45 **Extended Summary**

46 **Background:** Recently, associations between recurrent urinary tract infections (UTI) and
47 the urinary microbiome (urobiome) composition have been identified in adults. However,
48 little is known about the urobiome in children. We aimed to characterize the urobiome of
49 children with species-level resolution and to identify associations based on UTI history.

50 **Study design:** Fifty-four children (31 females and 21 males) from 3 months to 5 years of
51 age participated in the study. Catheterized urine specimens were obtained from children
52 undergoing a clinically indicated voiding cystourethrogram. To improve the analysis of the
53 pediatric urobiome, we used a novel protocol using filters to collect biomass from the urine
54 coupled with synthetic long-read 16S rRNA gene sequencing to obtain culture-
55 independent species-level resolution data. We tested for differences in microbial
56 composition between sex and history of UTIs using non-parametric tests on individual
57 bacteria and alpha diversity measures.

58 **Results:** We detected bacteria in 61% of samples from 54 children (mean age 40.7
59 months, 57% females). Similar to adults, urobiomes were distinct across individuals and
60 varied by sex. The urobiome of females showed higher diversity as measured by the
61 inverse Simpson and Shannon indices but not the Pielou evenness index or number of
62 observed species ($p = 0.05$, $p=0.04$, $p = 0.35$, and $p = 0.11$, respectively). Additionally,
63 several species were significantly overrepresented in females compared to males,
64 including those from the genera *Anaerococcus*, *Prevotella*, and *Schaalia* ($p = 0.03$, 0.04 ,
65 and 0.02 , respectively). Urobiome diversity increased with age, driven mainly by males.
66 Comparison of children with a history of 1, 2, or 3+ UTIs revealed that urobiome diversity
67 significantly decreases in the group that experienced 3+ UTIs as measured by the

68 Simpson, Shannon, and Pielou indices ($p = 0.03$, $p = 0.05$, $p = 0.01$). Several bacteria
69 were also found to be reduced in abundance.

70 **Discussion:** In this study, we confirm that urobiome can be identified from catheter-
71 collected urine specimens in infants as young as 3 months, providing further evidence
72 that the pediatric bladder is not sterile. In addition to confirming variations in the urobiome
73 related to sex, we identify age-related changes in children under 5 years of age, which
74 conflicts with some prior research. We additionally identify associations with a history of
75 UTIs.

76 **Conclusions:** Our study provides additional evidence that the pediatric urobiome exists.
77 The bacteria in the bladder of children appear to be affected by early urologic events and
78 warrants future research.

98 **Introduction**

99 The lower urinary tract of an adult human is inhabited by a microbiome composed
100 of bacteria, fungi, and viruses that are associated with several urological conditions,
101 including nephrolithiasis, urinary incontinence, urinary urgency, and bladder
102 overactivity.[1–4] Evidence also suggests that the presence of specific microbes and their
103 abundance may affect the development and progression of urinary tract infections
104 (UTI).[1,2,5,6] Several species of the adult urinary microbiome were identified as
105 protective against uropathogens *in vitro* and in animal models.[5–7] It remains unknown
106 how the urobiome is initially colonized, how it develops during childhood, and if early
107 urobiome development and changes can lead to a predisposition to recurrent UTIs.

108 The development of this microbial niche after birth and through childhood has not
109 been characterized in detail due to several obstacles. One complication is with the
110 feasibility and ethical concerns in collecting urine samples aseptically from younger
111 children with catheters or suprapubic aspiration. The current standard of urobiome urinary
112 collection uses catheterized urine, but this method is deemed too risky to be approved for
113 children who are not undergoing catheterization for a medically directed purpose.[8] The
114 alternative to this is obtaining voided clean-catch urine, which is complicated by the
115 transition of children from the diapered stage to the toilet-trained stage, leaving younger
116 children hard to sample. A second complication is that children have smaller bladder
117 capacities than adults.[9–11] Thus, it has been assumed that children’s urobiome
118 microbial abundance will be smaller and more difficult to detect. Kassiri et al reported
119 microbial load in pediatric males, which was on average less when compared to the adult
120 male urobiome[13].

121 Despite these complications, there have been seven pediatric urobiome studies
122 within the last four years that discuss the development of the urobiome from ~2 weeks to
123 18 years of age for both sexes.[12–18] There is little overlap among the subgroups
124 analyzed and the methods used (**Table S1**). Most studies used routine short amplicon
125 16S rRNA gene sequencing to record bacterial urobiome composition. Two of these
126 reports also used enhanced quantitative urine culture (EQUC) or a custom modification
127 of this to isolate species from pediatric urine samples, thus providing species-level
128 resolution of culturable microbes.[16, 17] This improved taxonomic resolution is critical
129 for understanding urobiome functioning, as identified species may be relevant in
130 discovering any predisposition for UTI.

131 In this pilot study, we sought to improve the resolution of the compositional analysis
132 of the pediatric urobiome. We implemented methods of microbiome collection from other
133 well-studied low-biomass niches and collected urine-suspended cells via filtering.[19–21]
134 In addition, we used a synthetic long-read sequencing method to establish better
135 taxonomic resolution of bacteria based on full-length 16S rRNA gene sequences.[22]
136 Using this protocol, we analyzed bacterial composition of the urobiome to the species
137 level in infants and young children. We detected differences in microbe diversity and
138 presence by age, sex, and history of UTI.

139

140 **Methods**

141 Clinical population

142 The research study was approved by Duke University Medical Center Institutional
143 Review Board under protocol #Pro0010031. From 2018-2021 children from birth to age

144 5 years who had a voiding cystourethrogram (VCUG) conducted for a clinical indication
145 were offered enrollment. At baseline, parents or guardians (hereafter “parents”) granted
146 permission for a urine sample to be collected and their child’s electronic medical record
147 to be accessed. Parents provided written consent for their child to be included in the study.
148 Identifiers presented in plots and data are deidentified and do not represent patient or
149 research subject identifiers.

150 Demographic variables collected included age (months), race, and sex. Children
151 who utilized intermittent catheterization to empty their bladder or who had neurogenic
152 bladder were excluded. Clinical variables included the number of confirmed UTIs using
153 the American Academy of Pediatrics definition for UTI, vesicoureteral reflux status (VUR)
154 and history of antibiotic use.[23] Chart review from our institution was used to identify
155 historical UTIs, along with pediatric office records and outside facility records, if an
156 interview with the family indicated a UTI may have occurred outside our institution. These
157 records were then examined to verify if they met the definition of UTI from the American
158 Academy of Pediatrics.

159

160 *Specimen collection*

161 Urine specimens were collected from catheterized urine (minimum volume 10 mL)
162 into a sterile urine specimen cup before introducing iodinated contrast for the VCUG
163 procedure. Urine was processed within 24 hours of collection via vacuum filtration on 0.22
164 μm filters. The urine biomass, collected on these filters, was stored in a -80°C freezer
165 until all samples were ready for DNA extraction.

166

167 *DNA extraction, preparation, and sequencing*

168 DNA was isolated from 0.5” x 0.5” fragments of the filters. 1ml of phosphate-
169 buffered saline (PBS) was used to wash the biomass off the filter. DNA isolation was
170 performed using an optimized version of the QIAamp Fast DNA Stool Mini Kit (Cat No./ID:
171 51604) protocol supplemented with 60 mg/mL lysozyme (Thermo Fisher Scientific, Grand
172 Island, NY).[24–26] The DNA samples were quantified (Qubit Quant-iT PicoGreen kit)
173 and divided into aliquots and then sequenced in triplicates by LoopGenomics (now –
174 Element Biosciences). The LoopGenomics technology uses unique molecular identifiers
175 to build a scaffold of high-quality Illumina short reads that cover the full length of the 16S
176 rRNA gene.[22] This approach minimizes biases found in traditional amplicon sequencing,
177 such as amplification bias of certain taxa and amplification of contaminants. This is
178 especially significant in samples of low biomass, which is expected in children’s urine
179 samples. PBS-treated filters were used as negative controls, and a mock community
180 dilutions series as positive controls to determine background noise and detection limits.

181

182 *Microbiome data processing*

183 The sequencing data was processed and summarized into bacterial taxa. Raw
184 sequences were processed using DADA2, following recent recommendations for
185 modifications to accommodate synthetic long reads.[22, 27] Taxonomy was assigned
186 using Bayesian LCA-based Taxonomic Classification Method (BLCA) with the NCBI 16S
187 microbial database (downloaded on 11/5/2021).[28] To broadly assess the characteristics
188 of microbial communities, we used a suite of analyses designed for 16S rRNA sequencing
189 available in R, primarily in the phyloseq and vegan packages.[29] The evenness and

190 richness of each individual's urinary microbiome were summarized using alpha diversity
191 metrics (number of observed species/genera, the Shannon Index, and Inverse Simpson
192 Index). The alpha and beta diversity measures were compared between groups using
193 standard statistical tests (non-parametric Wilcoxon rank sum for alpha diversity and
194 PERMANOVA for beta diversity). Differences in relative abundance of individual taxa
195 were assessed between groups when the distribution across the dataset was sufficient.

196 **Results**

197 Fifty-four urine samples were collected, with 31 (57%) from females and 23 (43%)
198 from males (**Table 1**). The mean age of the children was 40.7 months (range 3-130
199 months). Age was significantly different between sexes, with females being, on average
200 51.4 months and males being 26.2 months ($p = 0.001$). Due to this, for the between sex
201 analysis, we limited the data to individuals less than 60 months of age. Thirty-two percent
202 of children in the study reported greater than 3 UTIs, 48% had 1-2 UTIs, and 17% had
203 never had a UTI. Sixty-five percent were currently using a prophylactic antibiotic to reduce
204 their risk of UTI at the time of urine collection, 9% had never used an antibiotic for any
205 reason, and the remaining had intermittently used antibiotics in the past as treatment or
206 prophylaxis. The VUR status at the time of sample collection was 65% (36) had confirmed
207 VUR, 11% (6) had a history of VUR that had resolved, and 24% (13) had never had VUR.

208

209 *Feasibility of synthetic long-read sequencing of bacteria in pediatric catheterized urines*

210 Sequencing resulted in 0 – 318,342 reads per sample, with a mean of 17,207 reads.
211 All negative controls failed to produce sequences. To determine the minimum acceptable
212 sampling depth per sample, the data were randomly subsampled to various sampling

213 depths ranging from 100 to 10,000. The subsampled data were evaluated based on the
214 relative abundance of individual taxa and alpha diversity measures. We noted no
215 significant differences between these measures of the unrarefied and rarefied data at
216 various thresholds down to 500 reads per sample (**Fig. S1**). We additionally evaluated
217 our mock microbial positive-control samples, which showed the expected composition at
218 the 500 reads per sample threshold. Therefore, we used the threshold of 500 reads per
219 sample as the minimum number of reads to declare a sample as sequence positive and
220 as a subsampling depth for analysis. 33 of the 54 urine samples (61%) provided
221 sequencing data at this threshold and were deemed sequence-positive and subject to
222 further analysis. The overall summary for sequence-positive and sequence-negative
223 samples is given in **Table 1**. There were no significant associations between demographic
224 or clinical variables in individuals whose samples were sequence-positive versus
225 sequence-negative. The sample DNA concentration was significantly increased in the
226 sequence positive samples (5.23 +/- 6.28 ng/ml in sequence negative; 11.85 +/- 11.47
227 ng/ml in sequence positive samples, $p = 0.02$).

228 Each DNA sample was aliquoted for sequencing in triplicate and demonstrated
229 little variability compared to that seen across samples. Stacked bar plots representing the
230 relative abundance of bacteria in triplicate of four samples are shown in **Figure 1A**.
231 Overall variability across different taxa in each triplicate set is also low (**Fig. 1B**).

232 All additional analyses were performed using a single replicate of each of the 33
233 sequence-positive samples.

234

235 *Residential bacterial DNA detected in majority of pediatric catheterized urines*

236 Samples from the female and male sexes had polymicrobial urinary microbiomes
237 composed of several bacteria (**Fig. 2A**). We detected an insignificant increase of unique
238 species in females (median 31 species, IQR 18) compared to males (median 16.5 species,
239 IQR 14.25, p-value 0.11). Overall, there was high variability amongst individuals (3 to 42
240 species, and 2 to 36 genera per sample).

241 In boys, the dominant taxa included *Peptoniphilus*, *Ezakiella*, *Sphingomonas*,
242 *Ralstonia*, and *Anaerococcus* (**Fig. S2**). In girls, the most abundant were *Prevotella*,
243 *Peptoniphilus*, *Anaerococcus*, *Ezakiella*, and *Streptococcus* (**Fig. S2**). These
244 predominant taxa do not include taxa commonly associated with adult male and female
245 urobiomes – *Lactobacillus* in females and *Staphylococcus* in males. These taxa were
246 present in a small number of samples (2 for *Lactobacillus*, 8 for *Staphylococcus*), in low
247 abundances (maximum 1.0% for *Lactobacillus*, 6.8% for *Staphylococcus*), and not
248 associated with a specific sex. Of note, *Anaerococcus* and *Prevotella* were significantly
249 increased in females compared to males (p-value 0.03 and 0.04, respectively; **Fig. 2B**).
250 Additionally, *Schaalia* was also significantly increased in females ($p = 0.02$), though it was
251 only detected in 10 samples (9 female samples, one male sample) at low relative
252 abundance (maximum 5.6%). These genera were primarily attributed to the specific
253 species of *Prevotella timonensis*, *Schaalia turincensis*, and *Anaerococcus lactolyticus*.
254 We detected a low abundance of *Actinotignum schaali* in 10 samples, in which 9 were
255 females.

256

257 *Urobiome diversity is higher in girls and increases with age in boys*

258 Overall diversity was higher in samples from the females as measured with inverse
259 Simpson ($p=0.05$) and Shannon ($p=0.04$) metrics but not by the Pielou evenness ($p =$
260 0.35) or observed species ($p = 0.11$) (**Fig. 2C**). Increased age was also associated with
261 increased diversity ($\rho = 0.45$, $p = 0.02$, **Fig. 2D**). In samples from females the diversity
262 is largely unchanged across age ($\rho = -0.15$, $p = 0.62$), whereas, in males, diversity
263 increases with age (**Fig. 2D, Table 1**) with a correlation factor of 0.54 and $p = 0.07$.

264

265 *Recurrency of UTI results in reduced urobiome diversity*

266 There was variation in the number of UTIs a child had experienced to date (**Table**
267 **1**). When grouped by their history of UTI, there were significant differences in the Inverse
268 Simpson index ($p = 0.03$), the Shannon index ($p = 0.05$), and Pielou index ($p = 0.01$). The
269 group with a history of 3 or more UTIs demonstrated significantly reduced urobiome
270 diversity compared to those with a history of only 1 UTI (**Fig. 3A**). The four children who
271 had never had a UTI were excluded from this analysis. When individual taxa were
272 compared among the groups of patients with 1, 2, or 3 or more UTIs, several taxa were
273 decreased in individuals with 3 or more UTIs compared to those with 2 or fewer (**Fig. 3B**).
274 Those are genera of *Enterococcus* (*significant decrease between 2 UTIs and 1 UTIs, $p =$*
275 *0.05*), *Lawsonella* (*significant decrease between 3+ UTIs compared to 1 UTI, $p = 0.05$;*
276 *decrease between 3+ UTIs compared to 2, $p = 0.07$), and *Corynebacterium* (*significant*
277 *decrease between 1 UTI compared to 3+, $p = 0.05$; decrease between 2 UTIs compared*
278 *to 3+, $p = 0.07$). At the Phyla level, we noted a decrease in Bacteroidetes and an increase*
279 *in Proteobacteria in children with had 3+ UTIs, however, these changes did not reach*
280 *significance ($p=0.17$, $p=0.11$, respectively), likely due to our small sample size.**

281 Discussion

282 Results presented here show that even in the low biomass catheter-collected
283 urinary samples of children, we can obtain species-level compositional data without using
284 full shotgun metagenomic sequencing. Additionally, this method expands previously
285 successfully applied species-resolution methods (EQUIC and standard urine culture) to
286 obtaining species-level information for unculturable urinary constituents.

287 Prior studies established that adult urobiomes differ significantly by sex and have
288 different predominant taxa.[30-33] It is not clear whether these sex differences develop
289 early in infancy due to variable anatomy and early hormonal surges or later in childhood
290 due to the hormonal changes of puberty or a combination of these factors. From the
291 microbial ecology perspective, the bladder represents a unique set of conditions and
292 selective pressures that make it clearly distinct from the surrounding environments of skin
293 niches, vaginal and gut microbiomes. These environmental pressures (low oxygen,
294 fluctuating pH and nutrient composition, high concentration of chemicals like urea) may
295 define urobiome composition. In the absence of hormonal changes, one might
296 hypothesize that female and male sex urobiomes may be compositionally close before
297 puberty. The data we obtained contradicts such a hypothesis, showing a distinction
298 between female and male sex urobiome prior to puberty hormonal changes. Interestingly,
299 there are several taxa that appear to be common at high abundances between the two
300 sexes: *Peptonophilus* and *Anaerococcus*.

301 There are unique sex hormonal differences that occur before birth and within the
302 first year of life, but in our cohort, we did not have representation of infants below one
303 year of age. In the next four years of life, we observed increased urobiome diversity that

304 was driven by the male sex's samples. This observation correlates with the hypothesis
305 that the different lengths of the female and male urethra may influence the rate of diversity
306 change after birth. The shorter female sex urethra may allow for early population of the
307 urobiome, whereas the longer male sex urethra slows the rate of developing a diverse
308 urobiome. This may imply that the bladder niche has some equilibrium or overall capacity
309 for diversity.

310 Prior studies from Storm and colleagues did not observe age-related change,
311 which is likely due to collapsing the overall age group of 0-3 year old children and
312 comparing those with the older cohort only.[16] We did not observe the changes in the
313 female sex's urobiome diversity observed during puberty that was found in that study.
314 This was likely due to the lack of a comparable older age group of females. In a sample
315 of 85 children under 48 months of age, Kinneman et al. found that diversity increased with
316 age.[14] This is confirmed in our results. Our results also support Fredsgaard et al.'s
317 results from 30 clean catch voided urine samples of prepubertal children where females
318 had higher richness and diversity in their urinary microbiome than males.[18]

319 Considering the composition in the pediatric samples we presented, some
320 prominent genera from the adult urobiome are not prominent in children. For example,
321 in adult males *Corynebacterium* and *Staphylococcus* are frequently abundant in the
322 urobiome.[34–36] However, we did not detect these genera robustly in male samples;
323 they were only identified in a few samples at low abundance except for in one instance.
324 Moreover, genera previously classified as *Lactobacilli*[38] that are the most common
325 genera in adult female sex urobiomes were not found robustly in our dataset, with only 2
326 samples having a *Lactobacillus* genera, each at a low abundance. This is consistent with

327 the observations made by Storm et al. from their data that Lactobacilli appear in female
328 populations during puberty.[16] There are abundant taxa that appear to be present in
329 early childhood that may also remain prevalent in adult bladders, for example, *Prevotella*,
330 *Streptococci*, and *Porphyromonas*. Our population in this study was specific and
331 consisted of children referred for a VCUG due to urologic concerns with the majority
332 having a history of VUR. Results from this data may not be fully generalizable to larger
333 populations of healthy children, but the aims of this study were still achieved. Due to this,
334 60.6% of all sequence-positive samples (**Table 1**) came from children who were taking
335 prophylactic doses of antibiotics as a measure of preventing recurrent febrile UTIs.
336 Surprisingly, prophylactic use of antibiotics did not result in the elimination of the urobiome.

337 Males below 1 year of age are more susceptible to UTI.[39] Around 1 year of age,
338 females become more at risk for UTI compared to males, up until the late stages of life
339 when the immune system of both sexes weakens due to senescence. We observed early
340 male urobiome had low bacterial diversity. However within our cohort we did not have
341 males with 'sequence-positive' samples under one year of age.

342 Comparing patient cohorts who have had different numbers of UTIs showed that
343 the diversity was reduced in those individuals who had 3 and more UTIs. There are
344 several possible explanations for such observations, such as alterations of the urobiome
345 due to antibiotic exposure and changes associated with prior overgrowth of uropathogens
346 during the UTIs. In our dataset, only 2 samples were 'sequence-positive' from children
347 who had never used antibiotics, while all other 'sequence-positive' samples were from
348 children who were either currently taking prophylactic antibiotics or were treated with
349 antibiotics previously. We do not have enough statistical power to establish significance.

350 Still, there was no difference observed in the diversity of the urobiome between those with
351 prior antibiotic use and current prophylactic antibiotic use. This observation suggests that
352 if there is a reduction of the diversity or other parameters in the urobiome due to antibiotic
353 treatments (including current prophylactic use), the changes might be smaller than those
354 associated with UTI-caused shifts.

355 Our pilot study has some limitations, including the use of convenience sampling
356 and a small number of subjects. We did not capture the circumcision status of male sex
357 children; recent studies have identified a microbiome on the foreskin, which may have
358 been detected in catheterized urine, especially in younger children with physiological
359 phimosis whose foreskin can't be adequately retracted for catheterization directly into the
360 urethra.[30] We did not run short amplicon sequencing in parallel with LoopSeq due to
361 concerns of the limited amount of DNA extracted. This study also had strengths, including
362 using a filtering technique that does not utilize a high-speed centrifuge, potentially
363 expanding the number of centers where urine processing could be done. We additionally
364 used synthetic long-read sequencing that enabled species-level identification. Such
365 methodology balances access and cost between newly established methods for obtaining
366 compositional data for urine samples for microbiome analysis.

367 In summary, our study confirms prior observations that even infants have complex
368 urobiomes. In our cohort, we identified the urobiome in children as young as 3 months
369 and obtained species-level taxonomic resolution by using culture-independent full-length
370 16S sequencing. We showed that the urobiome composition varies amongst individuals
371 and demonstrates notable changes between sexes and with age. We identified specific
372 species overrepresented in females and patients with repeated UTIs. With observed

373 changes in urobiome diversity levels, our study suggests a connection between
374 decreased overall urobiome diversity and recurrent UTIs in children. Overall, our pilot
375 results show the feasibility of the species-level urobiome investigation in future broader
376 cross-sectional as well as longitudinal studies exploring urobiome stability within an
377 individual, changes with health status alterations, and drug applications.

521

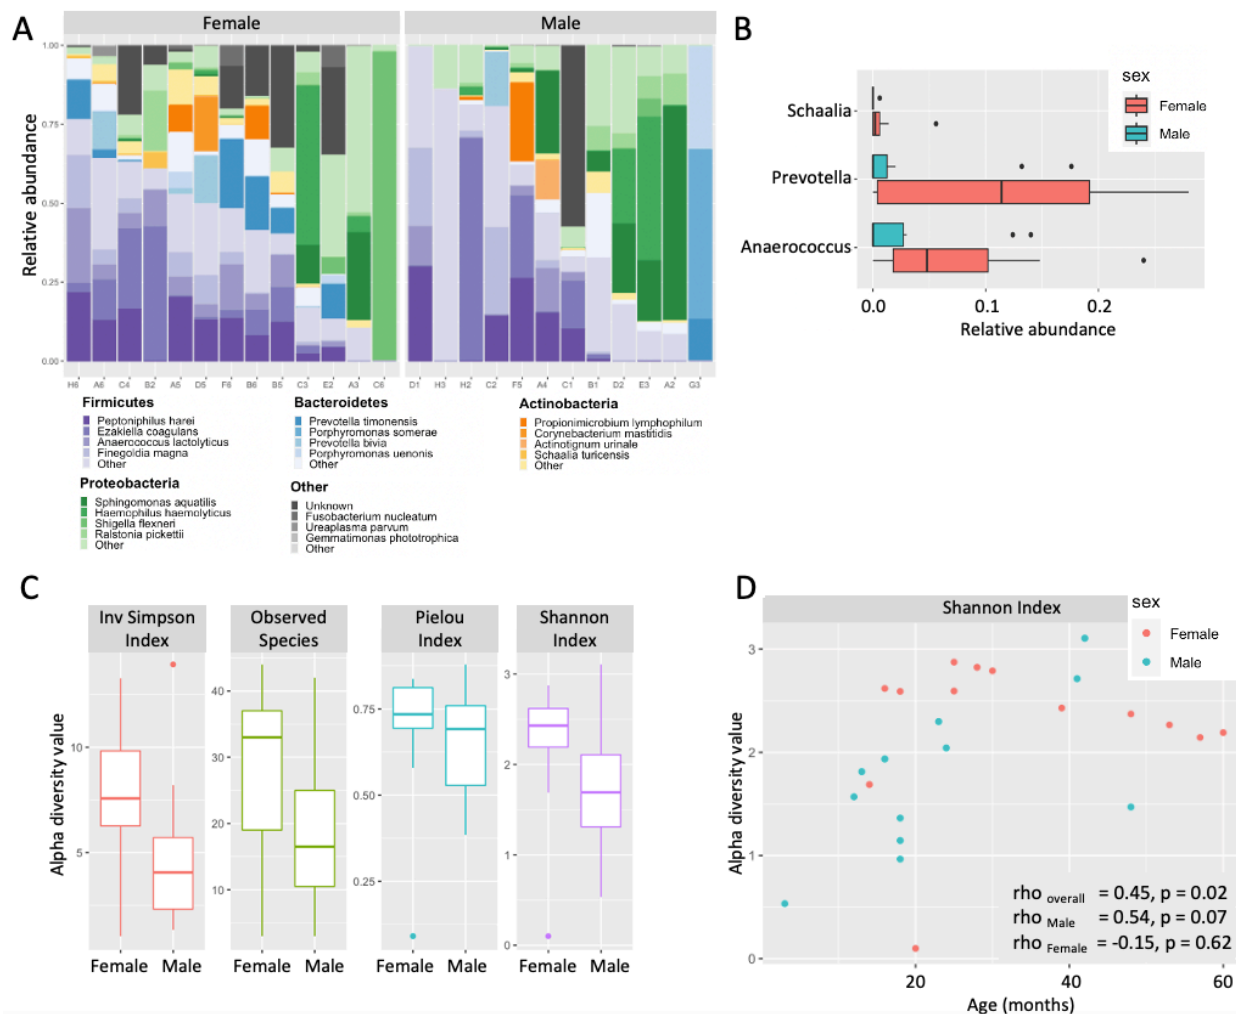

522 **Figure 1. Reproducibility of the synthetic long reads for pediatric urine samples.** Each
 523 sample was sequenced in triplicate. **(A)** Stacked barplots demonstrating overall similarity
 524 between replicate samples. Each sample (facet) was processed in triplicate (x-axis) and
 525 demonstrated little variability compared to that seen across samples. **(B)** Variability of relative
 526 abundance of select bacterial species across replicates. Values shown are average \pm standard
 527 deviation.

 535

536 **Figure 2.** The pediatric urobiome composition varies by sex and age. We observed that the
 537 pediatric urobiome is diverse between individuals (A), but there are some overall differences in
 538 specific taxa between males and females (B). Alpha diversity also demonstrates differences by
 539 sex, with significant differences in the Observed and Shannon Indices (p - , C). Diversity also
 540 has a significant positive correlation with age, which is mostly attributed to males (D).

541

542
 543
 544
 545
 546
 547
 548
 549

550 **Figure 3.** The pediatric urobiome composition varies by UTI history. (A) We observed that the
 551 pediatric urobiome is overall less diverse in children with a history of 3 or more UTIs in terms of
 552 diversity, with significant decreases in diversity as measured by the Inverse Simpson, Shannon,
 553 and Pielou indices between children with 3 or more UTIs compared to those with history of only
 554 1 UTI ($p = 0.03$, $p = 0.05$, and $p = 0.01$, respectively). (B) Three genera demonstrated
 555 differences based on UTI history: *Lawsonella* (significant decrease between 3+ UTIs compared
 556 to 1 UTI, $p = 0.05$; decrease between 3+ UTIs compared to 2, $p = 0.07$); *Enterococcus*
 557 (significant decrease between 2 UTIs and 1 UTIs, $p = 0.05$); and *Corynebacterium* (significant
 558 decrease between 1 UTI compared to 3+, $p = 0.05$; decrease between 2 UTIs compared to 3+,
 559 $p = 0.07$). (C) Relative abundance of bacterial phyla amongst cohorts of children with history of
 560 1, 2, 3+ UTI.
