29 Abstract

30 Introduction: Malaria-endemic countries are increasingly adopting data-driven risk stratification, often at district or higher regional levels, to guide their intervention 31 strategies. The data typically comes from population-level surveys collected by rapid 32 diagnostic tests (RDTs), which unfortunately perform poorly in low transmission 33 settings. Here, we conducted a high-resolution survey of *Plasmodium falciparum* 34 prevalence rate (PfPR) in two Tanzanian districts and compared the fine-scale strata 35 36 obtained using data from RDTs, microscopy and guantitative polymerase chain reaction 37 (qPCR) assays. 38 Methods: A cross-sectional survey was conducted in 35 villages in Ulanga and

Kilombero districts, south-eastern Tanzania between 2022 and 2023. We screened 39 40 7,628 individuals using RDTs (SD-BIOLINE) and microscopy, with two thirds of the samples further analyzed by qPCR. The data was used to categorize each district and 41 42 village as having very low (PfPR<1%), low (1%≤PfPR<5%), moderate (5%≤PfPR<30%), or high (PfPR≥30%) parasite prevalence. A generalized linear model was used to 43 44 analyse infection risk factors. Other metrics, including positive predictive value (PPV), sensitivity, specificity, parasite densities, and Kappa statistics were computed for RDTs 45 or microscopy using qPCR as reference. 46

47 **Results:** Significant fine-scale variations in malaria risk were observed within and between districts, with village prevalence ranging from 0% to >50%. Prevalence varied 48 by testing method: Kilombero was low risk by RDTs (PfPR=3%) and microscopy 49 (PfPR=2%) but moderate by qPCR (PfPR=9%); Ulanga was high risk by RDTs 50 (PfPR=39%) and qPCR (PfPR=54%) but moderate by microscopy (PfPR=26%). RDTs 51 52 and microscopy classified majority of the 35 villages as very low to low risk (18 - 21 villages). In contrast, qPCR classified most villages as moderate to high risk (29 53 villages). Using gPCR as the reference, PPV for RDTs and microscopy ranged from 54 <20% in very low transmission villages to >80% in moderate to high transmission 55 villages. Sensitivity was 62% for RDTs and 41% for microscopy; specificity was 93% 56 57 and 96%, respectively. Kappa values were 0.58 for RDTs and 0.42 for microscopy. 58 School-age children (5-15 years) had higher malaria prevalence and parasite densities

- than adults (P<0.001). High-prevalence villages also had higher parasite densities
- 60 (Spearman r=0.77, P<0.001 for qPCR; r=0.55, P=0.003 for microscopy).

Conclusion: This study highlights significant fine-scale variability in malaria risk within 61 and between districts and emphasizes the variable performance of the testing methods 62 when stratifying risk. While RDTs and microscopy were effective in high-transmission 63 areas, they performed poorly in low-transmission settings; and classified most villages 64 65 as very low or low risk. In contrast, qPCR classified most villages as moderate or high risk. While we cannot conclude on which public health decisions would be subject to 66 67 change because of these differences, the findings suggest the need for improved testing approaches that are operationally feasible and sufficiently sensitive, to enable 68 precise mapping and effective targeting of malaria in such local contexts. Moreover, 69 public health authorities should recognize the strengths and limitations of their available 70 71 data when planning local stratification or making decisions.

- 74 stratification; Malaria screening.

76 Background

Precise mapping of malaria prevalence is crucial for the eventual elimination of the 77 disease from different localities. In line with World Health Organization (WHO) 78 79 guidelines, National Malaria Control Programs (NMCPs) in Africa are increasingly adopting data-driven stratification of malaria risk, in most cases at either district or 80 higher regional levels [1–3]. These stratifications involve assessing risk levels in 81 geographical areas at the subnational level (e.g. zones, regions, and districts) [2,4,5]. 82 83 and can include fine scale mapping (down to wards and villages levels) as countries progress towards elimination [6–8]. The data for such stratification may come from 84 85 health facilities, active malaria screening during population surveys, or proxy data sources such as antenatal care clinic visits [6,9,10]. 86 87 When developing country-level malaria strategies, the prevalence of malaria,

representing the proportion of confirmed positive cases of *Plasmodium falciparum* (or

other *Plasmodium* sp.) among all individuals tested [11,12], can be classified into

various transmission categories. The WHO has previously used the following cutoff

points for malaria endemicities: below 1% as very low, 1-10% as low, 10-35% as

moderate, and above 35% as high risk malaria stratum [12]. Different NMCPs may

adapt these criteria with slight adjustments based on local epidemiological insights. For

94 instance, some countries, including Tanzania and Kenya, have used the parasite

95 prevalence data to categorize their geographic zones as either very low risk (PfPR <</p>

1%), low risk (1% \leq PfPR < 5%), moderate risk (5% \leq PfPR < 30%), or high risk strata

97 (PfPR \ge 30%) [2,13]. Another measure that can be used for generating these strata is

the annual parasite incidence (API), which is the number of diagnostically confirmed

⁹⁹ malaria cases per 1000 individuals per year and is usually obtained from health facilities

data [12,14]. API offers precise malaria stratifications, though it fails to account for sub-

101 clinical malaria infections, which can contribute to transmission and impede malaria

102 elimination efforts [15].

National malaria programs usually rely on different actively and passively collected data
 to inform malaria burden and monitor the effectiveness of control measures [16–18]. For
 instance, Tanzania employs multiple platforms, including the District Health Information

software (DHIS2) populated with data from routine health facility visits, the Malaria

- ¹⁰⁷ Indicator Surveys (MIS) and Tanzania Demographic and Health Surveys (TDHS), which
- are done every 4-5 years through household surveys, and the school malaria parasite
- surveillance targeting kids aged 5-16 years during (SMPS) [2,19–21]. A common
- 110 feature of these established systems is that most rely primarily on rapid diagnostic tests
- 111 (RDTs) and microscopy [13,22,23], though samples are sometime also preserved for
- 112 PCR assays.
- 113 Microscopy, long used in malaria diagnosis, can quantify parasite loads and identify
- different *Plasmodium* species, which are essential for precise treatment choices [24,25].
- However, its effectiveness depends significantly on the skill and experience of the
- microscopist, making it unreliable in some contexts, and it can miss a substantial
- number of true infections due to sub-optimal accuracy [26–28]. In contrast, Rapid
- 118 Diagnostic Tests (RDTs) offer a consistent and user-friendly option, enabling quick, on-
- site diagnosis without specialized skills or equipment. RDTs have become widely used
- in both point-of-care settings and population surveys due to their operational simplicity
- and cost-effectiveness [29–33]. While the technique enhances access to diagnostics,
- 122 especially in remote areas, RDTs have lower sensitivity for detecting low-level infections
- and cannot quantify parasite density or distinguish between *Plasmodium* species.
- 124 Additionally, current RDTs may detect antigens for over three weeks post-treatment,
- leading to poor specificity and potential overestimation of malaria cases in high
- transmission areas [30,33,34].
- 127 In contrast, polymerase chain reaction (PCR) assays are known for their high sensitivity
- and specificity [35]. While conventional PCR assays typically provide qualitative
- information on malaria infections, quantitative PCR (qPCR) can offer additional
- 130 quantitative measures of malaria parasite density [36,37]. Unfortunately, the widespread
- use of PCR assays for population surveys is hindered by cost constraints and the need
- 132 for specialized expertise and infrastructure for implementation [35,38,39].
- 133 The increased focus on evidence-based strategies in malaria control also includes a
- transition from broad subnational stratifications to more granular, fine-scale approaches
- 135 [6,10]. However, although current methods like RDTs and microscopy are favored for

their operational simplicity, their effectiveness in detailed risk stratification, which are 136 critical for targeting both clinical and sub-clinical infections for malaria elimination, 137 138 remains poorly understood. Some authors have also suggested that RDTs may have vastly reduced performance in settings where the malaria burden has been significantly 139 140 reduced [40]. This calls for a rigorous evaluation and comparison of these methods against highly sensitive techniques such as qPCR to refine malaria stratification 141 approaches for malaria elimination. Indeed, available evidence, including data from 142 Kenya and Tanzania, suggest that PCR assays are generally better at pinpointing main 143 malaria hotspots in communities than RDTs and microscopy [41,42]. The study from 144 Tanzania further showed that in subsequent treatment campaigns relying on RDT-145 based screening, ~45% of infections remain untreated, even if treatment is offered to all 146 members of households with an infected individual [42]. In the Kenyan study, the 147 authors went further to suggest that since detection of hotspots depends on the 148 sensitivity of diagnostic tools, health authorities working in malaria elimination settings 149 should consider using PCR to guide detection of the residual hotspots, as this provides 150 151 greatest opportunities to find asymptomatic individuals and sub-patent parasite

reservoirs in the communities [41].

153 All these studies clearly show that while sub-national stratification may be the most 154 effective approach to decide on how to allocate resources, the type of data used for 155 such epidemiological profiling matters significantly; especially when the stratification is 156 done at local-sub-district levels. In places like southeastern Tanzania, which has 157 experienced decades of sustained malaria interventions and progress, and where 158 robust entomological surveillance already exists [43], addition of detailed parasite 159 prevalence data from population-level surveys is required to enable more precise, finescale stratifications at both district and sub-district levels. 160

The aim of this study was therefore to generate a high-resolution population-level survey map of *P. falciparum* prevalence in two districts in south-eastern Tanzania, and compare the fine scale malaria risk strata obtained when using data from different test methods, namely RDTs, microscopy and qPCR. The study also examined the association between population-level parasite prevalence and the parasite densities as determined by both qPCR and microscopy in the different study villages. Lastly, we investigated the malaria detection capacity of RDTs and microscopy across villages with
 varying parasite prevalences and densities.

169 Methods

170 Study site

171 The study was conducted in Morogoro region, in south-eastern Tanzania (Figure 1), in

the two districts of Kilombero (population: ~583,000; 8.2414°S, 36.3349°E; elevation:

¹⁷³ ~270m) and Ulanga (population: ~233,000; 8.9889°S, 36.6133°E; elevation: ~800m).

174 The average malaria prevalence in the Morogoro region has previously been estimated

to exceed 10%, with *P. falciparum* as the dominant malaria species [19,20,44]. The

176 main economic activities for residents include rice farming, sugarcane farming and

maize farming, though the area also has other food crops and large commercial tree

plantations (teak). The known annual rainfall range is 1200-1400 mm in the lower-lying

plains of Kilombero district, and1400-2100 mm in the higher areas in Ulanga district

180 [45]. Approximately 90% of the rainfall occurs during the wet seasons between

181 December to April, with dry seasons typically lasting from June through September [45].

182 The annual mean daily temperature is around 27°C in the lowlands and approximately

183 23°C in the highlands. Relative humidity averages from 75% in the lowlands to 80% in

184 the highlands.

185

186

Figure 1: Study villages in Kilombero and Ulanga districts, south-eastern Tanzania.

188

189 Study design, procedures and survey tools

190 The cross-sectional surveys were conducted over two consecutive years, from 2022 to

191 2023, covering the transition from the end of rainy seasons to the peak of dry seasons.

192 Villages were randomly selected from each district, and sample sizes were

- 193 proportionately determined based on the population of each village using the Cochran
- 194 formula adjusted for finite populations [46–48]. The expected prevalence varied
- depending on the village and was derived from previous surveys and health centers
- 196 within each village. Based on the estimated sample size mentioned above,
- 197 representative households were selected by systematically randomizing the names of
- all households obtained from the respective village administrations.

199 The screening criteria included individuals aged 5-60 years who had not taken malaria 200 medications in the preceding two weeks. This precaution aimed to prevent potential 201 overestimation by RDTs, as they may detect residual traces post-treatment [49]. Individuals needing special medical attention, such as pregnant women, were excluded 202 203 from the study. Each consenting individual undergoing malaria screening was assigned a unique identity number that was also linked to their corresponding household ID. On-204 205 site malaria diagnosis was conducted using: 1) RDTs via finger prick, 2) creating thick and thin blood smears, and 3) collecting 3-5 dried blood spots (cycles) on Whatman[™] 206 filter paper cards. Subsequently, these samples were transported to the reference 207 208 laboratory for microscopy and qPCR analysis. For children under five years, only screening with RDTs was done for prevalence estimations and not used for strata 209

210 comparisons.

211 Ethical considerations, survey team, and trainings

212 Permission to conduct this study was obtained from the Ifakara Health Institute Review

Board (Ref: IHI/IRB/No: 1/2021) and the National Institute for Medical Research-NIMR

(NIMR/HQ/R.8a/Vol. 1X/3735). Additionally, approvals were obtained from regional,

district, ward, and respective selected village authorities before commencing the

surveys, given the screening was done at centralized location in each village. Written

informed consent was obtained from individual adult participants (and parents or

guardians of those aged below 18) on the day before the actual testing. The study team

consisted of 11 members, including three molecular laboratory technologists, four

licensed medical laboratory microscopists, two licensed clinical officers, and two social

scientists. Prior to the survey commencement, a five-day training session was

conducted at the Ifakara Health Institute laboratory. This training covered explanations

of the study protocols, pilot implementations, procedures for protecting human

224 participants, quality assurance and training on data collection tools.

225 **Tests using malaria rapid diagnostic tests (RDTs)**

A small blood drop obtained through a finger prick was collected onto the RDTs (SD

Bioline Ag *Pf*/Pan), following the manufacturer's instructions. The buffer solution was

228 applied according to standard RDTs procedures and left on the bench surface for up to

229 20 minutes. The type RDT used were capable of detecting *P. falciparum* infections by

targeting histidine-rich proteins 2, which react on the *Pf*-line. Additionally, they could

231 detect *P. malariae* and *P. ovale* by targeting glycolytic lactate dehydrogenase,

expressed by the Pan-line on RDTs [30]. The RDT results were recorded on a paper

form, and any individuals who tested positive for malaria were promptly treated with

Arthemether Lumefantrine (ALu), following Tanzania's national malaria treatment

235 guidelines [50].

236 **Tests using microscopy**

237 Thick and thin blood smears were created in the field, stained with 10% Giemsa for 15 238 minutes then examined for the presence of malaria parasites under oil immersion at 100X magnification [47,51,52]. Two experienced microscopists independently read the 239 240 slides, and discrepancies between them were resolved by a third, more experienced microscopist. They read the thick smear first, and if an infection was detected, the thin 241 242 smear was read to identify parasite species. The presence of both asexual and sexual malaria parasite stages discriminating P. falciparum, P. malariae, and P. ovale was 243 244 recorded. Asexual stage parasites were counted per 200 white blood cells and 245 assuming 8000 WBC/µL [53]. The mean count of malaria parasite by microscopy between the two readers was calculated and confirmed by the third reader. 246

247 **Tests using real-time qPCR assays**

A representative sample of approximately two thirds of all samples was randomly 248 selected from each village and screened further by quantitative polymerase chain 249 reaction (qPCR) i.e. 4905 samples out of the total 7628 samples. Out of five spots 250 created on the WhatmanTM filter paper card, three spots of DBS were used for DNA 251 extraction using Quick-DNA[™] Miniprep plus kit (Zymo Research, USA) [54], and eluted 252 with 50 µL of elution buffer, stored at -20°C for further detection and quantification of P. 253 falciparum infections using probe-level allele-specific quantification (PlasQ)-multiplex 254 255 gPCR assays protocols [37,55,56]. The detection and quantification of *P. falciparum* 256 parasites were performed using the Bio-Rad CFX96 real-time PCR system (Bio-Rad 257 Laboratories, USA) [55] and analyzed with Bio-Rad CFX maestro software. The gPCR 258 reaction, PlasQ primers and probes mix, are summarized in supplementary online table

1& 2. DNA amplification processes included: activation at 95°C for 1 min, denaturation
at 95°C for 15 seconds, and annealing and elongation at 57°C for 45 seconds for 45
cycles, followed by melting [55].

The qPCR assays were run with positive controls (samples with confirmed *P*.

falciparum) and a non-template control (samples with no *P. falciparum* as negative

control). For absolute parasite quantification, the WHO international standard for *P*.

265 *falciparum* nucleic acid amplification techniques were used (WHO reference from

NIBSC#04/176) [37]. The standard was reconstituted following the manufacturer's

instructions and serially diluted in the range of 100,000 parasites/µL to 0.01 and

analyzed in triplicates.

269 During the qPCR assay, the prepared standards were run together with unknown

samples, and at the end of the assay, the standard curve and samples were normalized

and analyzed with Bio-Rad CFX maestro software. The obtained normalized Ct values

of the samples and the linear regression equation derived from the standard curve were

used to calculate the parasites density of the unknown samples, expressed as parasites

274 per microlitre (parasites/µL) of blood.

275 Data analysis

All results from RDTs, microscopy, and qPCR were entered into the Open Data Kit

(ODK) system [57], and subsequently downloaded as an excel file for further cleaning.

278 The datasets for RDTs, microscopy, and qPCR results were merged based on the

279 participant's ID using the Pandas Python package [58].

280 Generalized linear models (GLM) were used to evaluate the association between malaria infection risk and the variables of age and gender in a univariate analysis, run in 281 282 Python using the stats model package [59]. Additionally, to evaluate the performance of RDTs and microscopy in fine-scale malaria stratifications compared to gPCR, their 283 284 agreement was tested using Kappa statistic [60], and the resulting Kappa values interpreted as follows: $\kappa \simeq < \odot 0.20$ as poor agreement, 0.21–0.40 as fair, 0.41–0.60 as 285 moderate, 0.61–0.80 as substantially good and 0.81–1 as almost perfect agreement 286 [61]. In addition, the positive predictive value (PPV) for RDTs and microscopy was 287

computed, using qPCR results as the reference, per village, as (proportion of positive

289 test results that are actually true positives, estimated as PPV = True Positives / (True Positives + False Positives)). Fine-scale stratification by villages using data from gPCR, 290 291 RDT, and microscopy were used to generate the prevalence maps using quantitative Geographic Information System (qGIS) software, allowing visualization of malaria 292 293 prevalence across villages. Additionally, the risk maps were created using inverse distance weighting (IDW) interpolation techniques. This method helped to estimate 294 295 malaria risk by spatially interpolating the prevalence data, which provided a continuous surface of malaria risk across the study area. 296

The geometric mean of parasite density estimated by microscopy and gPCR was 297 298 computed, and statistically compared the parasite densities between gender and age 299 groups. The non-parametric Mann-Whitney statistics were used to compare the parasite 300 densities between two categorical groups, while Kruskal-Wallis statistical tests were 301 used to compare more than two categorical groups [62,63]. For example, differences in 302 parasite densities between age groups were tested using Kruskal-Wallis statistics, and if 303 statistically significant, the Mann-Whitney statistics were applied for pairwise statistical significance tests. All analyses that compared parasite densities excluded the negative 304 305 class and focused solely on investigating parasite density distribution among malaria-306 positive patients. Lastly, to test for statistical correlations between parasite prevalence 307 and parasite densities estimated by both qPCR and Microscopy, non-parametric 308 Spearman's rank correlation tests were employed [64]. Additionally, logistic regression model was also used to assess the probability of diagnostic tools to detect malaria 309 310 infections at various parasite densities.

311 Results

312 **Baseline study population.**

This survey covered 35 villages and 93 sub-villages across Ulanga and Kilombero districts. A total of 7,628 participants (>5 years) were recruited upon consent and tested for malaria using RDTs and microscopy, with 64.3% (4,905) of them also tested by qPCR (Figure 2). Males comprised 38% of the study population, while females made up 62%. Among the participants, 35% were school-aged children (5-15 years), and 65%

were aged 16 years and above (Table 1). For children under five years, for whom

- 319 screening was conducted with only RDTs to estimate the burden, the results are not
- reported here.

323 **Table 1**: Baseline characteristics of the study populations

324

325 Malaria prevalence by RDTs, Microscopy and qPCR

In the Ulanga district, malaria transmission was found to be high by both qPCR and

327 RDTs, with *P. falciparum* prevalence rates of 53.89% [95% CI, 52.06-55.72] and

328 38.35% [95% CI, 36.92-39.79] respectively. However, microscopy categorized it as

moderate, with a prevalence rate of 26.07% [95% CI: 24.77-27.36] (Table 2). Within this

moderate to high transmission strata in Ulanga, males had a significantly higher

331 prevalence of malaria compared to females. The odds of malaria infection in males

compared to females were estimated as 1.54 [95% CI: 1.36-1.74] (P < 0.001) by RDTs,

333 1.45 [95% CI: 1.27-1.66] (P < 0.001) by microscopy, and 1.54 [95% CI: 1.36-1.74] (P <

0.001) by qPCR (Table 2). All tests - RDTs, microscopy, and qPCR - indicated that

school-age children (5-15 years) had a significantly higher prevalence of malaria

infections than the other age groups (Table 2).

In Ifakara council, within the Kilombero district, both RDTs and microscopy categorized

the area as a low risk stratum, with observed prevalence rates of 2.68 [95% CI: 2.12-

339 3.24] and 1.84 [95% CI: 1.37 – 2.30], respectively (Table 3). However, qPCR classified

340 Kilombero district as a moderate risk stratum with a prevalence rate of 8.77 [95% CI:

7.55-9.99] (Table 3). Notably, there were no statistically significant differences in

342 malaria infection risk between males and females in this low to moderate transmission

setting, as indicated by both RDTs (Odds prevalence 1.51% [95% CI; 0.97, 2.33],

- ³⁴⁴ P=0.065) and microscopy (Odds prevalence 1.33% [95% CI; 0.78, 2.25], P=0.293), as
- well as qPCR (Odds prevalence 1.09% [95% CI: [0.80-5.67], P = 0.567). Additionally,
- 346 school age children (5-15 years) exhibited a significantly higher risk of malaria infections
- compared to those above 15 years old, as demonstrated by both RDTs, microscopy,
- and PCR (Table 3).

Micro-stratification of malaria risk using data collected by qPCR, RDTs, and
 microscopy

- 351 Significant variability in malaria infections was observed at the individual village level,
- with prevalence rates ranging from 0% to over 50% across the study area (Figure 3 &
- Table 4). Additionally, the method used to test for malaria significantly impacted the risk
- categorization of villages. Among the 35 villages surveyed, qPCR data indicated that
- only one village (1.2% of all villages) had very low malaria prevalence (PfPR < 1%). In
- contrast, RDTs identified 12 villages (34.3% of all villages) and microscopy identified 11
- villages (31.4% of all villages) as having very low prevalence. For moderate
- transmission, qPCR, RDTs, and microscopy categorized 15, 9, and 8 villages,
- respectively. For high transmission, qPCR identified 14 villages, RDTs identified 8, and
- 360 microscopy identified 6. Notably, qPCR detected more malaria infections than RDTs
- and microscopy, resulting in many villages being classified into higher transmission
- 362 categories.
- ³⁶³ Overall, using qPCR data, over 80% of the villages were classified as moderate to high
- risk, significantly higher than the 48% classified by RDTs and 40% by microscopy.
- 365 Conversely, while only 17% of the villages were classifiable as having low or very low
- malaria risk based on qPCR data, as high as 51% and 60% of the villages were
- classified into these same categories based on RDT and microscopy data (Table 4 and
- 368 Figure 4)

388

Figure 4: Percentage of villages categorized by different testing methods as either very low risk, low risk, moderate risk or high risk (total number of villages = 35).

391 Comparison of the perfomance of RDTs and microscopy relative to qPCR.

- In this comparative analysis, only samples tested by all three methods—PCR, RDTs,
- and microscopy—were included, totaling 64.3% (n = 4905) of the samples (Table 5).
- Among these, qPCR identified 1712 (34.9%) as positive, whereas RDTs and
- microscopy classified 1289 (26.3%) and 843 (17.2%) positives, respectively (Table 5).

- A substantial number of positive samples, otherwise detectable by qPCR, were missed
- ³⁹⁷ by both RDTs and microscopy, suggesting the existence of subpatent infections (table 5
- and Figure 5). Of all samples analyzed by qPCR, RDTs, and microscopy, 647 out of
- 4,905 (13.2%) were categorized as positive by all three methods (Figure 5).
- Interestingly, qPCR classified 56 out of 4,905 (1.1%) samples as negative, while both
- 401 RDTs and microscopy agreed they were positive (Figure 5). Similarly, the same
- 402 proportion was agreed upon by qPCR and microscopy as positive, while RDTs
- 403 classified them as negative. Microscopy classified 415 out of 4,905 (8.5%) samples as
- negative, while both RDTs and qPCR agreed they were positive.

Table 5: Overall prevalence in the 35 surveyed villages estimated using qPCR, RDTs,

and microscopy. Additionally, the table summarizes the proportion of malaria positive

samples missed by RDTs and microscopy when qPCR is used as the reference.

	No. tested	Pf. Positive	Prevalence
qPCR	4905	1712	34.9%
RDTs	4905	1289	26.3%
Microscopy	4905	843	17.2%

Proportion of missed positives when qPCR is the reference

	Total Positive by PCR	Sample missed	(%) of missed Positive
RDTs	1712	650	37.9%
Microscopy	1712	1009	58.9%

- 408
- Both RDT and microscopy missed several infections otherwise identified by qPCR. This
- 410 category of false negatives included cases where qPCR identified a sample as positive,
- 411 but microscopy identified it as negative, cases classified as positive by qPCR but
- negative by RDTs, and cases where RDTs indicated positive results while microscopy
- indicated negative result. Out of the 1712 positives detected by qPCR, RDTs missed
- 414 650 (37.97%) and microscopy missed 1009 (58.9%) (Table 5). Additionally, when
- 415 comparing microscopy to RDTs, microscopy failed to detect 45.46% (586/1289) of
- 416 malaria infections detected by RDTs. RDTs correctly identified 1062 (62.03%) samples
- 417 as true positives, while microscopy identified 703 (41.06%) as true positives (Table 6).
- 418 Furthermore, RDTs misclassified 227 (7.10%) samples as false positives, while
- 419 microscopy misclassified 140 (4.38%) (Table 6).

420

421 **Figure 5:** The Venn diagram illustrates positive samples detected exclusively by a

specific tool while the other two missed them (qPCR only: 594 positive, RDT only: 171

423 positive, Microscopy only: 84 positive). Additionally, it shows intersections indicating

424 positive detection by two tools when one detects negative (qPCR & RDT: 415 positive;

425 qPCR & Microscopy: 56 positive; RDT & Microscopy: 56 positive). It also indicates

426 intersections where all tools detect positive samples (qPCR, RDT, & Microscopy: 647

427 positive).

Table 6: Evaluation metrics for assessing the performance of RDTs and microscopy relative to qPCR during the fine-scale
 stratification of malaria risk in Ulanga and Kilombero districts, south-eastern Tanzania.

Positive predictive values (PPVs), sensitivity, specificity, and agreement of RDTs and microscopy when compared to qPCR

Considering qPCR as the benchmark, the sensitivity (the proportion of actual positives 432 which were correctly identified as such) of RDTs was 62.0% [95% CI: 60.0-64.2], while 433 434 that of microscopy was 41.0% [95% CI: 38.8 - 43.4]. The specificity (proportion of actual negatives which were correctly identified as such) was 92.9% [95% CI: 92.00-93.7] for 435 RDTs and 95.6% [95% CI: 94.9- 96.3] for microscopy (Table 6). Overall, the positive 436 predictive value (PPV), i.e. the probability that individuals with a positive test result 437 438 actually have the disease, was 82.4% [95% CI: 80.3 -84.4] for RDTs and 83.4% [95% CI: 80.8-86.0] for microscopy (Table 6). Importantly however, the PPV for both RDTs 439 440 and microscopy varied with malaria endemicity, generally increasing with prevalence, 441 ranging from less than 20% in very low transmission areas to over 80% in high transmission areas (Figure 06). 442

443

444 When considering the micro-strata generated using gPCR data, the PPV of RDTs and microscopy started at 0% in very low risk strata and gradually increased to >80% as 445 446 villages shifted towards high risk strata (Figure 6A). However, when referring to the strata generated using RDTs data (Figure 6B), the PPV of both RDTs and microscopy 447 448 started at 20% in very low risk strata and gradually increased to >80% in high-risk strata. The agreement between RDTs and qPCR was good (Kappa value = 0.58 [95% 449 450 CI: 0.56-0.61]), while the agreement between microscopy and qPCR showed fair 451 agreement (Kappa value = 0.42 [95%CI: 0.39-0.44]), (Table 6). 452

The sensitivity of both RDTs and microscopy varied by age, where RDTs sensitivity was higher for school-aged children (>80%) and dropped to 75% and 60% for 16-20 years and >20 years, respectively (Figure 6C). A similar trend of sensitivity was observed for microscopy (Figure 6C), indicating that RDTs and microscopy perform better in detecting malaria in school-aged children compared to adults.

The relationship between parasite density and the malaria detection probability by RDTs and microscopy was also examined. In this analysis, the probability of RDTs detecting

- positive malaria infections was maximized reaching 1 at 100 parasites/µL, where the
- logistic regression (logit (p)) model saturated (Figure 6D). At this density in contrast, the
- 462 probability of microscopy to detect malaria infections was only 0.85% (Figure 6D),
- suggesting higher sensitivity of RDTs vs microscopy.

Figure 6: Estimates of the positive predictive values (PPVs) of RDTs and microscopy at
 different malaria endemicities across the study villages, defined based on either qPCR
 data (A) or RDT data (B). Panel C) illustrates the trend of sensitivity of both RDTs and
 microscopy relative to age groups. Panel D) displays the detection probability of both
 RDTs and microscopy relative to the parasite density estimated by qPCR.

470 Parasites density estimates and their correlations with *Plasmodium* prevalence

471 Further, asexual parasite densities estimated by both microscopy and gPCR were investigated and compared across different sex and age groups using Mann-Whitney 472 statistics for two categories and the Kruskal-Wallis statistical test for more than two 473 474 categories. Overall, PCR was capable of detecting approximately 100 fold lower parasite densities compared to microscopy. The geometric mean asexual parasite 475 density estimated by microscopy was 2206.4 parasites/µL (95% CI: 1976.7-2462.8), 476 477 while that estimated by PCR was 27.07 parasites/µL (95% CI: 23.23-31.54) (Table 7). 478 The asexual parasite density of infected individuals significantly differed between males 479 and females as estimated by qPCR (P < 0.001), with males harboring a higher parasite 480 481 density compared to females, though similar trend was observed by microscopy, this 482 sex difference was not statistically detectable by microscopy (P = 0.11). Importantly, the geometric mean parasite density estimated by both microscopy and gPCR per village 483 484 demonstrated a significant positive correlation with the parasite prevalence of the respective village. Thus, villages with high malaria prevalence also had high malaria 485 parasite densities compared to villages with lower prevalence (Figure 7C-F). 486 Considering qPCR-estimated geometric mean parasite densities, the Spearman rank 487 correlation score was 0.77 (P < 0.001) and 0.76 (P < 0.001) when the malaria 488 prevalence of the villages was estimated by qPCR and RDTs, respectively (Figure 7C & 489 490 7E). On the other hand, the Spearman rank correlation for the parasite density estimated by microscopy was 0.55 (P < 0.003) and 0.48 (P < 0.012) for gPCR and 491 RDTs estimated prevalence of the villages, respectively (Figure 7D & 7F). 492 When parasite density by age groups were analyzed, both microscopy and gPCR 493 revealed a significant difference in estimated malaria parasite densities between age 494 groups based on Kruskal-Wallis statistics (P < 0.001) (Table 7). Pairwise tests by Mann-495 496 Whitney statistics revealed that school-aged children (5-15 years old) harbored a higher parasite density than those 16 years old and above (P < 0.001) as indicated by both 497 498 microscopy and qPCR (Figure 7A & 7B).

Table 7: Parasite densities by gender and age as estimated using Microscopy slides and quantitative PCR assays

		Microscopy	qPCR			
	Geometric mean (/µL)	95% CI (/µL)	P-value	Geometric mean (/µL)	95% CI (/µL)	P-value

506 **Discussion**

507 In malaria-endemic countries, data-driven risk stratification is increasingly used at 508 district or higher regional levels to guide intervention strategies and optimize resource allocation. Additionally, the geographical variations in levels of endemicities and the shift 509 510 towards elimination in some settings necessitates finer resolution for optimal resource allocation [6,10,72]. In most settings in Africa, the data used for epidemiological 511 512 stratification of malaria typically comes from rapid diagnostic tests (RDTs) or 513 microscopy-based testing, which despite wide scale availability and low operational costs, often perform poorly in low transmission settings [41,73,74]. While direct 514 515 comparisons of these diagnostic tools for fine-scale stratification are currently limited, 516 selecting the most appropriate data sources and testing methods is crucial, as different 517 methods can yield significantly different results depending on endemicity, particularly in 518 elimination settings. Even without alternative testing methods, data users and decisionmakers need to understand the limitations of their selected approaches, especially the 519 520 weaknesses of current dominant data sources like RDTs or microscopy. In this study, we conducted a high-resolution survey of *P. falciparum* malaria in two Tanzanian 521 522 districts, comparing fine-scale strata obtained using RDTs, microscopy, and gPCR 523 assays. The findings will provide the necessary evidence to the malaria programs at 524 national and district levels on how RDTs, microscopy, and gPCR compare when used at 525 local levels. Moreover, the findings demonstrate that selection of appropriate test methods is essential for more precise resource allocation and improved understanding 526 527 of disease patterns.

The findings highlight significant variability in malaria risk at a fine scale. Within less 528 than 150 kilometers, malaria prevalence estimates ranged from 0% to over 50% across 529 530 contiguous villages in an area broadly classified as moderate risk (~17% PfPR) by recent government stratification [44]. Such fine-scale variability is not uncommon and 531 532 has been observed in several other settings [75]. In one study in Madagascar, there was a tenfold difference of malaria prevalence within a radius of less than 50 kilometers 533 [76]. For precise micro-stratifications, this study emphasizes the importance of carefully 534 selecting diagnostic tools, especially for local malaria elimination efforts. Our findings 535 indicate that RDTs and microscopy have poor positive predictive values, which can be 536

537 even less than 20% in villages with very low and low transmission as the proportion of 538 truly infected individuals is very small compared to non-infected persons. There were 539 also significant discrepancies in the resulting micro-strata depending on the test method used. For instance, among the 35 surveyed villages, RDTs and microscopy classified 540 541 12 and 11 as very low and 6 and 10 as low risk strata, respectively, while qPCR identified only 1 village as very low and 5 as low transmission. This means RDTs and 542 543 microscopy classified majority of the villages as very low to low risk while qPCR classified most villages as moderate to high risk (Table 4). 544

Clear demarcation of areas with very low to low risk versus those with moderate to high 545 risk is essential, particularly in the push towards elimination. As countries increasingly 546 adopt data-driven decision-making for malaria control, there is a risk of improper 547 548 resource allocation or premature withdrawal of effective interventions from localities 549 erroneously deemed as nearing elimination. Local authorities need to decide which data to use for local-level micro-stratification and whether RDTs, commonly used for broader-550 551 scale sub-national stratification, suffice for fine-scale local decision-making. Previous 552 evidence has shown that hotspots identified by RDTs are less stable than those 553 identified by microscopy and PCR [41]. Hotspots of febrile malaria infections are also 554 generally unstable and variable over geographical spaces, while hotspots of 555 asymptomatic cases tend to be more permanent and can be more practically targeted 556 for transmission control [77]. In this current study, we also found significant positive 557 correlations between malaria parasite densities and malaria prevalence in southeastern 558 Tanzania, emphasizing the need to incorporate tests that depict sub-microscopic 559 infections into malaria stratification and decision making to better target the hotspots. As already reported in other studies, villages in our study area, which were classified as 560 low transmission areas had lower geometric mean parasite density compared to those 561 with higher transmission rates. 562

Our findings, benchmarked against qPCR, reveal limited detection capabilities of RDTs
 and microscopy in overall fine-scale stratifications, especially in low transmission
 settings. Previous studies have emphasized the usefulness of routine hospital data for
 micro-stratifications [8,10,78,79]. However, evidence indicates that both microscopy and
 RDTs are less effective in identifying stable febrile malaria hotspots, except for

568 asymptomatic hotspots, which are reliably identified by microscopy [77], however still 569 not stable when transmission is low [80]. Our research underscores the importance of 570 identifying subclinical infections using sensitive tools to advance malaria elimination, particularly through fine-scale population surveys. Additionally, there is evidence 571 572 suggesting potential benefits from integrating hospital and school-age children survey data or even antenatal care centers [2,9]. Nevertheless, these approaches heavily rely 573 574 on rapid diagnostic tests (RDTs) as the primary tool for malaria detection. While the World Health Organization (WHO) recommends monitoring RDT performance alongside 575 microscopy, our study is particularly relevant as we have directly compared the fine-576 scale stratification capabilities of RDTs, microscopy, and qPCR at a fine scale. 577 578 This study demonstrated overall good agreement between RDTs and qPCR, while 579 microscopy showed fair agreement. However, RDTs missed over 38% of malaria 580 infections, particularly among adults over twenty years old, who were found to harbor lower parasite densities compared to those under twenty years old. However, RDTs 581 582 remain useful in testing fever-positive malaria cases in hospitals and are widely 583 employed in population surveys due to their cost-effectiveness and ease of 584 implementation [32]. As evidenced in this study, carefully re-consideration of using 585 RDTs for finer-scale mapping and intervention planning at sub-district level should be a 586 priority. Similarly, microscopy missed >50% of the malaria infections detected by qPCR. which is consistent with previous studies, including a meta-analysis of 42 studies, which 587 showed that microscopy misses over 50% of malaria infections [26,66]. Operational 588 challenges, such as the level of expertise required for accurate detection and the need 589 590 for electricity and precise sample handling procedures, contribute to these limitations. 591 Interestingly, microscopy underestimated malaria risk by classifying more villages as low strata compared to qPCR. Nonetheless, microscopy still plays a crucial role when 592 used in conjunction with tools like RDTs, providing valuable information about malaria 593 594 parasite densities [81–83]. Here, we estimate a 100-fold higher parasite density when 595 measured by microscopy compared to densities measured by qPCR, consistent with 596 similar trends observed in previous studies [55]. The findings of this study also indicate that the false-negative rate of microscopy decreases with increasing parasite density, a 597 598 pattern observed in other studies too [81].

The analysis also revealed variations in parasite densities across different age groups, 599 600 with school-age children (5-15 years old) exhibiting higher parasite densities compared 601 to individuals aged 16 and above. Notably, our study identified a reduced sensitivity of both RDTs and microscopy among adults aged over 16 years, consistent with findings 602 603 from prior studies conducted before 2015 in various regions [84–91]. It is possible this pattern is driven by the age-related differences in malaria parasite prevalence, which 604 605 was also observed (Table 3). Furthermore, our findings suggest that this trend may be attributed to the lower parasite density estimates observed in adults within the study 606 (Figure 7A & 7B). Significantly, our research provides valuable insights, highlighting the 607 potential implications of these trends, particularly in fine-scale mapping scenarios, 608 where RDTs and microscopy may underestimate stratifications at very low and low 609 610 transmission strata, with qPCR serving as the reference standard in this study.

611 Ultimately, this study underscores the potential need to expand the use of molecular approaches such as qPCR to achieve more precise mapping of malaria infections, 612 613 which could reduce false negatives and facilitate more precise resource allocations. However, qPCR has operational challenges, including the need for well-designed 614 615 infrastructure, high costs, and expertise, and it is not portable for remote areas [82]. Efforts are underway to develop portable qPCR technologies, but cost and expertise 616 617 remain significant barriers. To address these gaps, NMCPs should develop innovative 618 plans, which might include: a) centralized facilities receiving and processing qPCR samples and then doing such surveys only infrequently, say every 3 years; b) partnering 619 with local research organizations to support the high accuracy evaluations with nucleic 620 acid based tests. A related point to emphasize is the overall need for highly-sensitive, 621 cost-effective, and potentially reagent-free tools that align with the economic context of 622 malaria-endemic settings. Recent innovations such as the saliva-based tests [92] or the 623 624 use of Infrared spectroscopy (IR) and machine learning (ML) [82,93] have shown promise in detecting malaria infections at sensitivities equivalent to PCR, but further 625 research are needed before these technologies can be routinely deployed. Such 626 627 reagent-free assays like the IR-AI based approaches would be particularly transformative for scaling up effective micro stratification of malaria risk in Africa. 628 This study also raised some important new questions. For example, it is baffling to 629

observe that areas with low transmission also have persistently low parasite densities

despite individuals having low immunity compared to those in higher transmission

settings who acquire immunity and become protective. Studies have demonstrated that

in low transmission areas, highly virulent parasites are more exposed to facilitate

malaria transmission by mosquitoes compared to low virulent ones [26,94–96].

- 635 Consequently, high virulent parasites are detected and treated, leading to their removal
- 636 from the population [26,94–96]. This leaves behind low virulent parasites that are less
- exposed and maintain low densities, becoming symptomatic, undetectable, and
- untreated [26,94–96]. This phenomenon may contribute to long-term parasite
- transmission strategies, highlighting the importance of using highly sensitive tools for
- 640 screening [55,97,98].

One limitation of this study is its failure to consider factors that may contribute to the

broader heterogeneity of malaria infections in southeastern Tanzania. Future

643 investigations should delve into potential environmental, geographical, immunological or

genetic diversity of the parasite influences underlying this variability. Additionally, the

biological significance of missed infections by both RDTs and microscopy was not

646 explored. Consequently, the study did not estimate the transmission burden associated

- 647 with these undetected positive samples, nor assess the parasite densities necessary to
- 648 sustain transmission in the population.

649 **Conclusion**

650 As countries progress towards malaria elimination, fine-scale mapping of malaria risk becomes increasingly important. This study highlights significant variability in village-651 652 level malaria risk within and between districts in southeastern Tanzania, an area where the scale-up of effective interventions has led to substantial progress, yet cases persist 653 654 despite high intervention coverage. Secondly, the study underscores the variable 655 performance of different testing methods in stratifying risk. While RDTs and microscopy, the primary test methods used in low-income endemic settings and the main sources of 656 data for ongoing epidemiological stratification efforts, were effective in high-transmission 657 areas, they performed poorly in low-transmission settings, often classifying most 658

villages as very low or low risk. In contrast, qPCR classified most villages as moderate

660 or high risk. These findings demonstrate the importance of using appropriate testing 661 methods for data-driven, fine-scale risk stratification to enhance targeted interventions 662 aimed at reducing and eliminating malaria. The study underscores the need for improved testing approaches that are both operationally feasible and sufficiently 663 sensitive to enable precise mapping and effective targeting of malaria in local contexts. 664 More importantly, public health authorities must recognize the strengths and limitations 665 of their available data when planning local stratification or making decisions. While 666 innovation for more effective strategies is ongoing, sensitive molecular tools like qPCR, 667 despite their operational challenges, will be crucial for accurate malaria risk mapping 668 669 and intervention planning, especially in settings with significantly reduced risk. Going forward, developing new tools that balance operational costs and sensitivity, particularly 670 in low transmission settings, will be essential for effective malaria control and eventual 671 elimination. 672

673 Acknowledgements

We extend our sincere gratitude to the dedicated team of the Deep Diagnostics Project 674 675 at Ifakara Health Institute for their invaluable support throughout this survey. Special 676 recognition is due to Abigael W. Magesa, Tumpe G. Mwandyala, Magreth C. Magoda, 677 Scolastica N. Hangu, Alex T. Ngonyani, Magreth I. Henry, Jiddah A. Ally, Alfred J. Simfukwe, Amisa N. Rajabu, Scolastica A. Ndonde, Rahma S. Kikweo, Benson D. 678 679 Makua, Jacob J. Nyooka, Festo I. Tangaliola, Stephen J. Magasa, Joyce Y. Jackson, 680 Fidelis D. Mbena, Slyakus V, Mlembe, and Agnes Kimaro for their invaluable contributions to conducting the surveys, administering guestionnaires, screenings, and 681 laboratory procedures. We also express our gratitude to Judith Mshumbusi and the 682 procurement team for their assistance in procuring materials, often on short notice. 683 684 Additionally, we extend our thanks to Faraji Abilahi, the Ifakara laboratory manager, and fellow scientists, students and staff at Ifakara Health institute and University of Glasgow, 685 who contributed direct or indirectly to this study. 686
