28

29 **Abstract**

30 **BACKGROUND:**

31 Small extracellular vesicles (sEVs) released in the cardiac microenvironment are reported to
32 regulate cardiac remodelling, partially via microRNA transfer. Harvesting sEVs produced
33 exclusively from the myocardium remains challenging and a solid research platform for sEV
34 cardiovascular testing needs to be established. Organotypic living myocardial slices (LMS)
35 allow to mimic cardiac disease and to record electrophysiological responses to biological
36 and pharmacological stimuli. This study aims at understanding how cardiac sEVs obtained
37 from donor and failing human LMS and rat LMS under physiological or heart failure-
38 mimicking conditions impact myocardial function and remodelling.

39

40 **METHODS & RESULTS:**

41 Human LMS were obtained from the left ventricle (LV) of human donor non-failing and end-
42 stage failing hearts and cultured at 2.2 μm sarcomere length (SL). Rat LV LMS from healthy
43 Sprague-Dawley rats were cultured at a preload of 2.2 or 2.4 μm SL, to recapitulate
44 physiological load and overload, respectively. Following 48-hours biomimetic culture, sEVs
45 were isolated from the culture media by size exclusion chromatography and characterized
46 for their size, concentration, and expression of exosome markers. LMS from human failing
47 hearts presented impaired contractility ($P < 0.05$ vs donor-LMS), which was improved by
48 application of donor heart-derived sEVs at 15 and 20% stretch. Whilst rat overloaded sEVs
49 did not alter the force production of physiological LMS, physiological sEVs significantly
50 increased the active force and decreased their passive force. In rat LMS, 1×10^8 physiological
51 EVs/slice restored the contractility of overloaded slices, reduced apoptosis, fibrosis-related
52 gene expression and promoted angiogenesis. microRNAs analysis showed significant
53 upregulation of miR-23a-3p and miR-378a-3p in rat physiological sEVs. Finally, to test
54 whether sEVs have a direct effect on cardiomyocytes, we applied sEVs on cultured induced
55 pluripotent stem cell-derived cardiomyocytes (iPSC-CMs). sEVs did not affect the
56 contractility of iPSC-CM monoculture but increased the contractility of iPSC-CM co-cultured
57 with human microvasculature endothelial cells (MVECs).

58

59 **CONCLUSIONS:**

60 Cardiac sEVs isolated from healthy hearts increase the contractility of failing LMS. This effect
61 is associated with, and possibly brought about by, a combination of inhibition of apoptosis,
62 reduction of fibrosis and increased microvascular density, and could involve the transfer of
63 sEV-microRNA into myocardial cells. Our data support the hypothesis that the sEV inotropic
64 action is mediated by endothelial cells.

65 Introduction

66 Increased mechanical load caused by either excessive pressure or volume in the left
67 ventricle is an important driver of cardiac remodelling. Multiple changes take place during
68 remodelling caused by mechanical overload, such as development of hypertrophy,
69 myocardial cells death, fibrosis, and blood vessel rarefaction. Over time these changes lead
70 to ventricular dysfunction and ultimately heart failure¹.

71 During both physiology and disease, cell-cell communication is responsible for driving
72 cellular and molecular changes to respond to changes in the environment^{2,3}. Numerous
73 mechanisms of cell-cell communication, from direct contact to the release of soluble
74 paracrine and endocrine factors, have been extensively investigated and are known to be
75 important mediators of both cardiac homeostasis and remodelling.

76 Extracellular vesicles (EVs) encompass several types of nanosized and micro-sized vesicles
77 with a lipid bilayer membrane and bioactive cargoes, including nucleic acids, proteins, lipids
78 and metabolites⁴. Small EVs (sEVs), also known as exosomes, have been already recognized
79 as important mediators of intercellular and extracellular communications in the
80 cardiovascular system⁵. Both proteins and microRNAs (miRNAs) have been found to mediate
81 cellular responses induced by sEVs, including cardiac remodeling and cardiac protection^{6, 7, 8,}
82 ⁹. Despite the interest for sEVs in cardiovascular research, the understanding of the role of
83 endogenous cardiac sEVs in the local microenvironment has been so far hindered by the lack
84 of appropriate research models. Previous *in vitro* and *in vivo* studies have adopted sEVs
85 prepared from either complex and non-cardiac specific samples, such as the human
86 plasma¹⁰, or cultured cells, which are unable to recapitulate the complexity of the
87 myocardium, making most studies of low translational value².

88 Living myocardial slices (LMS) are 300 µm thin layers of ventricular myocardial tissue that
89 can be obtained from human heart of donors and heart failure patients and, also, from
90 different small and large animal species¹¹. LMS not only retain the multi- and hetero-
91 cellular composition, the electrophysiology, and the extracellular matrix of the adult
92 myocardium, but also possess the ability to long term culture while performing physiological
93 functions, the ability to be manipulated in a specific and controlled manner by various
94 stimuli, and the capacity to be studied for cellular and molecular mechanisms¹¹⁻¹³.
95 Noteworthy, pathological stimuli known to affect cardiac remodelling and sEVs biology, such
96 as mechanical overload, can be reliably reproduced in LMS¹⁴⁻¹⁶.

97 In this study, we have employed LMS to isolate and characterize sEVs released from human
98 donors and failing hearts. We have complemented the human studies with analyses of rat
99 LMS subjected to different degrees of mechanical load to investigate the effects of cardiac-
100 derived sEVs on the regulation of cardiac contractility and structural and molecular
101 overload-induced myocardial remodelling.

102 Methods

103 Methods are described in detail in the Supplemental Material.

104 Ethical statements for the use of human and rat hearts

105 Human failing hearts were obtained from the NIHR Cardiovascular Biomedical Research Unit
106 at the Royal Brompton and Harefield NHS Foundation Trust and Imperial College London.
107 The study was approved by a UK institutional ethics committee (NRES ethics number for
108 biobank samples: 09/H0504/104 + 5; Biobank approval number: NP001-06-2015 and
109 MED_CT_17_079) and Imperial College London.

110 Human donor hearts were obtained from the NHS Blood and Transplant INOAR program
111 (IRAS project ID: 189069) approved by the NHS Health Research Authority, in accordance
112 with the Governance Arrangements for Research Ethics Committees. This study is fully
113 compliant with the Standard Operating Procedures for Research Ethics Committees in the
114 UK. Informed consent was obtained from each patient/family involved in this study.

115 All experiments performed on animals were approved by the UK Home Office, in accordance
116 with the United Kingdom Animals (Scientific Procedures) Act 1986 and Amendment
117 Regulations 2012; killing procedures were performed in accordance with the established
118 guidelines of the European Directive on the protection of animals used for scientific
119 purposes (2010/63/EU). The investigation conforms to the Guide for the Care and Use of
120 Laboratory Animals published by the US National Institutes of Health (NIH Publication No.
121 85-23, revised 1985) and to the principles outlined in the Declaration of Helsinki (Br Med J
122 1964; ii: 177).

123 **Statistical analysis**

124 All data are expressed as mean \pm standard error of the mean. Data were analysed using
125 GraphPad Prism 9 software. To assess normality, Shapiro-Wilk's test was used. For multiple
126 groups comparisons of normally distributed data where unpaired samples were used, such
127 as contractility data in physiological, overloaded and EVs treated LMS at different stretch
128 increments, two-way ANOVA was used, followed by Tukey's multiple comparison test. For
129 multiple groups comparison of normally distributed data where paired samples were used,
130 such as contractility data in human failing LMS treated with donor sEVs and untreated,
131 multiple paired t-test was used, as control and treated preparation were handled in parallel.
132 To measure sEVs particle size distribution in human and rat samples, the area under the
133 curve for the particle size distribution was calculated, and an unpaired 2-tail t-test
134 performed, using the average concentration, SEM and N number for the respective
135 conditions, which were previously calculated in the area under the curve analysis. For
136 experiments assessing remodelling aspects in physiological, overloaded and EVs treated
137 LMS, one-way ANOVA was used followed by Tukey's multiple comparison test. Kruskal
138 Wallis test and Dunn's multiple comparison test were used when data were not normally
139 distributed. 2-tailed student t-test was used to compare the treated versus non-treated
140 groups in iPSC-CMs-only and co-culture experiments.

141

142 **Results**

143 **Active force in human failing LMS is significantly lower compared with human donor LMS**

144 All human donor and failing LMS were cultured at a SL of 2.2 μm . To investigate
145 contractility, we performed a force-stretch relationship experiment after 48 hours of
146 culture. As shown in Figure 1 A and B, donor LMS generated a larger force upon stimulation
147 compared with failing LMS; there was no significant change in passive force (Figure 1C).

148 **Human failing sEVs are more abundant compared to human donor EVs**

149 Cardiac sEVs were extracted from the supernatant of donor and failing LMS culture. The sEV
150 particle-size distribution and concentration were analysed by Nanoparticle Tracking
151 Analysis. The analysis showed a higher concentration of sEVs/ml from the failing heart,
152 compared to the donor heart (Figure 1 D). The sEV identity was confirmed by tetraspanin
153 (CD63, CD81 and CD9) chips for sEV capture and imaging on the ExoView™ R100 imaging
154 platform (NanoView Biosciences). As shown in Figure 1 E, the human sEVs expressed all
155 three tetraspanins ¹⁷, in different quantities, with CD81 being the most abundant
156 (Supplementary figure 1 B). Transmission electron microscopy with immunogold-labelled
157 antibodies targeting the human CD63 tetraspanin marker further confirmed the successful
158 enrichment of sEVs secreted by human LMS (Figure 1 F).

159

160 **Human sEVs released by the donor LMS increase the active force produced by human** 161 **failing LMS**

162 Given the biological relevance of cardiac sEVs isolated from the human donor LMS, we
163 sought to investigate whether these sEVs affect cardiac contractility of human failing LMS.
164 We observed that failing human LMS cultured with 10^9 donor sEVs, which corresponded to
165 the number of particles released from an individual human donor LMS after 48 hours, had
166 increased contractility compared with their untreated counterpart (Figure 2 A). In fact, the
167 active force of failing LMS treated with donor sEVs was significantly higher at 15 and 20%
168 stretch compared with non-treated LMS, whilst no change in passive force was observed
169 (Figure 2 B and C).

170 **Active force production in rat physiological LMS is higher compared with overloaded LMS**

171 To recreate physiological load and overload, we stretched rat slices uniaxially in order to
172 obtain a SL of 2.2 and 2.4 μm , respectively (Figure 3 A, from ¹⁴). Following 48 hours of
173 culture, we observed that physiological and overloaded LMS exhibited a different contractile
174 phenotype (Figure 3 B). Figure 3 C shows that physiological LMS generated significantly
175 higher active force from 5 to 25% stretch, compared with the overloaded LMS. The passive
176 force did not change significantly between the two conditions (Figure 3 D).

177 **Rat overloaded LMS secrete an equal amount of sEVs to physiological LMS but the sEVs** 178 **contain more proteins**

179 A particle-size distribution analysis revealed a similar concentration of sEVs released from
180 overloaded LMS compared to physiological LMS (Figure 3 E and supplementary figure 1 A).
181 However, measurements of internal protein content of sEVs revealed a higher amount of
182 protein in the sEVs from overloaded LMS, when compared to physiological LMS (Figure 3 F).
183 Electron microscopy with CD63 immunogold labelling confirms the presence of rat sEVs

184 (Figure 3 G). Given the more immediate availability of rat hearts, the following functional,
185 structural, and molecular studies were performed on rat LMS and rat LMS-derived sEVs.

186 **Physiological cardiac sEVs increase the active force and decrease the passive force of** 187 **physiological LMS**

188 Both physiological and overloaded sEVs were applied on rat physiological LMS to assess
189 whether sEVs would mediate changes in contractility on healthy tissue (Figure 4 A). Force-
190 stretch relationship of physiological LMS treated with either PBS vehicle, physiological sEVs
191 or overloaded sEVs revealed that physiological sEVs increase the active force of
192 physiological LMS at 25% and 30% stretch (Figure 4 B) and decrease the passive force from 0
193 to 20% stretch (Figure 4 C). However, the application of overloaded sEVs on physiological
194 LMS had no significant effect on the production of both active and passive force, compared
195 to untreated physiological LMS (Figure 4 B and C).

196 **Physiological cardiac sEVs increase the active force of overloaded LMS in a dose-response** 197 **manner**

198 To assess the functional effect of rat physiological sEVs on the overloaded LMS,
199 concentrations ranging from 10^7 to 10^{10} were tested (Figure 4 D). We observed that the
200 minimum amount of sEVs per LMS required to achieve a significant increase in active force
201 was 1×10^8 sEVs (Figure 4 E). However, no significant difference was observed in the passive
202 force of overloaded rat LMS treated with physiological sEVs (Figure 4 F). The following
203 structural and molecular experiments to assess cardiac remodelling were performed using
204 1×10^8 sEVs.

205 **Application of physiological cardiac sEVs does not affect the size of cardiomyocytes in** 206 **overloaded LMS**

207 In a condition of volume overload, eccentric hypertrophy develops, where the
208 cardiomyocytes elongate, and sarcomeres are added in series¹⁸. In our model of uniaxial
209 mechanical overload, we saw a significant elongation of the cardiomyocytes, compared to
210 the physiological condition (Supplementary figure 2 A). This resulted in an overall increase
211 of the cardiomyocytes area, whilst no difference was observed in the width (Supplementary
212 Figure 2 B and C). The application of physiological sEVs on overloaded slices did not change
213 cell size (Supplementary Figure 2 D).

214 **Application of physiological cardiac sEVs attenuates the transcriptional expression of** 215 **profibrotic genes in overloaded LMS**

216 The development of fibrosis following mechanical overload is an important determinant of
217 cardiac contractility¹⁹. Production and deposition of collagens in the ECM and proliferation
218 of stromal cells are crucial factors in the identification of cardiac fibrosis. Therefore, we first
219 examined the amount of Collagen I and Vimentin deposition through immunostaining
220 (Figure 5 A); no difference was observed between physiological and overloaded LMS (Figure
221 5 B and C, respectively). The expression of Collagen I was also studied at protein level, along
222 with the protein α -smooth muscle actinin (α -SMA), to assess fibroblasts activation. No
223 significant change was observed in the expression of Collagen I (Figure 5 D) and α -SMA

224 (Figure 5 E) between physiological and overloaded slices. Likewise, the application of
225 physiological sEVs on overloaded slices did not have any effect on fibrosis development at
226 either structural or protein level. However, when we analysed expression of some of the
227 fibrosis-related genes by q-RT-PCR, we observed increased levels of α -SMA, Fibronectin,
228 TGF- β , Collagen I and SMAD3 in the overloaded LMS, compared with physiological.
229 Application of physiological sEVs on overloaded slices prevented/reversed the activation of
230 Fibronectin, TGF- β and SMAD3 (Figure 5 F).

231 **Application of physiological cardiac sEVs reduces cell death in overloaded LMS**

232 To assess cell death, another possible determinant of reduced cardiac contractility²⁰, we
233 first measured the level of cleaved PARP-1. PARP-1 is cleaved when it gets activated during
234 apoptosis²¹. Cleaved PARP-1 was increased in overloaded LMS compared with physiological
235 LMS. Moreover, upon application of physiological sEVs, the cleavage of PARP-1 was reduced
236 to almost physiological levels (Figure 6 A). Bcl-2 is a potent pro-survival protein. Whilst its
237 expression was maintained at basal level in physiological and overloaded slices, the level of
238 Bcl-2 increased following application of sEVs on overloaded LMS. These data suggest that
239 sEVs activate pro-survival pathways in the slices subjected to increased mechanical load
240 (Figure 6 B).

241 Cell death in the LMS was further investigated by TUNEL staining. Transversal LMS
242 cryosections showed increased TUNEL positive nuclei mostly on the surface of overloaded
243 LMS, compared with physiological LMS. Application of physiological sEVs on overloaded LMS
244 reduced the abundance of TUNEL positive nuclei to almost physiological levels (Figure 6 C).

245 **Application of physiological cardiac sEVs reduces microvascular rarefaction in overloaded LMS**

247 Heart failure is associated with microvascular rarefaction^{22,23}. In our study, Isolectin B4
248 staining confirmed reduced microvascular density in the overloaded LMS compared with
249 physiological slices. Application of physiological sEVs in overloaded slices partially prevented
250 this phenomenon (Figure 7 A) and increased the mRNA expression of VEGF-A, a prototypical
251 proangiogenic and angiocrine factor (Figure 7 B).

252 **Exogenous cardiac sEVs preferentially localize around the nuclei of non-cardiomyocytes in the recipient LMS**

254 We first performed sEV incorporation studies at 1, 24 and 48 hours using ExoGlow-stained
255 sEVs to understand the time course of sEV uptake. We observed the presence of sEVs on the
256 surface of LMS at 1- and 24-hours, but this was reduced at 48-hours (Supplementary Figure
257 3 A), suggesting that after 48 hours of incubation, sEVs are mostly internalised by the LMS.
258 To assess the biodistribution of sEVs, we performed experiments using the 24-hours
259 timepoint, to quantify the presence of sEVs on the cells surface at their maximum visibility.
260 We observed that sEVs were preferentially localized around the nuclei of non-
261 cardiomyocytes: 19.3% of the total nuclei of vimentin-positive cells, and only 5.76% of α -
262 actinin-positive cells were co-localised with sEVs (Supplementary Figure 3 B).

263 **Physiological cardiac sEVs contain higher level of microRNA-378a-3p and -23a-3p in**
264 **comparison with pathological sEVs**

265 To investigate differences in miRNAs cargo between physiological and overloaded rat sEVs,
266 we performed a miRNA array to assess the expression of 372 miRNAs which are conserved
267 between rat and human species. We found two miRNAs (miR), miR-378a-3p and hsa-miR-
268 23a-3p, to have higher expression in physiological compared with overloaded sEVs. By
269 contrast, miR-16-5p and miR-346, were significantly increased in the overloaded sEVs
270 (Supplementary Figure 4 A and B). We focussed on the upregulated miRNAs in physiological
271 sEVs, as these could directly repress the expression of their target genes in overloaded LMS.
272 miRNA qPCR analysis confirmed the upregulation of miR-378a-3p and miR-23a-3p in
273 physiological sEVs compared with overloaded sEVs (Supplementary Figure 4 C and D).

274 **Bioinformatics analysis reveals potential mRNA targets of miR-378a-3p and miR-23a-3p**
275 **that are increased in cardiomyocytes extracted from overloaded LMS**

276 We performed a bioinformatics analysis to find potential target genes for miR-378a-3p and
277 hsa-miR-23a-3p. Predicted targets of miR-378a-3p and hsa-miR-23a-3p were cross-
278 referenced with genes that were significantly differentially expressed in cardiomyocytes
279 isolated from overloaded LMS, compared to physiological (Supplementary Figure 5 A). Six
280 target genes, Gadd45g, Slc4a11, Xirp2, Dusp13, Usp13 and Triadin, were identified, which
281 were overexpressed in overloaded cardiomyocytes and regulated by miR-378a-3p and hsa-
282 miR-23a-3p (Supplementary Figure 5 B and C). Pathway analyses performed on these genes
283 revealed their possible involvement in cardiac contractility and apoptosis (Supplementary
284 Figure 5 D).

285 **Physiological cardiac sEVs do not regulate the contractility of human cardiomyocytes**
286 **monocultures.**

287 Given the interplay between different cardiac cells in the LMS, it is challenging to assess
288 whether cardiomyocytes are directly affected by sEVs to increase cardiac contractility. To
289 address this issue, we employed human iPSC-CMs that express the calcium indicator
290 GCaMP6f²⁴, to simultaneously assess the impact of cardiac sEVs on calcium handling and
291 cardiomyocyte contractility (Figure 10 A and B). iPSC-CMs were seeded on 7 mm diameter
292 MatTek dishes at a density of 80,000 cells per dish for 48 hours and treated with 10⁹ sEVs or
293 PBS control. Calcium handling and contractility were assessed and compared between sEVs-
294 treated and untreated (PBS only) iPSC-CMs. There was no significant difference in the
295 amplitude of calcium transients between sEV-treated iPSC-CMs and controls (Figure 10 C).
296 Nevertheless, the iPSC-CMs time to peak of the calcium transients was increased after sEV-
297 treatment (Figure 10 D). The time to 50% and 80% decay remained unchanged between the
298 2 conditions (Figure 10 E and F). Likewise, the amplitude of iPSC-CM contractility was not
299 different in sEV-treated and control iPSC-CMs (Figure 10 G).

300 **Physiological cardiac sEVs increase contractility of iPSC-CM co-cultured with endothelial**
301 **cells**

302 Given the increased VEGF-A and vascular response observed in overloaded LMS treated with
303 physiological cardiac sEVs (Figure 7 A and B), and the prevalent non-CM distribution of
304 exogenous sEVs in recipient LMS (supplementary Figure 3 B), we hypothesised the
305 importance of endothelial cells for the CM response to sEVs. We therefore co-cultured
306 iPSC-CMs with human coronary microvascular endothelial cells (MVECs) before sEVs
307 application (Figure 10 H and I). Physiological cardiac sEVs did not affect calcium handling
308 parameters compared to control (Figure 10 J-M). However, cardiac sEV increased the
309 contractility of iPSC-CM co-cultured with MVEC (Figure 10 N).

310 Discussion

311 We report the successful isolation and characterisation of sEVs secreted from the
312 ventricular myocardium of human failing and donor healthy hearts and from rat LMS
313 cultured under physiological and overloaded conditions. Our protocols open unprecedented
314 possibilities for the characterization of the cardiac sEVs in the cardiac microenvironment.

315 This study has demonstrated that cardiac sEVs released from the human donor hearts
316 increase the contractility of failing LMS. Moreover, rat physiological sEVs increase
317 contractility of both physiological and overloaded LMS, at a minimum concentration of 10^8
318 particles/LMS. In contrast, sEVs released from the rat overloaded LMS had lost the capacity
319 to regulate contractility.

320 We have showed that overload reduces LMS contractility, increases the expression of
321 profibrotic genes, reduces cell survival and induces microvascular rarefaction, simulating the
322 feature of failing myocardium. Importantly, these pathogenic features are repressed by
323 stimulating the LMS with rat physiological cardiac sEVs, thus suggesting that sEVs released
324 from healthy hearts contribute to preventing and possibly reversing, pathological cardiac
325 remodelling.

326 HF with reduced ejection fraction (HFrEF) is characterised by lower muscle contractility. In
327 clinical cases of HF, there is a downward shift in the Frank-Starling curve, which correlates
328 with the inability of the heart to work effectively²⁸. LMS are an ideal *ex vivo* platform to
329 study myocardial contractility because they retain the electrophysiology and multicellularity
330 of the adult myocardium²⁹. Here we show that human failing LMS shifted the Frank Starling
331 curve downwards compared with donor LMS, in accordance with what is observed clinically
332^{30,31}.

333 By applying different degrees of mechanical load on rat LMS, we were able to induce a
334 distinct contractile phenotype, similar to what was observed in the human slices. This
335 finding has been previously reported by us in^{14,32}. For instance, we experimentally
336 determined the best SL to culture LMS for 24 hours, and found that slices cultured at 2.2 μm
337 maintained the same viability, gene expression and minimal change in force compared to
338 fresh slices, where contractility was measured immediately after slicing¹⁴. We reported a
339 significant difference in the amplitude of maximum contractility between rat slices cultured
340 at 2.2 and 2.4 μm after 48 hours. The significant decrease in force produced by the
341 overloaded slices was associated with an increase in Collagen I deposition and the
342 overexpression of major profibrotic genes³². While 48-hour culture might not be sufficient

343 to induce a complete remodelling of the LMS *in vitro*, the rat overloaded LMS recapitulate
344 several features of human failing myocardium.

345 Native sEVs are considered for their potential to regulate cardiac homeostasis. This is in line
346 with the knowledge that sEVs isolated from specific cardiac cell types contain cargoes that
347 can confer cardioprotection in a damaged heart³³; however, the effects of cardiac sEVs
348 released from the myocardial tissue remain untested. In this study, we demonstrate that
349 LMS release sEVs; we show the ability of healthy sEVs derived from the human and rat
350 hearts to restore contractility and partially reverse/prevent remodelling after cardiac
351 damage³⁵⁻³⁸.

352 In our study, despite observing a significant difference in sEV release between human failing
353 and donor LMS, we showed that there was no difference in the concentration of sEVs
354 released by either rat overloaded or physiological LMS after 48 hours culture. However,
355 overloaded LMS-derived sEVs did not significantly affect the production of either active or
356 passive force in physiological slices, in clear contrast with physiological sEVs, suggesting that
357 the formulation of the sEVs derived from physiological and pathological is different. In line
358 with this, we recorded different levels of total protein content between overloaded and
359 physiological sEVs.

360 Several studies have shown that sEV actions are mediated by miRNA transfer^{39,40}.
361 Therefore, the beneficial effects of cardiac sEVs may be mediated by miRNA transfer. In line
362 with this hypothesis, we found increased expression of miR-378a-3p and hsa-miR-23a-3p in
363 the physiological cardiac sEVs when compared with the sEV from rat overloaded LMS. These
364 miRNAs have been previously shown to repress cardiac hypertrophy⁴¹ and apoptosis⁴² and
365 to promote angiogenesis⁴⁵. A limitation of our miRNA array approach is that it contained a
366 limited number of miRNAs selected for their conservation between humans and rats.
367 Alternative miRNA candidates might emerge in future studies based on RNA-sequencing
368 approaches.

369 A miRNA canonical mechanism of action is to repress the expression of a pool of targeted
370 genes acting at post-transcriptional level by binding to the 3'UTR of mRNAs⁴⁶. In line with
371 this, bioinformatic target prediction revealed that potential target genes of miR-378a-3p
372 and hsa-miR-23a-3p were involved in the regulation of cardiac contractility and apoptosis of
373 cardiomyocytes.

374 Excessive mechanical preload of the heart results in the development of eccentric
375 hypertrophy, where cardiomyocytes elongate through the addition of sarcomeres in series
376⁴⁷. In our model of mechanical overload, we observed a significant elongation of
377 cardiomyocytes compared to the physiological counterpart. The addition of sarcomeres in
378 series leads to a decrease in force being generated by the cardiomyocytes, as to reach an
379 optimal SL, longer cardiomyocytes may need to be stretched more, compared to shorter
380 cardiomyocytes containing less sarcomeres⁴⁸.

381 In our study, we found that after 48 hours of culture under overloaded conditions, the
382 process of fibrosis activation is only initiated at transcriptional level, with no significant
383 changes at protein and structural level. However, physiological sEVs were able to inhibit the

384 overexpression of the major pro-fibrotic genes in overloaded slices. A previous study on
385 fibrosis conducted on LMS showed that, although there was a significantly higher Collagen I
386 deposition in overloaded slices after 48 hours compared with the physiological controls, the
387 difference in the amount of stromal cells proliferation on the slices was unchanged¹⁵.
388 Moreover, the changes in Collagen I were only seen with immunofluorescence staining and
389 could not be detected by western blot analysis.

390 The cleavage of PARP-1 is a hallmark of cell death⁴⁹. In our study, we observed a significant
391 increase in cleaved PARP-1 in the overloaded slices compared with the physiological LMS.
392 TUNEL staining revealed that cell death was prevalently localized on the surface of the
393 myocardial slices. During LMS preparation, the blade cutting along the surface of the tissue
394 damages ~3% of the total LMS cells, and only on the surface of the slice, leaving the rest of
395 the preparation intact¹¹. We speculate that surviving cells on the LMS surface are more
396 fragile and sensitive to the detrimental actions of overload. Physiological sEVs were able to
397 inhibit the process of cell death on overloaded slices. However, because changes in cell
398 death were limited to the LMS surface, is unlikely that prevention of cell death by the
399 healthy sEVs is the only contributor to the increase in contractility produced by these sEVs.

400 Microvessels rarefaction is a hallmark of cardiac remodelling and reportedly contributes to
401 HF with preserved ejection fraction (HFpEF)⁵⁰. Microvessels are tasked not only to
402 constantly deliver oxygenated blood and nutrients to cardiomyocytes, but also act as a
403 source of paracrine regulatory molecules that help in the modulation of cardiac contractility
404⁵¹. In the overloaded slices, we observed a significant loss in microvessels. It is worth noting
405 that vessels are not perfused in LMS, therefore regulation of cardiomyocyte contractility is
406 likely to occur through direct contact and/or paracrine interactions. VEGF was maintained at
407 basal levels in physiological and overloaded conditions but, upon application of sEVs, these
408 levels raised significantly, suggesting that sEVs may contain cargoes that promote the
409 production of VEGF. We found that most of the sEVs are taken up by the non-
410 cardiomyocytes. This could indicate an indirect effect on contractility, mediated by other
411 cell types other than CMs, in particular ECs.

412 To confirm whether sEVs have a direct effect on CM contractility, we analysed calcium
413 handling and contractility of iPSC-CMs monoculture. Physiological sEVs did not affect the
414 contractility of iPSC-CMs nor the amplitude of calcium transients, suggesting that
415 physiological sEVs may act on other cell types. Given the effect of physiological sEVs on LMS
416 microvessels, we co-cultured iPSC-CMs with MVECs. In the co-culture experiments, despite
417 no change in the calcium handling parameters, we observed a significant increase in
418 contractility when physiological sEVs were applied. This suggests that changes in iPSC-CM
419 contractility are: i) mediated by the effect of sEVs on ECs, and ii) due to changes in
420 myofilament sensitivity to calcium. There are few limitations of these cellular experiments:
421 although iPSC-CMs lines have been extensively used in cardiovascular research to
422 recapitulate disease models, these cells are still very different from adult CMs, due to their
423 relatively immature phenotype, and therefore it might not be a fully representative model
424 to describe the changes in contractility that occur in the LMS⁵². Moreover, in our study

425 mechanical load is a major determinant of remodelling, but overload could not be recreated
426 in iPSC-CMs.

427 If these results are extrapolated to the LMS model, whereby sEVs had a significant effect on
428 contractility, preserved microvessel density and increased VEGF production, they may
429 suggest that the beneficial effects of sEVs are indirect and mediated, at last in part, by ECs. It
430 could be speculated that once sEVs (and their associated miRNAs) are taken up by ECs, they
431 would release factors (such as VEGF) that improve CM contractility⁵³. As example, miR-
432 378a-3p was already shown to indirectly increase VEGF-A in skeletal muscles⁵⁴.

433 **Conclusions**

434 Myocardial-specific sEVs from healthy human and rat hearts restore contractility and
435 reverse/prevent remodelling of failing myocardium. The effects on contractility could be
436 mediated by inhibition of cell death, inhibition of pro-fibrotic gene pathways or by
437 preservation of blood vessels, or a combination of them, via indirect heterocellular
438 interactions. The miRNA signature of the healthy sEVs may contribute to explain these
439 effects. Our findings support the importance of sEVs in physiology and disease, and their
440 potential utilisation in the treatment of cardiovascular disease.

441 **Acknowledgements:**

442 We would like to thank Steve Rothery for the support with confocal microscopy, Fatemeh
443 Kermani for the gift of MVECs and Danya Agha-Jaffar for the support with the human tissue.
444 We are grateful to the British Heart Foundation for financial support (FS/19/57/34894).

659 of VEGF gene expression by qPCR in physiological, overloaded and overloaded + sEVs slices.
660 Data are presented as mean +/- SEM. One-Way ANOVA with Tukey's multiple comparisons
661 test. over physiological slices. *P<0.05. Data are expressed as fold change expression.

662 **Figure 8. The effect of physiological sEVs on iPSC-CMs and on iPSC-CMs cultured with**
663 **microvasculature endothelial cells. A.** Representative traces of calcium transients in iPSC-

664 CMs treated with physiological sEVs and control. **B.** Representative traces of contractility in
665 iPSC-CMs treated with physiological sEVs and control **C.** Amplitude **D.** Time to peak **E.** Time
666 to 50% decay and **F.** Time to 80% decay of calcium transients and **G.** amplitude of
667 contractility in iPSC-CMs treated with rat physiological sEVs or control. Unpaired t-test.
668 $*=P<0.05$. **H.** Representative traces of calcium transient amplitude in iPSC-CMs and
669 microvasculature ECs co-culture treated with physiological sEVs and control. **I.**
670 Representative traces of contractility in iPSC-CMs and microvasculature ECs co-culture
671 treated with physiological sEVs and control **J.** Amplitude **K.** Time to peak **L.** Time to 50%
672 decay and **M.** Time to 80% decay of calcium transients and **N.** amplitude of contractility in
673 iPSC-CMs co-cultured with microvasculature endothelial cells treated with rat physiological
674 sEVs or control. Data are presented as mean +/- SEM. Unpaired t-test. $*P<0.05$.
