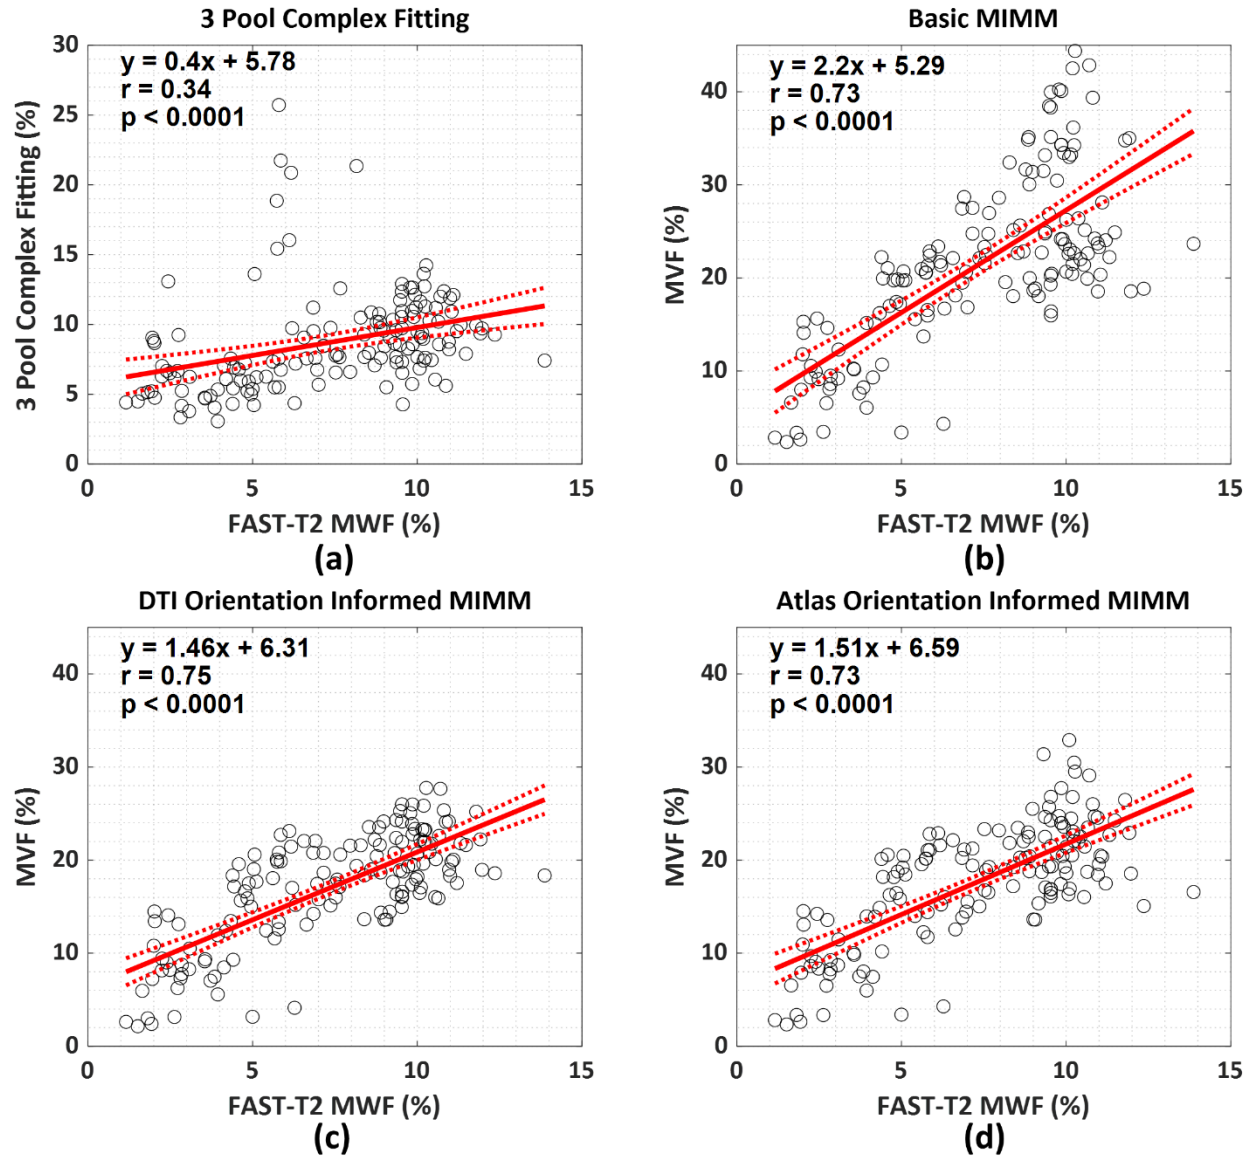

706 example subject for basic MIMM. b) MVF maps obtained using basic and DTI orientation

707 informed MIMM using different dictionary sizes using $\lambda_\chi = 0.015$.

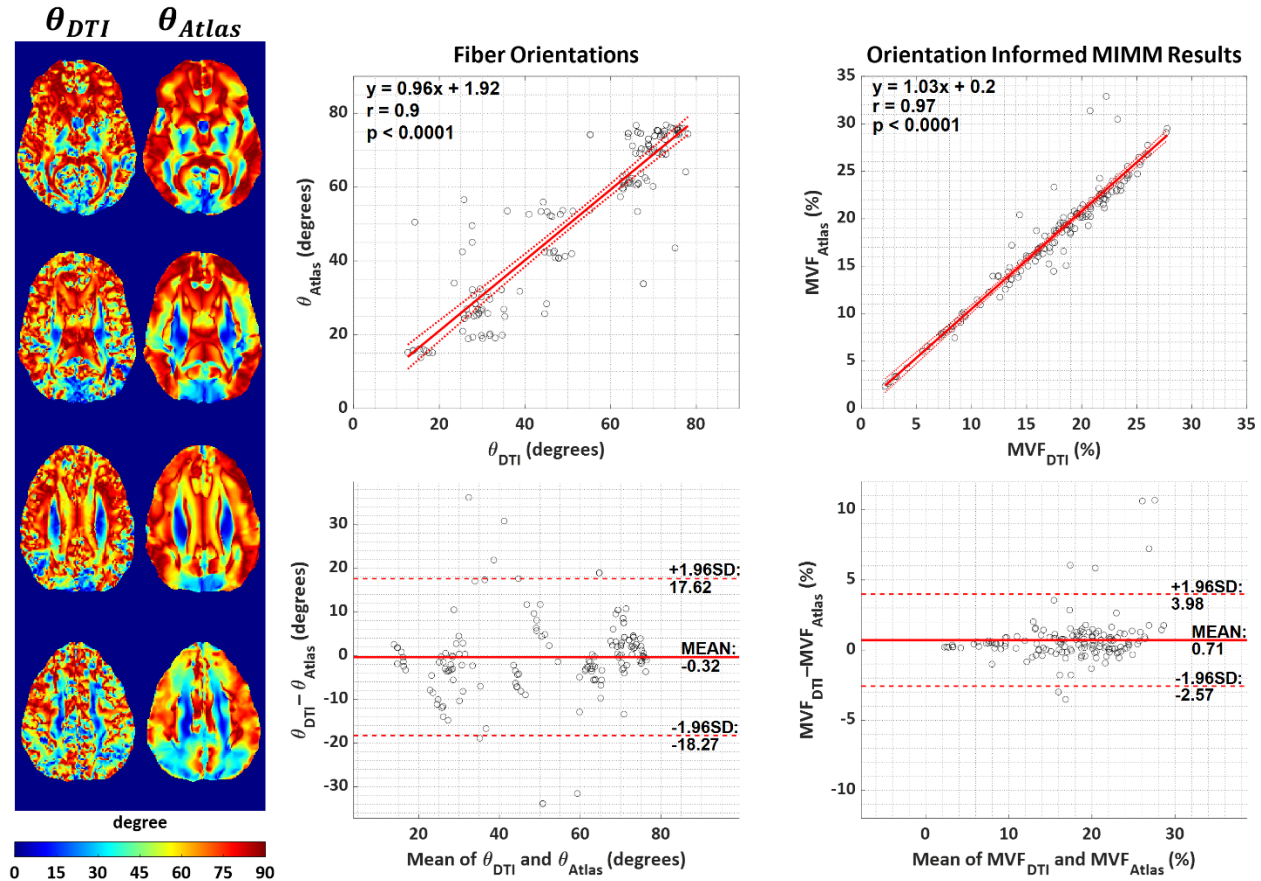

708

709 Figure 6. Example results from a single subject. From left to right: T1-weighted images
710 (T1w), QSM maps, MWF maps obtained with 3 pool complex fitting (3PCF), MWF maps
711 obtained with basic MIMM, DTI orientation informed MIMM, and atlas orientation informed
712 MIMM, MWF maps obtained using T2-relaxometry from the FAST-T2 data, and FA maps
713 obtained from diffusion tensor images. All images are registered to the QSM space.

714

715 Figure 7. Linear correlation analysis results between the FAST-T2 based MWF maps and
716 a) the MWF maps obtained using the 3 pool complex fitting, the MVF maps are acquired
717 from maps obtained using b) basic MIMM, c) DTI orientation informed MIM, and d) atlas
718 orientation informed MIMM.

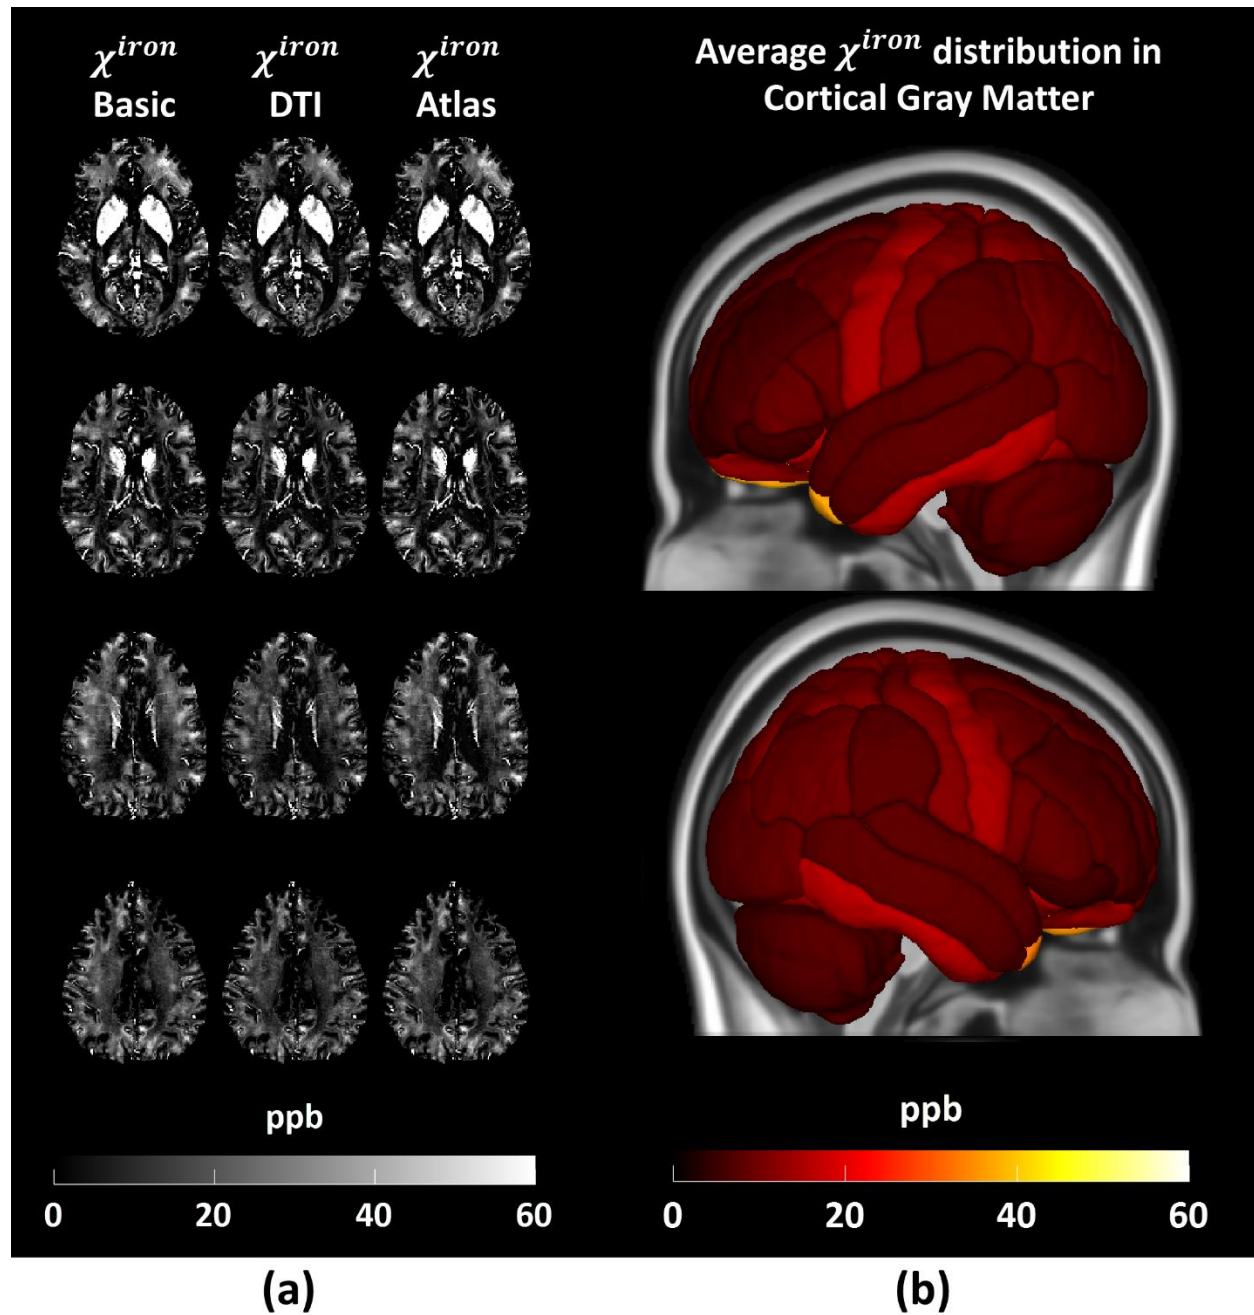

719

(a)

(b)

720 Figure 8. a) Comparison of the orientation maps extracted from DT images (θ_{DTI}) and
 721 ICBM DTI-81 atlas (θ_{Atlas}). b) Results of the linear correlation and Bland-Altman analysis
 722 between the ROI orientation angle values (left column) and the ROI MVF values obtained
 723 using orientation informed MIMM using the corresponding orientation maps.

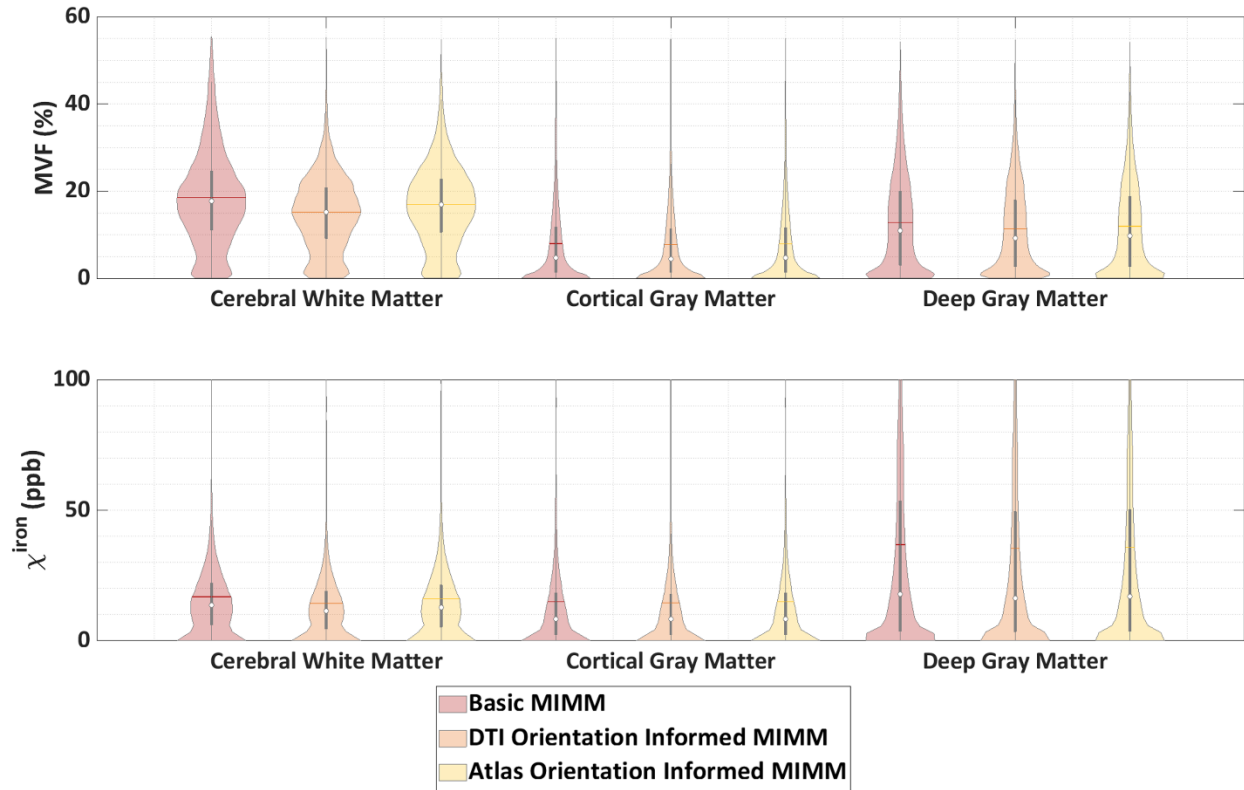

724

725 Figure 9. Example results of the χ^{iron} maps. a) χ^{iron} maps obtained from a single subject.

726 From left to right: χ^{iron} maps obtained with basic MIMM, DTI orientation informed MIMM,

727 and atlas orientation informed MIMM. b) Average χ^{iron} values across all subjects within

728 different cortical gray matter parcellations.

729

730 Figure 10. Violin plots showing the distribution of the voxel values in MVF (top row) and

731 χ^{iron} (bottom row) maps combined over all 10 subjects for 3 major brain regions.

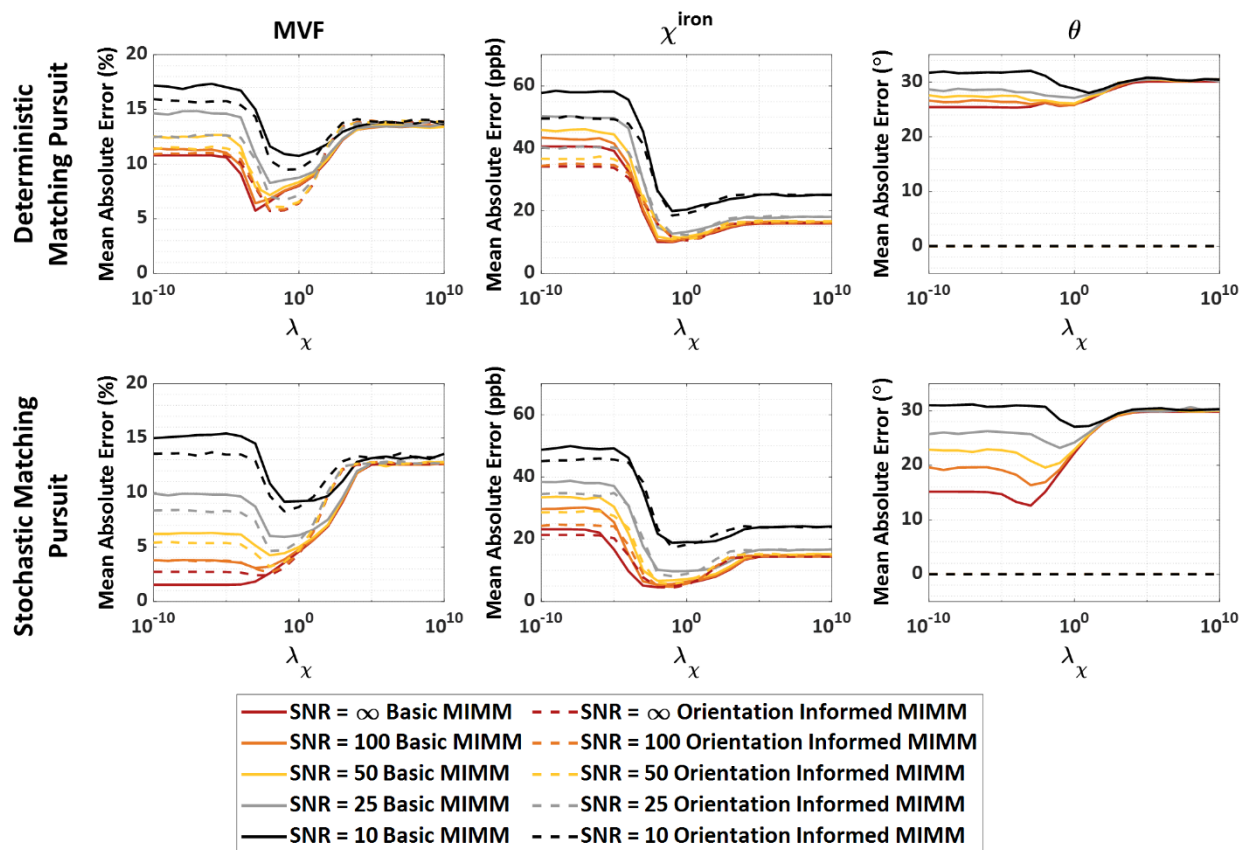

732 TABLES

733 Table 1: 3D microstructure informed dictionary simulation parameters and the utilized
 734 ranges of the parameters. The parameters are shown in 4 different categories based on
 735 their functions. 4 input parameters are the parameters that need to be defined for the
 736 simulations required to create a dictionary element. Intermediate parameters are the
 737 volume fractions that are estimated from the created volume distribution of myelin and
 738 iron and utilized to estimate voxel susceptibilities. Output parameters are the labels of
 739 each dictionary element that are assigned to each voxel after MIMM. The final set is the
 740 constant parameters that have been used in the dictionary generation. The values of the
 741 constant parameters are determined using the reported literature values. The
 742 corresponding studies for each constant parameter are also provided.

	Parameter	Range
Dictionary Generation Process Input Parameters	2DFD	[0,1]
	g – ratio	[0.5,1]
	θ	[0°,90°]
	EID	[0,1]
Intermediate Parameters	FVF	[0,0.75]
	IVF	[0,1]
MIMM Output Parameters	MVF	[0,0.55]
	χ^{iron}	[0 ppb,300 ppb]
Constant Parameters	$\chi_{\text{iso}} = \chi_{\text{ani}}$	–100 ppb (Wharton & Bowtell, 2012)
	χ_{iron}	300 ppb (Zheng, Nichol, Liu, Cheng, & Haacke, 2013)
	T_2^{IEW}	70 ms (S. H. Kolind, Mädler, Fischer, Li, & MacKay, 2009)
	T_2^{MW}	16 ms (Hédouin et al., 2021; Xu, Foxley, Kleinnijhuis, Chen, & Miller, 2018)
	ρ^{IEW}	1 (Hédouin et al., 2021; Xu et al., 2018)
	ρ^{MW}	0.5 (Hédouin et al., 2021; Xu et al., 2018)

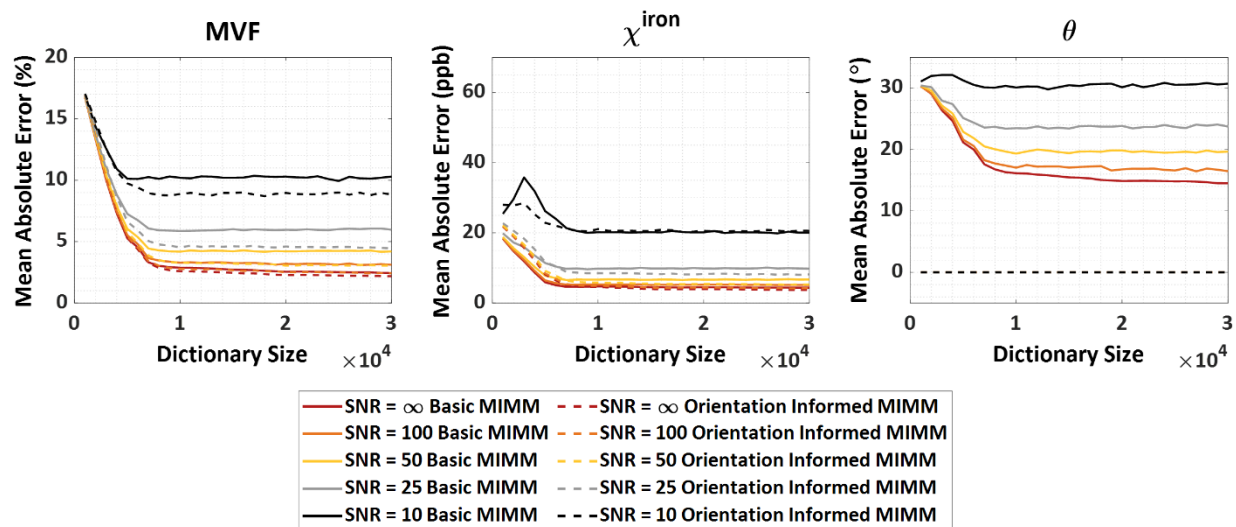

743

744 **SUPPLEMENTARY MATERIALS**

745
 746 Figure S1. Monte Carlo simulation results using both the deterministic (top row) and
 747 stochastic (bottom row) matching pursuit to demonstrate the SNR performance of the
 748 algorithms with different λ_χ values. Columns show the mean absolute errors for the 3
 749 outputs of the matching pursuit process: MVF, χ^{iron} , and θ . Solid lines show the errors
 750 for the basic matching pursuit whereas dashed lines show the errors for orientation
 751 informed matching pursuit for 5 different SNR levels.

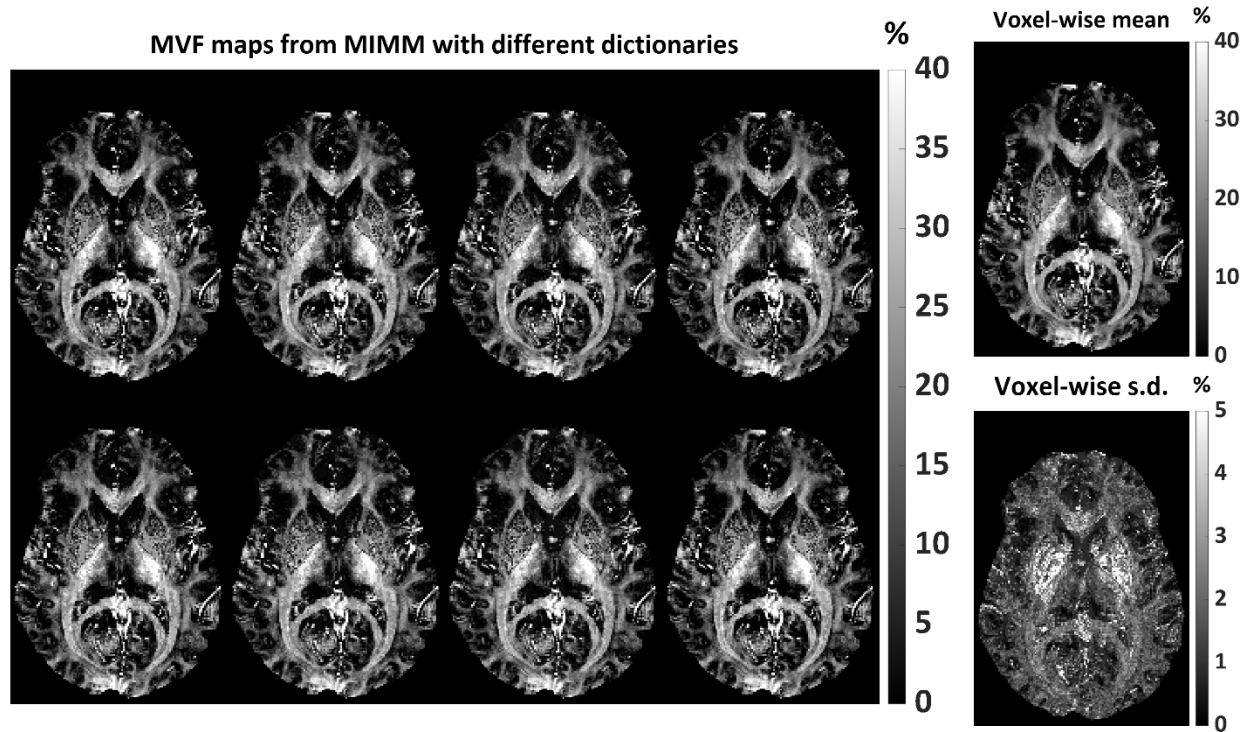

752

753

754 Figure S2. Monte Carlo simulation results to demonstrate the SNR performance of MIMM
 755 with different dictionary sizes. Columns show the mean absolute errors for the 3 outputs
 756 of the matching pursuit process: MVF, χ^{iron} , and θ . Solid lines show the errors for the
 757 basic MIMM whereas dashed lines show the errors for orientation informed MIMM for 5
 758 different SNR levels.

759

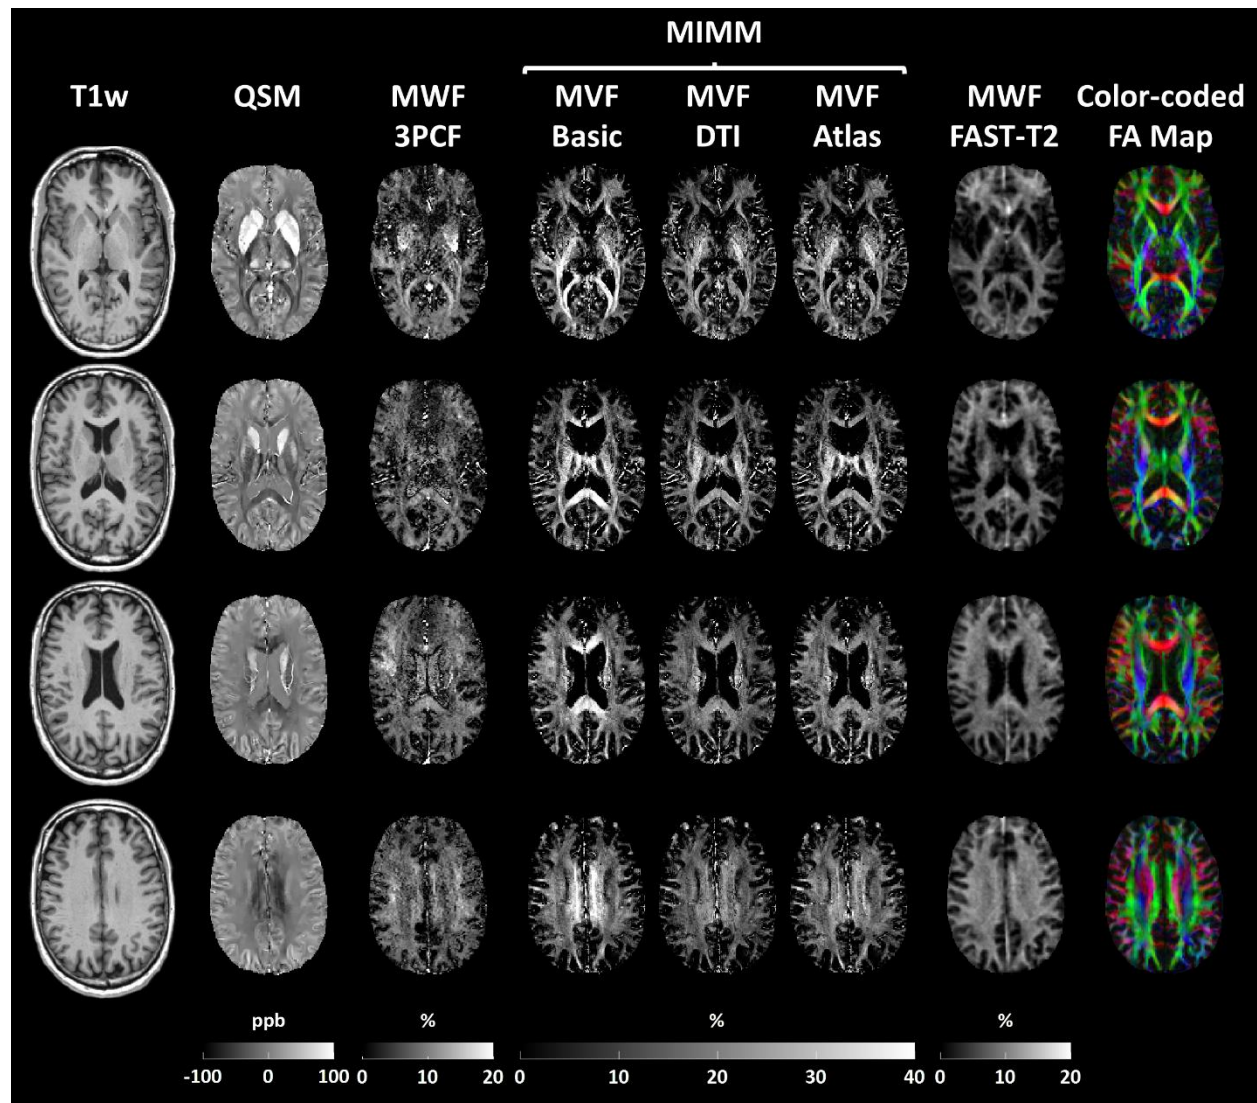

760

761 Figure S3. MVF maps obtained using orientation informed MIMM using DTI and 8
762 different and independently created dictionaries of size 10000 (left). $\lambda_\chi = 0.015$ is used.

763 The voxel-wise mean and standard deviation (S.D.) maps of the 8 MVF maps (right).

764

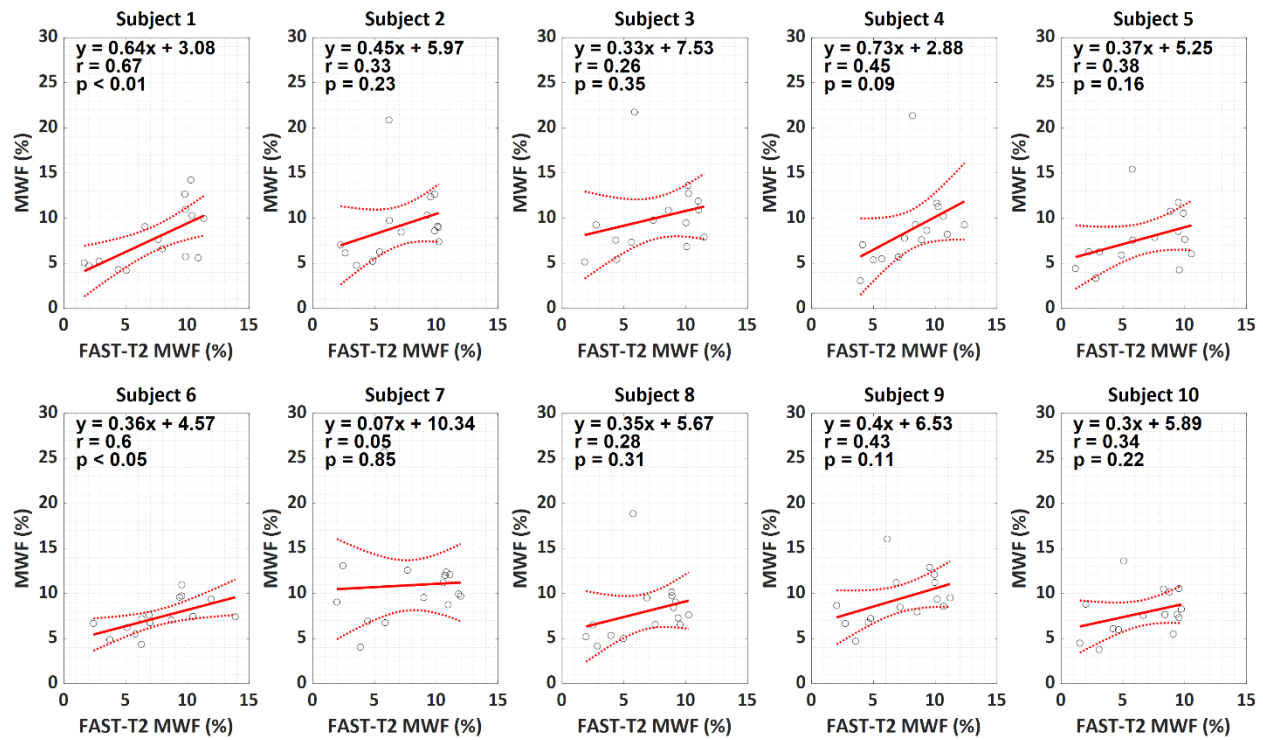

765

766 Figure S4. Example results from another subject. From left to right: T1-weighted images
767 (T1w), QSM maps, MWF maps obtained with 3 pool complex fitting (3PCF), MWF maps
768 obtained with basic MIMM, DTI orientation informed MIMM, and atlas orientation informed
769 MIMM, MWF maps obtained using T2-relaxometry from the FAST-T2 data, and FA maps
770 obtained from diffusion tensor images. All images are registered to the QSM space.
