17 Abstract

18 There are few data from sub-Saharan Africa on the virological outcomes associated with
19 second-line ART based on protease inhibitors or dolutegravir (DTG). We compared viral load
20 (VL) suppression among people living with HIV (PLWH) on atazanavir (ATV/r)- or dolutegravir
21 (DTG)-based second-line ART with PLWH on efavirenz (EFV)-based first-line ART. We
22 analyzed data from the electronic medical records system of Newlands Clinic in Harare,
23 Zimbabwe. We included patients aged ≥ 12 years when commencing first-line EFV-based ART or
24 switching to second-line DTG- or ATV/r-based ART with ≥ 24 weeks follow-up after start or
25 switch. We computed suppression rates (HIV VL < 50 copies/mL) at weeks 12, 24, 48, 72, and 96
26 and estimated the probability of VL suppression by treatment regimen, time since start/switch of
27 ART, sex, age, and CD4 cell count (at start/switch) using logistic regression in a Bayesian
28 framework. We included 7013 VL measurements of 1049 PLWH (61% female) initiating first-line
29 ART and 1114 patients (58% female) switching to second-line ART. Among those switching, 872
30 (78.3%) were switched to ATV/r and 242 (21.7%) to DTG. VL suppression was lower in second-
31 line ART patients than first-line ART patients, except at week 12, when those on DTG showed
32 higher suppression than those on EFV (aOR 2.10, 95%-credible interval [CrI] 1.48-3.00) and
33 ATV/r-based regimens (aOR 1.87, 95%-CrI 1.32-2.71). In weeks ≥ 48 , first-line patients had
34 around 3 times the odds of VL suppression compared to second-line patients. There was no
35 evidence of a difference between DTG and ATV/r for follow-up times ≥ 24 weeks in PLWH on
36 second-line. Second-line ART patients had lower VL suppression rates than those receiving first-
37 line ART, and there was no difference in suppression between DTG- and ATV/r-based second-
38 line ART ≥ 6 months after switching. Virologic monitoring and adherence support remain essential
39 to prevent second-line treatment failure in settings with limited treatment options.

40 **Introduction**

41 Antiretroviral therapy (ART) has become more effective, more affordable, and safer since
42 the advent of combination therapy in the mid-90s [1]. Currently, the integrase inhibitor
43 dolutegravir (DTG) in combination with two nucleoside reverse transcriptase inhibitors (NRTIs)
44 is recommended for patients initiating ART and for second-line ART among patients who
45 experienced virologic failure on regimens that did not include DTG [2]. Previously, efavirenz
46 (EFV) was recommended for first-line, and the ritonavir-boosted protease inhibitors atazanavir
47 (ATV/r) or lopinavir (LPV/r) for second-line ART, always combined with two NRTIs. DTG
48 achieves earlier virologic suppression compared to ritonavir-boosted protease inhibitors, has fewer
49 toxicities and may have a lower or similar incidence of resistance among patients receiving second-
50 line ART [2–4]. Compared with efavirenz, DTG had superior viral suppression over 96 weeks,
51 was protective against drug resistance, and led to fewer discontinuations [5–7].

52 The success of second-line ART depends on several factors. Poor adherence to treatment has
53 been identified in many studies as the critical determinant of virologic failure and the emergence
54 of drug resistance [8,9]. A high viral load, a low CD4 cell count or advanced HIV infection at the
55 time of switching, concomitant treatment for tuberculosis, and younger age are also associated
56 with poorer outcomes on second-line ART [10–13]. The availability of DTG in a fixed dose
57 combination with lamivudine (3TC) and tenofovir disoproxil fumarate (TDF), commonly referred
58 to as TLD, may improve treatment compliance and lead to better virologic suppression rates among
59 people living with HIV (PLWH) on second-line ART [2].

60 Compared with boosted protease inhibitors for ART naïve and treatment-experienced
61 PLWH with background NRTI resistance, DTG was neither inferior nor superior for viral

62 suppression [14–16]. In PLWH switching to DTG-based second-line ART, viral replication is
63 typically reduced to undetectable levels within the first four to 24 weeks of therapy [17,18].
64 However, long-term real-world virologic suppression and clinical outcomes after switching to
65 second-line ART are less well documented. Indeed, there is a lack of data on the outcomes
66 associated with second-line ART based on boosted protease inhibitors and second-line and first-
67 line ART based on DTG-containing regimens, particularly in sub-Saharan Africa. We compared
68 virologic suppression among adolescents and adults switching to DTG- or ATV/r-based second-
69 line ART after experiencing virologic failure with those starting EFV-based first-line ART in an
70 HIV care and treatment program in Zimbabwe.

71 **Methods**

72 **Setting and data**

73 We analyzed data of patients receiving ART at Newlands Clinic in Harare, Zimbabwe.
74 Newlands Clinic is an outpatient HIV referral centre with approximately 7,300 patients in care as
75 of June 2022. The clinic provides comprehensive HIV care to clients of low socio-economic status,
76 including ART, laboratory monitoring, psychosocial support, reproductive health care and other
77 ancillary services. It is supported by the Ruedi Luethy Foundation, a Swiss-based private voluntary
78 organization, and part of the International epidemiology Databases to Evaluate AIDS (IeDEA) in
79 Southern Africa. More details on the clinic’s activities are provided elsewhere [19,20]. From 2010
80 to 2019, EFV-based ART was predominantly used as first-line ART and ATV/r as second-line
81 ART at Newlands Clinic. Since 2019, DTG-based ART has been used both in first- and second-
82 line ART [2,21].

83 The present analysis was based on the database compiled from the clinic’s electronic
84 medical records system. The system is password protected, and only approved clinic staff can log
85 in and view patient records in accordance with the level of permission. We abstracted longitudinal
86 data of patients receiving ART between February 2013 and June 2022, including demographic
87 information, CD4 cell counts, and HIV-1 RNA viral loads. Viral loads were typically measured at
88 the time of switching or starting (baseline). After baseline, viral loads were measured at weeks 12
89 and 24 and then every 24 weeks. Measurements were done using the COBAS
90 Ampliprep/Taqman48 platform and Roche HIV-1 version 1.0 kits. CD4 counts were measured at
91 baseline using a Partec Cyflow Counter II machine with CD4 Easy Count reagents by Sysmex.

92 Patients enrolling into care at Newlands Clinic provided informed written consent that
93 allows the use of data accumulating during their routine care for research under the IeDEA
94 collaboration. IeDEA was approved by the Medical Research Council of Zimbabwe (MRCZ No.
95 A1336) [22]. The study data were stored in a password protected electronic medical records system
96 and were accessed on the 30th of August 2022 by authorised clinic personnel. The abstracted data
97 were supplied to the statistical analysis team as de-identified records that could not be traced to
98 individual patients.

99 **Inclusion criteria**

100 We included patients aged 12 years and older at the time of commencing ART or switching
101 to second-line ART who had at least 24 weeks on the new ART regimen. For patients commencing
102 ART, we included those starting with a regimen containing EFV, lamivudine (3TC) and one of
103 tenofovir (TDF), zidovudine (AZT), or abacavir (ABC). For second-line ART, we included
104 patients switching with a viral load above 200 copies/mL from an NNRTI-based first-line to

105 second-line regimens containing DTG or ATV/r combined with an NRTI backbone, as described
106 above.

107 **Outcome**

108 The outcome of interest was viral load suppression (HIV viral load <50 copies/mL) at week
109 12, 24, 48, 72 and 96 after baseline, in line with the clinic visits with scheduled VL measurements.
110 We allowed for a one-month window around these time points to account for shifts in visit dates.
111 For example, the “Week 24” measurements included VL measurements done 24 ± 4 weeks after
112 baseline. If several measurements were available, the one closest to the visit date was chosen for
113 analysis. Some VL measurements fell between two windows (for example, a measurement drawn
114 35 weeks after baseline was neither assigned to “Week 24” nor to “Week 48”). These
115 measurements were used to impute missing VL information when a patient did not have a VL
116 measurement for a visit date but did have a measurement right before and after the window around
117 the visit date. We assumed that the missing measurement indicated suppressed or unsuppressed
118 VL if both measurements (before and after) showed a suppressed or unsuppressed VL. If the
119 measurements before and after were different (suppressed and unsuppressed), we did not impute
120 the VL suppression information for the visit date.

121 **Explanatory variables**

122 Explanatory variables included the time of the VL measurement (as defined above as Week
123 12, Week 24, Week 48, Week 72, or Week 96 after baseline), the ART regimen, the patient’s sex,
124 age and CD4 cell count at baseline. Age at baseline was grouped into 12-19 years, 20-29, 30-39
125 years and ≥ 40 years. CD4 cell count at baseline was grouped into 0-199 cells/mm³, 200-349

126 cells/mm³ and ≥ 350 cells/mm³. ART regimens included “EFV” for first-line ART, and “ATV/r”
127 and “DTG” for second-line ART.

128 **Statistical analysis**

129 We calculated crude proportions of viral load suppression after baseline by ART regimen.
130 We then estimated the probability of viral load suppression using multivariable logistic regression
131 models in a Bayesian framework. To account for the dependence of viral load measurements
132 within patients, we included a random intercept by patient. As fixed effects, we included the
133 covariates ART regimen, time since baseline, sex, age and CD4 cell count. We checked if the
134 inclusion of any two-way interaction between covariates improved the model fit in two steps. First,
135 we compared model fits of the simple model without any interactions to alternative models
136 containing one single two-way interaction. All two-way interactions for whom the comparison to
137 the simple model showed a difference in expected log pointwise density that was larger two times
138 its standard error were considered "eligible" for inclusion in the final model [23]. In the second
139 step, we looked at all possible combinations of the eligible two-way interactions. The final model
140 was the one with the best fit (again, according to the expected density).

141 We report adjusted odds ratios (aOR) for VL suppression and crude and predicted
142 proportions of VL suppression with 95% credible intervals (CrIs). For both aORs and predicted
143 probabilities, we report marginalized (“sample-averaged”) estimates derived by integrating over
144 the distribution of random effects. Next to reporting predicted proportions stratified by all levels
145 of covariates, we also report them standardized and non-standardized by time and treatment
146 regimen. For standardized predictions, we predicted the probability of VL suppression at weeks
147 12, 24, 48, 72, and 96 for every study patient, assuming they were on DTG, then assuming they

148 were on ATV/r and finally on EFV. We then averaged all the predicted probabilities of viral load
149 suppression for each treatment regimen and time point. Non-standardized predictions consisted of
150 predicting the probability of VL suppression for the observed data only.

151

152 **Results**

153 Overall, we included 2163 PLWH (59.9% female), of whom 1114 were switching to
154 second-line ART, and 1049 were initiating first-line ART ([Table 1](#)). Patients switching to second-
155 line ART were younger (median age 29 years; IQR 19-42) than those starting first-line ART (36
156 years; IQR 28-44). Among the second-line ART patients, 872 (78.3%) switched to ATV/r-based
157 ART, while 242 (21.7%) switched to DTG-based ART ([Table 1](#)). Patients switching to ATV/r-
158 based second-line ART had lower CD4 cell counts than those switching to DTG or starting an
159 EFV-based first-line regimen ([Table 1](#)). The 2163 patients contributed 7413 VL measurements, of
160 which (7181, 96.9%) were observed and 232 (3.0%) imputed. Around three-quarters of patients
161 had a VL measurement at shorter follow-up times (weeks 12, 24, 48), while this proportion was
162 lower for longer follow-up times ([Table 1](#)). For DTG, fewer patients had a VL measurement at
163 longer follow-up times than the other two regimens. As indicated by the later calendar years of
164 starting/switching ART for DTG, this was mainly due to the follow-up time of patients switching
165 to DTG being too short to contribute VL measurements for later weeks ([Table 1](#)). Only a few
166 patients were lost to follow-up or died during the follow-up time relevant to this study ([Table 1](#)).

167

168 **Table 1. Baseline demographic and clinical characteristics of patients by treatment regimen.**

	First line	Second line		Overall
	EFV	ATV/r	DTG	
Total	1049	872	242	2163
Female	645 (61.5%)	506 (58.0%)	145 (59.9%)	1296 (59.9%)
Male	404 (38.5%)	366 (42.0%)	97 (40.1%)	867 (40.1%)
Age [years]				
Median (IQR)	36 (28-44)	29 (19-41.25)	28.5 (19-42)	34 (22-43)
12 - 19	97 (9.2%)	224 (25.7%)	67 (27.7%)	388 (17.9%)
20 - 29	202 (19.3%)	219 (25.1%)	58 (24.0%)	479 (22.1%)
30 - 39	348 (33.2%)	161 (18.5%)	49 (20.2%)	558 (25.8%)
40+	402 (38.3%)	268 (30.7%)	68 (28.1%)	738 (34.1%)

Median (IQR)	251 (122-363)	182 (73-331)	253 (78-469)	224 (97-360)
<200	426 (40.6%)	461 (52.9%)	98 (40.5%)	985 (45.5%)
200-349	331 (31.6%)	219 (25.1%)	51 (21.1%)	601 (27.8%)
>=350	292 (27.8%)	192 (22.0%)	93 (38.4%)	577 (26.7%)
Number of viral load measurements				
Median (IQR)	4 (2-4)	4 (3-5)	3 (2-4)	4 (3-4)
Viral load suppression				
at week 12	800 (76.3%)	683 (78.3%)	202 (83.5%)	1685 (77.9%)
at week 24	884 (84.3%)	722 (82.8%)	175 (72.3%)	1781 (82.3%)
at week 48	812 (77.4%)	663 (76.0%)	155 (64.0%)	1630 (75.4%)
at week 72	424 (40.4%)	506 (58.0%)	108 (44.6%)	1038 (48.0%)
at week 96	627 (59.8%)	565 (64.8%)	87 (36.0%)	1279 (59.1%)
Year of ART start/switch				
Median (IQR)	2016 (2015-2017)	2017 (2016-2018)	2021 (2020-2021)	2017 (2016-2018)
Status at end of follow-up*				
In care	988 (94.2%)	832 (95.4%)	230 (95.0%)	2050 (94.8%)
LTFU	42 (4.0%)	18 (2.1%)	4 (1.7%)	64 (3.0%)
Dead	19 (1.8%)	22 (2.5%)	8 (3.3%)	49 (2.3%)

169 * LTFU and Dead correspond to patients who were lost to follow-up or died within the follow-up time
 170 relevant to this study. In care corresponds to those who remained in care by week 100 after
 171 starting/switching ART or at database closure, whichever came first. EFV, efavirenz; ATV/r, ritonavir-
 172 boosted atazanavir; DTG, dolutegravir; IQR, interquartile range; LTFU, lost to follow-up.

173
 174 Crude rates of virologic suppression were lower on second-line ART than first-line ART
 175 (Figure 1). The exception was week 12 when the DTG-based regimen showed higher suppression
 176 (crude proportion 69.9%, 95%-CrI 63.6-75.9%) than ATV/r (crude proportion 53.9%, 95%-CrI
 177 50.1-57.8%) and EFV-based regimens (crude proportion 57.1%, 95%-CrI 53.6-60.5%). Among

178 the second-line ART regimens, crude rates of virologic suppression for follow-up times greater
179 than 24 weeks were slightly higher for DTG (73.5%, 95%-CrI 69.7-77.5%) compared to ATV/r
180 (68.2%, 95%-CrI 66.2-70.0%).

181 **Figure 1. Crude proportions (with 95% credible intervals) of viral load suppression by**
182 **treatment regimen and time post switch (ATV/r, DTG) or start (EFV) of ART.** EFV,
183 efavirenz; ATV/r, ritonavir-boosted atazanavir; DTG, dolutegravir.

184

185 Only the two-way interactions between time and ART regimen and between time and age
186 met the criteria for potential inclusion in the final model. The model including only the time-ART
187 regimen interaction, and the model including both the time-ART regimen and the time-age
188 interaction led to similar model fits, with a slightly better fit for the simpler model ([Supplementary](#)
189 [Table S1](#)). The final logistic regression model thus only included the two-way interaction between
190 time and ART regimen. The final model fitted the data well, with a few exceptions when there was
191 large uncertainty due to small numbers ([Supplementary Figure S1](#)).

192 The regression model confirmed the higher odds of VL suppression for DTG at short
193 follow-up (aOR 1.87, 95% CrI 1.32-2.71 comparing DTG to ATV/r at Week 12 and aOR 2.10,
194 95% CrI 1.48-3.00 comparing DTG to EFV, [Figure 2](#)). While for DTG, the odds of VL suppression
195 did not increase substantially for longer follow-up periods, they did so for patients on ATV/r and
196 even more for those on EFV ([Figure 2](#), [Figure 3](#)). After 24 weeks, the estimated odds of VL
197 suppression were relatively stable for both second-line regimens, and there was no evidence of a
198 difference between DTG and ATV/r. For EFV, the odds of VL suppression also reached a stable
199 plateau but slightly later, at 48 weeks. At that time, the odds of VL suppression was estimated to

200 be around 3 times higher than the second-line regimens ([Figure 2](#), [Figure 3](#)). Apart from the
201 differences between first- and second-line regimens, the odds of VL suppression were higher for
202 females and increased with age and CD4 cell count ([Figure 2](#)). VL suppression was lowest for
203 adolescents, with estimated suppression rates mostly below 75% in adolescents switching to
204 second-line ART and below 60% for those switching with CD4 cell counts below 200 cells/mm³
205 ([Supplementary Figure S1](#)).

206 **Figure 2. Adjusted odds ratios (aOR) for viral load suppression with 95% (red) credible**
207 **intervals.** Results derived from a Bayesian logistic regression model including a random intercept
208 by patient and the covariates sex, baseline age, baseline CD4 cell count, time since start/switch,
209 and ART regimen. The model also includes a two-way interaction between ART regimen and time
210 since start/switch, so that the aORs comparing ART regimens are shown stratified by time.
211 Estimates are marginalized by integration over the distribution of random effects. EFV, efavirenz;
212 ATV/r, ritonavir-boosted atazanavir; DTG, dolutegravir.

213 **Figure 3. Non-standardized (left panel) and standardized (right panel) predicted**
214 **proportions and 95% credible intervals of viral load suppression by treatment regimen and**
215 **time since switch (DTG, ATV/r) or start (EFV).** Results from a Bayesian logistic regression
216 model including a random intercept by patient and the covariates sex, baseline age, baseline CD4
217 cell count, time since start/switch, ART regimen, and a two-way interaction between time since
218 start/switch and ART regimen. Estimates are marginalized by integrating over the distribution of
219 random effects.

220 Standardized and non-standardized differences in VL suppression rates between regimens
221 were overall similar, but standardization attenuated differences between the two second-line
222 regimens ([Figure 3](#)). At week 48, standardized predicted proportions of VL suppression were

223 89.1% (95% CrI 86.9-90.9%) for EFV, 74.5% (95%-CrI 68.0-80.7%) for DTG, and 72.9% (95%-
224 CrI 69.5-76.1%) for ATV/r ([Figure 3](#)). Corresponding non-standardized proportions of VL
225 suppression at week 48 were 90.3% (95%-CrI 88.4-91.9%) for EFV, 72.9% (95%-CrI 66.1-79.3%)
226 for DTG, and 69.9% (95%-CrI 66.2-73.2%) for ATV/r ([Figure 3](#)).

227

228 **Discussion**

229 In this longitudinal analysis of routine clinical data collected in an urban ART program in
230 Zimbabwe, we examined virologic suppression among PLWH switching to DTG- or ATV/r-based
231 second-line ART after experiencing virologic failure, and PLWH starting ART on EFV-based
232 first-line regimens. Suppression rates were highest for first-line patients receiving EFV-based ART
233 from weeks 24 through 96. Older age and higher CD4 cell count at switch or start were associated
234 with higher odds of virologic suppression. In contrast, male sex was associated with reduced odds
235 of virologic suppression across all regimens. Our results confirm the more rapid suppression of
236 viral replication with DTG-based ART than EFV-based ART, even if used in second-line ART
237 [3,4].

238 Our study's limitations include the absence of objective measures of treatment adherence
239 and baseline drug resistance profiles. Also, not all patients had VL measurements taken at all time
240 points, especially in later weeks and patients switching to DTG. This was mainly due to the shorter
241 follow-up time of patients switching to DTG. Contrary to EFV and ATV/r, which were mainly
242 used before 2019 and thus allowed most patients to have ≥ 2 years of follow-up, DTG was only
243 introduced in 2019. Therefore, recently switched patients can only contribute VL measurements
244 to the earlier weeks. Further, many patients switched to DTG-based second-line during the Covid-

245 19 national lockdown period. The different periods are a limitation of this study, as we cannot
246 exclude residual confounding by the Covid-19 pandemic or other factors that might have changed
247 over time.

248 Our study took advantage of a long-standing, well-characterized cohort with high retention
249 in care and reliable data collection [20]. This is reflected in the fact that we had little loss to follow-
250 up over the study period and very few missing CD4 counts, which is rare for observational cohorts
251 in similar settings. Another strength lies in using a Bayesian approach, which allowed us to test
252 for many interactions and calculate standardized probabilities of viral load suppression that allow
253 more informative comparisons between treatment regimens correcting for differences in
254 characteristics between first- and second-line patients.

255 Many of the PLWH on second-line ART will probably have a history of poor adherence,
256 which led to virologic failure on first-line ART and, in some patients, could have led to the
257 development of drug resistance. However, NNRTI pretreatment resistance likely played a more
258 significant role in the last decade [24–27]. Second-line virologic failure (DTG or ATV/r) may
259 more likely be related to poor treatment compliance based on literature showing almost no
260 pretreatment or transmitted drug resistance among protease inhibitor- and INSTI-naïve PLWH in
261 Zimbabwe and the demonstrated efficacy of both DTG and protease inhibitors with suboptimal
262 NRTI backbones [15,25,28–30]. In addition, a longer duration of ART is associated with a higher
263 likelihood of treatment failure [31,32]. Even though both DTG and ATV/r are potent
264 antiretrovirals, with DTG being superior to EFV for both viral suppression and tolerability
265 [5,7,33], the overall suppression rates among the second-line patients were lower than those
266 observed for first-line patients in all age groups, sex, and baseline CD4 cell count strata. This
267 suggests that for patients with a history of treatment failure, switching to DTG or ATV/r alone

268 without other adherence support interventions may not be sufficient to reach the programmatic
269 targets of 95% or higher VL suppression [34,35]. Failure to achieve virologic suppression among
270 patients receiving second-line DTG-based ART can expose these patients to the emergence of drug
271 resistance against DTG and the beginning of transmitted drug resistance to the INSTI class. Several
272 cases of acquired and pretreatment DTG resistance have already been reported [36–38].

273 Almost half of the patients analyzed in this study had advanced HIV disease with baseline
274 CD4 cell counts <200cells/mm³. Although lower CD4 cell counts are the consequence of HIV
275 replication, it is unclear why lower baseline CD4 counts are associated with failure to suppress VL
276 across all the regimens in this study. Higher viral loads at ART commencement are associated with
277 prolonged durations before viral suppression leading to increased odds of virologic failure on
278 NNRTI containing ART [39,40]. Further, severe immune suppression might indicate a lower
279 commitment to starting/switching ART or engaging in adherence support initiatives, which in turn
280 is likely associated with reduced treatment adherence [35]. Low CD4 cell counts when switching
281 to second-line ART may also result from previous loss to follow-up, treatment interruption, or
282 inconsistent clinic visits. Some studies have also shown a relationship between low baseline CD4
283 cell counts and subsequent virologic failure, while another study from Mozambique showed an
284 association between higher baseline CD4 cell counts and virologic failure [24,41,42].

285 Patients switching to second-line ART were younger than those starting first-line.
286 Likewise, younger patients were also less likely to achieve virologic suppression across all
287 regimens. Younger age has previously been associated with poorer adherence and virologic failure
288 without accompanying drug resistance [24,43]. This observation warrants investment in custom
289 treatment support interventions that foster improved treatment adherence among young PLWH.

290 **Conclusion**

291 Patients receiving second-line ART were less likely to achieve virologic suppression than
292 those on first-line ART, despite switching to robust or even superior regimens. The probability of
293 virologic suppression increased with increasing age and baseline CD4 cell count. Further efforts
294 are needed to enhance treatment adherence among young PLWH and, more broadly, those
295 switching after virologic failure in settings with limited treatment options.
